Glossary

Basal metabolic rate Oxygen consumption in a nonexercising, nondigesting, awake animal. Standard metabolic rate is used for fish because they are rarely motionless.

Lipids Group of naturally occurring hydrophobic compounds including fats, oils, waxes, phospholipids, and others.

Nonesterified fatty acids (NEFAs) Free fatty acids, not in the form of glycerol esters.

Oxidative phosphorylation (OXPHOS) Aerobic ATP production using the energy in a proton electrochemical gradient to phosphorylate ADP via the F_1F_o ATPase.

Q_{10} or temperature coefficient Factorial change in the rate of a biochemical reaction or process with a 10 °C increase in temperature.

Triacylglycerol (TAG) Storage lipid consisting of three fatty acids linked to a glycerol backbone.

Cellular Metabolism

The main goal of cellular respiration is to produce energy in the form of adenosine triphosphate (ATP) at the same rate at which ATP is consumed by cellular processes (**Figure 1**), that is, balancing ATP supply and demand. Cellular respiration, through oxidative phosphorylation (OXPHOS), constitutes the main oxygen-consuming and ATP-producing processes, and whole-animal metabolic rate is the sum of respiration from all tissues. ATP production by OXPHOS requires an adequate delivery of both oxygen and metabolic fuels to cells. While the delivery of oxygen depends on the environmental levels of oxygen (e.g., atmospheric or dissolved oxygen) and the pathway from gas transfer organs to tissues, fuels are typically drawn from the stores already within the body. Although many cells still rely on the delivery of exogenous fuels (lipids, carbohydrates, and proteins) from other tissues that store large amounts of these substrates (e.g., lipids are stored in fat cells or adipocytes), most cells have their own stores to draw upon.

The various cell types that make up the different tissues in vertebrates show considerable variation in their energetic demands and their aerobic scope, where

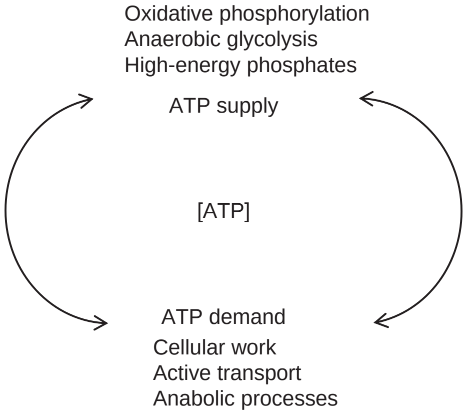

Figure 1 ATP homeostasis is maintained through the balance between ATP-supply pathways and ATP-demand pathways.

aerobic scope is defined as the difference between basal and maximal rates of aerobic ATP production. For example, in most animals, skeletal muscle has the largest aerobic scope (~100-fold). Basal metabolism also differs between tissues affecting their relative contribution to whole body basal metabolic rates (BMRs). Mammalian and fish muscles, despite having a rather low resting metabolic rate, contribute about 20–30% to BMR because they constitute the largest proportion of body mass (approximately 40–60%). For this reason, we use muscle cells (myocytes) as a primary model to discuss cellular metabolism and respiration (**Table 1**).

Cellular metabolism ultimately aims at maintaining homeostatic ATP concentrations despite dynamic fluctuations in ATP demand. Cellular processes that consume ATP include all active ion transport processes, whether it is to maintain membrane potentials (e.g., Na^+/K^+-ATPase), to transport calcium for actin–myosin cross-bridge cycling (e.g., Ca^{2+}ATPase) or for neurotransmitter release, to name a few. Protein turnover, the balance between protein synthesis and degradation, can also be a major ATP-consuming process, especially during the periods of growth. Other energy-consuming processes in vertebrates include urea synthesis and gluconeogenesis. Therefore, to balance all these ATP-consuming reactions there must be a corresponding equivalent rate of ATP synthesis. As discussed subsequently, this involves the coordinated delivery of oxygen and metabolic fuels to cells.

Table 1 The relative contribution of various tissues to basal or routine metabolic rate in a typical mammal and fish

	Relative metabolism (% total metabolism)	
Tissue	*Fish*	*Mammal*
Gill/ lung	19	<16[a]
Liver	13	21
Brain	1	20
Heart	4	9
Kidneys	5	8
Muscle	30	22

[a] Includes bones, skin, intestines, and lungs.

Cellular processes in most vertebrates are supplied energy by aerobic ATP production via OXPHOS (**Figure 2**). OXPHOS uses oxygen as a terminal acceptor for electrons that travel down the electron transport chain (ETC). The electrons are donated to the ETC by molecules termed 'reducing equivalents', namely nicotinamide adenine dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$), and it is the breakdown of the food consumed and fuels stored onboard that are the ultimate source of these electrons.

In vertebrates, the major fuels for cell metabolism are lipids, carbohydrates, and proteins. Major sources of lipid for ATP synthesis are the fatty acids in plasma known as

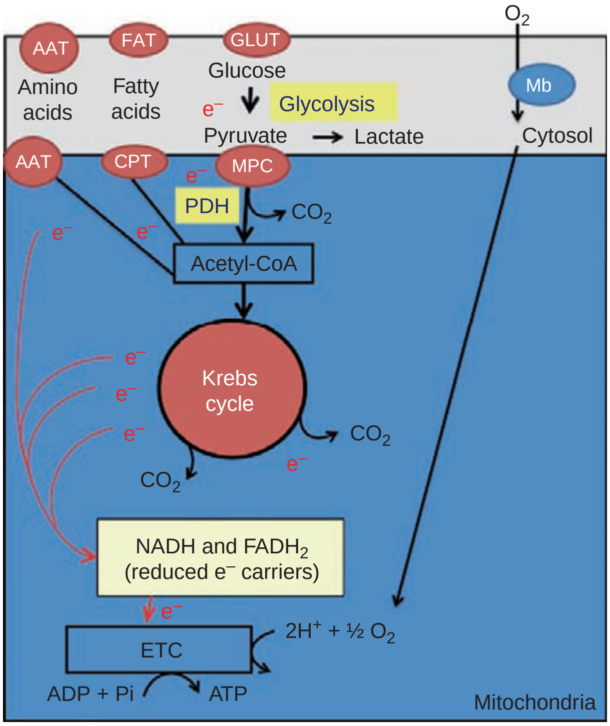

Figure 2 The pathway for oxygen from capillary to mitochondria and the major ATP-supply pathways from amino acids, glucose, and fatty acids. The three major fuels enter cells through specific transporters and enter the cytosol. Entry into the mitochondria for complete oxidation also involves specific transporters. All three fuels enter the Krebs cycle as acetyl-CoA. Electrons are transferred to reducing equivalents $FADH_2$ and NADH at various steps in catabolism. The reducing equivalents donate the electrons to the ETC and ultimately to oxygen as the terminal electron acceptor. AAT, amino acid transporter; FAT, fatty acid translocase; GLUT, glucose transporter; CPT, carnitine palmitoyltransferase; MPC, mitochondrial pyruvate carrier; PDH, pyruvate dehydrogenase; and ETC, electron transport chain.

nonesterified fatty acids (NEFAs). Further, lipids can be stored in large amounts in adipose tissue or liver as triacylglycerol (TAG); these reserves can be mobilized by the process of lipolysis and then released into the circulation as NEFA. Most cells have their own TAG reserves but at much lower concentrations than the specialized storage organs. However, these intracellular stores represent a readily available source of fuel for ATP production.

Carbohydrates are stored mainly in liver as glycogen, consisting of monomers of glycosyl units. Once broken down by the glycolytic pathway, glucose is released into the circulation for oxidation by other tissues. As is the case for lipids, most cells also have their own store of glycogen that is readily available for use but exists in much smaller concentrations in extraheptatic tissues. Glucose can also be produced in some tissues from specific precursors (e.g., alanine, glycerol, and lactate) via the process of gluconeogenesis. In most vertebrates, the liver and, to a lesser extent, the kidneys are the major gluconeogenic tissues.

Protein turnover rates are higher in fish than mammals but vary depending on many factors, including growth or feeding status. Since we focus here on fuel catabolism for ATP production, we have to consider the potential of amino acids to provide energy for cellular metabolism. When proteins are broken down by the ubiquitin–proteasome pathway in mammals and by lysosomes in fish, amino acids are liberated and may serve as a fuel source. In mammals, amino acids are not a major source of fuel for metabolism; they only contribute to a small percentage of total ATP production at rest and even less so during exercise. In contrast, protein metabolism may play a more important role in fish, as discussed later.

Fuel oxidation can be determined by measuring the rates of cellular $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ to determine respiratory quotients (RQs) for tissues or respiratory exchange ratio (RER) for whole-animal respiration. Defined as the ratio of $\dot{V}_{CO_2}/\dot{V}_{O_2}$, these ratios are unique to the three major metabolic fuels due to their stoichiometries of oxidation, at 1.0 for carbohydrates, 0.71 for lipids, and 0.81 for proteins (**Table 2**).

Fuel and O_2 Delivery to Tissues

Fuel and oxygen delivery share a convective transport step in the circulation, and the rate of delivery of both depends on cardiac output and their respective concentrations in the blood and/or plasma (eqns (1) and (2)):

$$T_{O_2} = \dot{Q} \times C_{aO_2} \qquad (1)$$

$$\text{Fuel delivery} = \dot{Q} \times (1 - H_{ct}) \times [\text{Fuel}] \qquad (2)$$

where T_{O_2} is the oxygen transport rate, C_{aO_2} is the oxygen concentration of arterial blood, $\dot{Q}$ is the cardiac output, H_{ct} is hematocrit fuels refers to carbohydrates, lipids, and amino acids.

They differ in a number of ways:

1. Oxygen is mainly carried bound to hemoglobin and fuels are principally circulating dissolved in the plasma, although some, notably hydrophobic NEFAs, must be bound to a carrier protein. Indeed, NEFA circulatory transport rates depend on the plasma concentration of the carrier protein albumin, the number of binding sites available for NEFA, and the plasma flow rate ($\dot{Q}_{\text{plasma}}$).
2. Unlike metabolic fuels, oxygen cannot be stored to any great extent in the body. For this last reason it has been speculated that the circulatory system has evolved to favor oxygen over fuel delivery.
3. Probably more importantly is that oxygen enters the cell by simple diffusion and the net flux across cell membranes depends on surface area for transport, permeability coefficient of oxygen in the membrane, and is inversely related to the thickness of the diffusion barrier. Membrane transport of fuels, on the other hand, depends on transmembrane proteins (transporters). The surface area for transport thus depends on the density of each fuel-specific transporter.

The rate of tissue oxygen consumption ($\dot{V}_{O_2}$) can be determined empirically by using the Fick equation (eqn (3); **see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs):

$$\dot{V}_{O_2} = \dot{Q} \times (C_{aO_2} - C_{VO_2}) \qquad (3)$$

Table 2 Stoichiometries of oxygen and carbon dioxide used to infer fuel use via gas-exchange measurements in air or water

Fuel	*CO_2 (mol)*	*O_2 (mol)*	*Respiratory exchange ratio (RER)*
Glucose ($C_6H_{12}O_6$)	6	6	1
Palmitoyl-stearoyl-oleaoyl-glycerol ($C_{55}H_{104}O_6$)[a]	55	78	0.71
Protein[b]	4.1	5.1	0.81

[a] Representative triacylglycerol.

[b] Average amino acid.

RER = $\dot{V}_{CO_2}/\dot{V}_{O_2}$.

where $\dot{V}_{O_2}$ is the rate of oxygen consumption, $\dot{Q}$ is the cardiac output, and $C_{aO_2} - C_{VO_2}$ is the arterial-venous difference in oxygen concentration.

This equation describes how tissue $\dot{V}_{O_2}$ depends directly on cardiac output and the arterial to venous difference in oxygen content. It is assumed that all of the oxygen that has entered the cells is consumed in OXPHOS or other minor oxygen-consuming reactions (e.g., P450 enzymes). In contrast, although a modified version of the Fick equation (eqn (4)) can be used to determine cellular uptake of fuels, generally not all of the fuels taken up by a tissue become directly oxidized:

$$\text{Fuel uptake} = \dot{Q}_{\text{plasma}} \times (a - v)\text{fuel} \qquad (4)$$

where fuels entering cells is the product of plasma flow ($\dot{Q}_{\text{plasma}}$) and the arterial-venous difference for carbohydrates, lipids, or amino acids.

For instance, in mammals, only approximately 50% of the NEFA taken up by muscle will eventually be oxidized in that tissue. This highlights the many different fates for a fuel once it enters a cell. In addition to being broken down and transferring electrons to reducing equivalents for electron donation to the ETC, NEFA can be re-esterified and stored as TAG, incorporated into membranes, and can act as signaling molecules or as ligands for nuclear receptors (e.g., the peroxisomal proliferator-activated receptors, PPARs). In contrast, most of the glucose that enters muscle cells during exercise ultimately is oxidized. At rest or in other cell types, glucose entering a cell can undergo gluconeogenesis and be incorporated into glycogen for storage. The fate of fuels in a cell often depends on the ability of cells to either oxidize the fuel or incorporate it into cellular stores, which depends on whether that cell has: (1) a high density of mitochondria, (2) enzymes in specific metabolic pathways, and (3) high membrane-transporter density for metabolites and other metabolic intermediates. A good example is the slow-oxidative skeletal muscles in both mammals and fish, which have a low capacity for gluconeogenesis but a high capacity for glucose and NEFA oxidation.

Cell Membrane Transport

Oxygen uptake into cells occurs by simple diffusion across a diffusion barrier consisting of the capillary endothelium and the target cell membrane. The rate of net flux is directly related to the total surface area for transport, the partial pressure gradient for oxygen to enter the cell, and is inversely proportional to the thickness of the diffusion barrier. Fuels rely on facilitated diffusion for uptake involving fuel-specific transporter systems, both at the cellular and at the mitochondrial membranes (**Figure 2**). However, for both oxygen and fuels the surface area for transport can vary, in part, due to the amount of capillarization a tissue receives (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis).

Many fuel transport systems have been identified in both mammals and fish. NEFA transport at the cell membrane occurs via three possible transporters, fatty acid translocase (CD36/FAT), fatty-acid-binding protein plasma membrane (FABPpm), and fatty acid transport protein (FATP). Current evidence in mammals supports CD36/FAT as the major transport pathway for NEFA. Diffusion gradients for NEFA to enter the cell are maintained by the conversion of NEFA to fatty acyl-coenzyme A (CoA) by acyl-CoA synthase (ACS) or, possibly, by the membrane-bound FATP.

Glucose enters cells through a family of transporters called 'glucose transporters' (GLUTs), of which there are several members in mammals and many homologs in fish. In mammals, the GLUT transporters have tissue-specific distributions, for example, with GLUT 2 occurring in liver, GLUTs 1 and 4 in muscle, and GLUT 1 in red blood cells. Plasma glucose levels are under tight hormonal control in mammals, with release and uptake being continuously adjusted. Fish, on the other hand, are considered to be glucose intolerant because they have high circulating glucose even when insulin levels (the major glucose homeostasis hormone in mammals) are high. Glucose uptake into cells depends on the maintenance of an inward diffusion gradient. This is controlled by the enzyme hexokinase, which phosphorylates glucose as it enters the cell and keeps intracellular glucose concentrations low.

A host of other membrane transporters exist to facilitate the transport of other metabolites. The metabolic intermediates (lactate, pyruvate, and ketone bodies) are transported by a family of membrane transporters called the 'monocarboxylate transporters' (MCTs), of which there are now 12 members known in mammals. In fish, at least nine MCTs have been identified and found to facilitate transport of both lactate and pyruvate, although it has been speculated that there may be functional divergence between some fish and mammal MCTs. To vary membrane transport capacity, rapid recruitment of transport proteins from the intracellular stores to the plasma membrane can adjust transporter densities. This has been demonstrated in mammals for both CD36/FAT and GLUT 4. In addition, gene expression can be induced for many of these transporters in response to chronic energetic or environmental stress.

Cytosolic Transport

Since diffusion over long distances is often too slow to support biological processes or because some molecules are poorly soluble in aqueous solutions, carrier proteins exist in the intracellular fluid. Oxygen is poorly soluble in water and is typically associated with various storage/carrier proteins. Myoglobin (Mb) is a monomeric oxygen-binding protein that occurs in heart and muscle cells. Each Mb binds a single oxygen molecule and the amount of Mb correlates with the oxidative potential of the tissue. Mb does not demonstrate cooperative binding like hemoglobin (Hb) (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin) but its affinity for O_2 is much higher ($P_{50} \sim 3$ torr), which facilitates offloading of O_2 from the blood to the cells. Mb can also increase the rate of diffusion in the cytosol by several-fold. In muscle, Mb is never 100% deoxygenated even with maximal oxygen consumption. For this reason, Mb is considered an O_2 buffer for intracellular $[O_2]$, which remains homeostatic. Mb binds oxygen in the areas of high P_{O_2} and releases it in the areas of low P_{O_2}, thus aiding diffusion, in addition to the diffusion gradient (although thought to be shallow) from the cell membrane to cytochrome oxidase that aids intracellular O_2 transport. Moreover, it has been hypothesized that intracellular lipids increase O_2 diffusion rate because O_2 has a greater solubility in fat. Interestingly, an additional hypothesis proposes that an intracellular perfusion system is responsible for cytosolic transport for both oxygen and fuels.

Hydrophobic NEFAs are converted to acyl-CoAs in the cytosol and rely on cytosolic fatty acid binding proteins (FABPs) for transport to the mitochondria for breakdown by β-oxidation. Homologous FABPs have been identified in mammals, birds, and fishes. FABP increases NEFA solubility in the cytosol by ~700-fold and FABP is abundant in highly aerobic tissues. Interestingly, the whole NEFA–FABP complex moves within the cell rather than the NEFA moving from one FABP molecule to another, and this association is thought to increase the rate of diffusion through the cytosol by ~17-fold. FABPs also tend to aggregate close to mitochondria, with the majority bound to the cytosolic side of the outer mitochondrial membrane. Similarly, newly formed FA-CoAs are bound to an acyl-CoA-binding protein (ACBP) for transport to the mitochondrial membrane. When glucose crosses the cell membrane, it is rapidly converted to glucose-6-phosphate by hexokinase and enters glycolysis. The rates of glucose diffusion in the cytoplasm are adequate to support glucose oxidation, and the enzymes of glycolysis are often strategically located so that the pyruvate generated can quickly enter the mitochondria. As the oxidation of lipids, carbohydrates, and amino acids occurs in the mitochondrial matrix, these fuels must be transported across the mitochondrial membranes.

Mitochondrial Transport

Oxygen enters the mitochondria by simple diffusion and relies on the partial pressure gradient between the cytosol and cytochrome oxidase. Matching fuel transport into mitochondria relies on specific mitochondrial membrane transporters (**Figure 2**). Pyruvate generated by glycolysis in the cytosol crosses the mitochondria membrane via a mitochondrial pyruvate carrier (MPC) and is further converted to acetyl-CoA by pyruvate dehydrogenase complex (PDH). Entry of lipids into the mitochondria begins with the conversion of FA-CoA into a fatty-acylcarnitine by carnitine palmitoyltransferase (CPT)I on the inner side of the outer mitochondrial membrane. This is generally considered a major controlling step in mitochondrial fatty acid oxidation. Fatty-acylcarnitine is transferred into the mitochondrial matrix by carnitine acyltransferase (CAT) and converted back to FA-CoA by CPTII on the inner surface of the inner mitochondrial membrane. FA-CoA enters β-oxidation generating acetyl-CoA. Acetyl-CoA produced from glucose, NEFA, and amino acid catabolism enters the Krebs cycle.

Along with oxygen and fuels, the reducing equivalents NADH and $FADH_2$ generated in the cytosol need to be transferred into the mitochondria. Because the cell membranes are impermeable to these molecules, a number of redox shuttles exist for their membrane transfer. These include the malate–aspartate shuttle and the glycerol-3 phosphate shuttle. Recent evidence suggests that a lactate–pyruvate shuttle may exist in peroxisomes, but its role in mitochondrial redox shuttling has not been firmly established.

Cellular Respiration in Fish

Most, but not all, of the aspects of cellular respiration outlined above have been examined in fish. Probably the biggest difference between mammals and fish are the fuels used to power muscle during exercise and their plasticity in response to environmental and energetic stress.

Fuel usage during exercise is fairly well described in mammals. Low-intensity aerobic exercise is primarily fueled by lipids, and as intensity increases carbohydrates become a more important component of total metabolism. Some evidence points toward a roughly similar pattern occurring in fish, but with a higher contribution of protein metabolism to power swimming. In fact, measurements of NEFA turnover and glucose uptake suggest that these fuels do not meet all of the muscle energy requirements.

Protein (amino acids) and lipoproteins are two fuel sources that appear to play a more important role for energy production in fish than in mammals. Lipoproteins represent a very high proportion of energy in circulating lipids, and migrating salmon show a dramatic decrease (~27-fold) in circulation of lipoproteins over the course of their annual migration. Furthermore, in fish, a large part of resting metabolism is covered by protein catabolism (10–20%). The importance of proteins as a metabolic substrate also markedly increases in fish during extended periods of starvation or during migration. Migrating salmon lose about half of their white muscle mass over the course of a 1000+ km migration (**see also Fish Migrations**: Pacific Salmon Migration: Completing the Cycle). This represents a release of approximately 1200 g of protein that are broken down to amino acids, principally by lysosomes. These amino acids play several roles for the migrating salmon: they provide intermediates for the Krebs cycle to ensure continued OXPHOS, glucogeogenic precursors (alanine) to form glucose used during spawning, and finally amino acids that can be used as oxidative fuels. Like mammals, fish red muscle expresses the enzyme branched-chain oxoacid dehydrogenase for the oxidation of branched-chain amino acids (leucine, isoleucine, and valine). In fact, levels of this enzyme are higher in fish red muscle than in mammalian liver, suggesting the increased importance of amino acids to muscle metabolism in fish. In addition, excretion of nitrogenous wastes from protein breakdown is less energetically expensive in fish than in mammals (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia).

Unlike mammals, most fish do not have a great ability to oxidize ketone bodies. In this respect, one notable exceptional group is the elasmobranchs (sharks and rays), as they rely on ketone bodies to power muscle contraction. This is probably a compensatory adaptation of this group for the inability to transport NEFA in the circulation and to oxidize NEFA to any great extent in muscle. As a result, a high level of lipid oxidation in the livers of elasmobranchs ensures an adequate supply of ketones for extrahepatic tissues.

Environmental and Energetic Stress

Acute changes in oxygen and fuel delivery occur in response to changes in environmental temperature and oxygen and also with changes in energetic demand with the transition from rest to exercise. Since both oxygen and fuels share a convective transport step, increased cardiac output increases oxygen and fuel delivery to tissues to support an increase in metabolic rate during exercise or to enhance oxygen delivery during hypoxia. In fish, metabolic rate will increase by a factor of 2 or 3 with a 10 °C increase in temperature ($\dot{Q}$ of 2–3; **see also Temperature**: Effects of Temperature: An Introduction). Acutely, this is met with corresponding changes in oxygen and fuel delivery as kinetic processes respond directly to temperature. For example, an acute drop in temperature reduces resting heart rate and cardiac output in fish and consequently decreases fuel delivery to working tissues. Cold also increases the viscosity of intracellular fluids and decreases the diffusion rate of metabolites from the cell membrane to mitochondria. In addition, lower temperature can increase Mb affinity for O_2 and slow down dissociation and rate of diffusion. Interestingly, fish have Mb that rapidly binds and releases O_2 at greater rates than mammals and this aids in cold adaptation. Acute hypoxia and low environmental temperature cause distinct changes in plasma concentrations and turnover of NEFA and glucose in rainbow trout (*Oncorhynchus mykiss*). NEFA turnover declines with both hypoxia and temperature, while glucose appearance increases only in hypoxia. More importantly, in trout, turnover and plasma concentration are not correlated, which highlights the pitfalls of using concentration measurements to predict fuel kinetics (**see also Temperature**: Membranes and Temperature: Homeoviscous Adaptation).

Chronic exposure to low temperature in fish and other ectothermic animals demonstrates distinct compensatory responses (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature). This is especially dramatic in eurythermal fish that undergo seasonal changes in temperature. These fish will increase the aerobic capacity of cells by increasing mitochondrial density. This compensation for the decelerating effect of cold temperature is thought to aid in oxygen delivery by reducing the diffusion distance from capillary to mitochondria. Chronic cold-temperature exposure also causes an increase in tissue capillarity (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis) and cardiac hypertrophy, both of which aid in enhancing oxygen delivery. Fish muscles also respond to energetic stress brought about by repeated contractions (i.e., swim training). This also increases the aerobic capacity of the muscle to deal with higher energetic demands. Interestingly, distinct molecular mechanisms lead to cold- and contraction-induced remodeling in fish, and these regulatory pathways are divergent from the typical mammalian response to exercise training. There is a possibility that these differences in the regulation of fuel use in fish are due to their evolutionary history. As a group, fish experienced several large-scale genome duplication events that resulted in the presence of multiple forms of important regulatory proteins for which mammals only possess a single version (**see also Tissue Respiration**: Mitochondrial Respiration).

Limits to Cellular Respiration

The upper limit to cellular respiration is set by the upper limits to oxygen and fuel delivery, and the oxidative capacity of the cell. The upper limit to oxygen delivery is set by the oxygen transport system, namely the upper limit to gill diffusion capacity, blood oxygen-carrying capacity, and cardiac output. The upper limit to fuel delivery is a bit more complex since fuels are stored intracellularly, essentially right next to the mitochondria. Therefore, it is the rate of reducing equivalent production and capacity of the ETC for electron flux that limit the fuel side of the equation. Interestingly, some animals seem to have reached an upper limit to density of ETC components. For example, hummingbirds and bees have extremely high densities of inner mitochondria membrane that are packed with ETC proteins. However, because of their relatively low metabolic rate compared to an endotherm of the same size, fish do not ever reach this level of cristae density. Looking across body size in fish or at so-called high-performance fish such as tuna, gives us an idea of how increased energy demand is met by energy supply pathways. Tuna, billfish, and other predatory fish have very high metabolic rates that can approach those of similar-sized endotherms. These fish have oxygen and fuel supply systems that are upregulated to support these high energetic demands. For example, tuna have glucose turnover rates that are similar to those of similar-sized mammals. High turnover rates are partially the result of mammalian-like cardiac outputs (see **Design and Physiology of the Heart**: Physiology of Cardiac Pumping) in these high-performance fish species (**see also Pelagic Fishes**: Physiology of Tuna).

Novel Species

There are two very interesting groups of fish that can be thought of as models to investigate alternative oxygen or fuel delivery systems. The first has already been discussed and is the altered lipid metabolism of elasmobranchs. The second is the altered oxygen delivery system in the channichthyid icefish. Both of these examples can be thought of as natural knockout models with elasmobranchs lacking a key β-oxidation enzyme and icefish lacking oxygen transport proteins. The elasmobranchs circumvent their inability to oxidize NEFA in muscle by upregulating ketone body metabolism. The species of icefish lacking Hb and/or Mb compensate by decreasing diffusion distances through increased tissue vascularization, mitochondria densities, and lipid content. Moreover, icefish must maintain large blood volumes and heart masses to achieve much higher cardiac outputs than other similar-sized fish (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). Many, but not all, of these adaptations are thought to be the result of high nitric oxide (NO) levels. High levels result from the lack of Hb and Mb, proteins that would normally break down NO – a molecule involved in angiogenesis and mitochondrial biogenesis (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature).

Conclusions

The adequate transport of oxygen and fuels to working cells is essential for the homeostatic regulation of intracellular ATP concentrations. Both the oxygen- and fuel-delivery pathways share a convective transport step in the circulation. Thus, cardiac output and tissue capillarization play important roles in their supply to tissues. While the pathway for oxygen is roughly linear from environment to mitochondria, the pathway for fuels can be considered branched. The increased complexity of fuel-delivery systems stems from their multiple storage sites both intra- and extracellular. Besides, fuels must rely on specialized transport proteins to cross membranes and then specific metabolic pathways for their catabolism. Special adaptations may exist in fish to maintain adequate oxygen- and fuel-delivery rates. This can take the form of unique physiologies in species that show distinct rearrangements of specific fuel pathways or in the oxygen cascade.

Glossary

Complex I The first enzyme of the electron transport system (ETS). It oxidizes reduced nicotinamide adenine dinucleotide (NADH) and transfers electrons to ubiquinone. It is also known as NADH dehydrogenase.

Complex II The first enzyme of the ETS. It oxidizes reduced flavin adeninine dinucleotide ($FADH_2$) and transfers electrons to ubiquinone. It does not pump protons. It is also part of the tricarboxylic acid cycle and, when considered in this role, is called succinate dehydrogenase.

Complex III A proton-pumping complex that accepts electrons from ubiquinol (reduced ubiquinone) and transfers them to cytochrome *c*.

Complex IV The final enzyme of the ETS. It accepts electrons from cytochrome *c* and transfers them to oxygen, forming water. Like complexes I and III, this is a proton pumping complex. It is also known as cytochrome *c* oxidase, or COX.

Complex V The multiprotein mechanoenzyme that uses the energy of the proton motive force to generate ATP within the mitochondria. It is also known as the F_1F_o ATPase.

Creatine phosphate An energy store alternative to adenosine triphosphate (ATP). It is also known as phosphocreatine.

Electron transport system (ETS) A series of four multiprotein complexes (I, II, III, IV) and two mobile electron carriers (ubiquinone, cytochrome *c*) that transfer electrons from reducing equivalents to molecular oxygen to form water. It was previously called the electron transport chain, or ETC.

Mitochondria Cellular organelles that act as the powerhouse of the cell and produce the chemical energy source adenosine triphosphate, using oxygen as the final electron acceptor.

mtDNA The mitochondrial genome composed of circular DNA encoding critical subunits of OXPHOS and the tRNA and rRNA required for translation within the organelle.

Oxidative phosphorylation (OXPHOS) The coupling of oxidation in the ETS and phosphorylation by the F_1F_o ATPase.

Proton motive force (PMF) The electrochemical gradient across the inner mitochondrial membrane, produced by the ETS and used by the F_1F_o ATPase.

Reducing equivalents Molecules derived from vitamins that transfer electrons in redox reactions, mainly NADH, $FADH_2$ and reduced flavin mononucleotide ($FMNH_2$).

Introduction

Mitochondria are the main consumers of oxygen within the body and thus mitochondrial energy metabolism is the primary reason why fish breathe. Most of the impressive respiratory and circulatory adaptations described elsewhere in this encyclopedia are in place primarily to deliver oxygen to mitochondria. Consequently, understanding how mitochondria respire is at the core of most aspects of fish physiology.

Mitochondria are membranous organelles found within most eukaryotic cells. They have important roles in biosynthesis, but we focus here on their role in oxygen-dependent energy production. Animals consume complex food and break it down to macromolecules (carbohydrates, lipids, proteins, and nucleic acids). Multicellular organisms, including fish, further metabolize some of these dietary products into forms that can be imported by cells for energy production. Carbohydrates are converted to monosaccharides

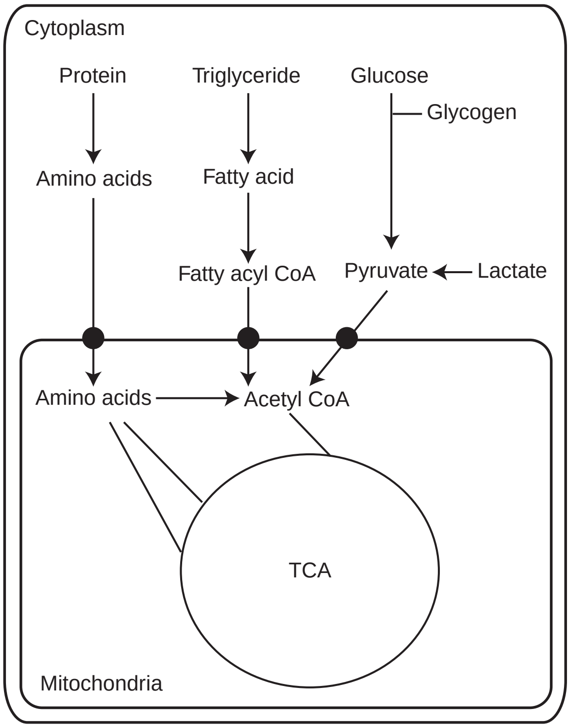

Figure 1 Production of mitochondrial substrates by cells.

(glucose), lipids are converted into fatty acids, and proteins are broken down to amino acids; nucleic acids have a minor role in energy production. These molecules – glucose, fatty acids, and amino acids – can then be metabolized by the cell to produce the substrates for mitochondria (**Figure 1**). Mitochondria metabolize their substrates using the enzymes of the tricarboxylic acid (TCA) cycle, producing reducing equivalents (nicotinamide adenine dinucleotide (NADH), flavin adeninine dinucleotide ($FADH_2$)). These in turn are oxidized by the electron transport system (ETS), which consumes oxygen while producing a proton gradient across the mitochondrial membrane. This electrochemical gradient can be utilized by the F_1F_o ATPase to produce adenosine triphosphate (ATP). The combination of electron transfer reactions (oxidation) and ATP synthesis (phosphorylation) is oxidative phosphorylation, or OXPHOS. This pathway is completely dependent on oxygen. Thus, the main reason why animals breathe is to get oxygen to mitochondria for efficient ATP synthesis. Without oxygen, cells must rely on preformed energy stores (ATP, creatine phosphate) and the fast, but inefficient, glycolytic pathway.

Many general aspects of mitochondrial structure and function are shared among all eukaryotic organisms. The basic structure of mitochondria, the nature of OXPHOS, the complement of enzymes, and the genetics, organization, and regulation are all fairly conserved among animals and thus much of what follows in this article can apply equally well to any species. However, evolution has led to surprising diversity in the specific features of mitochondria and these have been particularly well studied in fish in relation to evolution and development. The specializations of fish are discussed in **Tissue Respiration**: Specializations in Mitochondrial Respiration of Fish.

Importance of the Endosymbiotic Origin of Mitochondria

More than 1 billion years ago, life on the Earth was limited to prokaryotes, probably similar to the eubacteria and archaebacteria alive today. These living prokaryotes possess a remarkable array of metabolic strategies that allow them to survive even in the harshest environments on the planet. One of the earliest events in the evolution of more complex life was the invention of a membrane surrounding and protecting the genetic material (DNA), giving rise to the first eukaryote. This organism was probably unable to use oxygen, but entered into a functional relationship with another ancient organism, something resembling a modern alpha-proteobacterium. According to the endosymbiosis theory, the host cell engulfed the bacterium, and instead of digesting it as food, it negotiated a functional relationship that enabled the host cell/endosymbiont to utilize oxygen in energy metabolism. Over generations, the relationship changed with the endosymbiont/mitochondrion surrendering control over its own regulation to the host, even losing most of its genetic machinery to the host nucleus.

This ancient origin of mitochondria explains the conservation of many mitochondrial properties among diverse taxa. The basic features of mitochondria are similar among animals, plants, and fungi because mitochondria appeared in an ancestor shared more than a billion years ago. Indeed, many characteristics of mitochondria, such as genetic regulation and protein structure, remain similar to those of the modern purple bacteria. When talking about mitochondria function in an encyclopedia about fish, it is helpful to understand that many properties are highly conserved among all vertebrates, all animals, and indeed, all eukaryotes. Thus, the description of mitochondria that follows could apply equally to any animal because of the way mitochondria are built. Despite this general similarity, there are unique features of mitochondrial structure and function that have evolved, accounting for important differences between species and tissues.

Mitochondrial Structure

Most traditional depictions of mitochondria show the organelle to exist as ovals, about the size of bacteria, suggesting that mitochondria exist within a cell as multiple discrete entities. However, as revealed by three-dimensional reconstructions and whole cell imaging, it is now clear that mitochondria in many tissues exist as a connected membranous network, or reticulum. It is thought that a reticulum allows mitochondria to act like a giant electrical cable, allow a membrane potential to be transmitted throughout the entire network.

If one were to look inside a living cell, one would see the mitochondria moving throughout the cell. They are carried along cytoskeletal tracks (actin and microtubules) by motor proteins (myosin, kinesin, and dynein). In neurons, mitochondria travel along the axon, moving between the cell body and the axon terminus. In other cells, the mitochondria are taken to semi-permanent locations and mounted on the cytoskeletal framework. In muscle, separate populations of mitochondria exist beneath the cell membrane (subsarcolemmal) and others woven between bundles of myofibrils (interfibrillar).

Whether mitochondria exist as discrete organelles or extensive networks is determined by suites of GTPases and other proteins. Dynamin-like proteins pinch off pieces of the network, whereas mitofusins extend the network by recruiting individual mitochondria into the reticulum. This remodeling process is generally thought to provide the cell with a capacity to identify defective mitochondrial regions and send them to autophagosomes for degradation. It may also be important when tissues need to reduce mitochondrial content as a means of regulating bioenergetics.

The main structural features of mitochondria are seen in cross section. Surrounding the mitochondria is the outer mitochondrial membrane. Inside this membrane is the tightly folded inner mitochondrial membrane. Where the inner membrane is arranged into overlapping leafs, the layers are called cristae. The intermembrane space is between the inner and outer membranes, and the matrix is the space inside the inner mitochondrial membrane. Each of these four compartments has a characteristic complement of proteins, including transporters and enzymes (**Figure 2**).

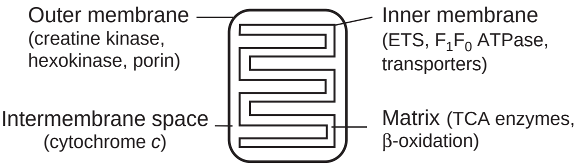

Figure 2 Mitochondrial compartments.

The outer mitochondrial membrane delimits the mitochondria. It is similar in composition to the cell's internal membrane system (cell membrane/endoplasmic reticulum/Golgi apparatus). As with most membranes, it has a relatively low permeability to small molecules. However, inserted into the outer membrane are large channels called porins. These channels permit the free movement of molecules smaller than about 10 000 Da into and out of the intermembrane space according to their chemical gradients. This means that metabolites, such as ATP, pyruvate and fatty acids, as well as ions, can cross the outer membrane but large proteins, such as cytoplasmic enzymes and cytochrome *c*, cannot. Due to this permeability, the intermembrane space is similar in solute composition to cytoplasm but distinct in terms of protein profile. The outer membrane also possesses some intrinsic proteins embedded within the lipid bilayer and peripheral proteins reversibly associated with the membrane.

The inner mitochondrial membrane is unusual in many respects. The membrane is unusually rich in proteins; as much as 80% of the membrane mass is protein, with the remainder lipid. In addition, the profile of phospholipids that make up its bilayer is very distinct from the outer membrane. Some classes of phospholids are unusually abundant, but there is also a phospholipid (cardiolipin) that occurs in this inner membrane and nowhere else in the cell. Cardiolipin has an important role in regulating many of the membrane-bound proteins of the inner membrane. Furthermore, the folded arrangement of the inner membrane into many layers (cristae) greatly increases the surface area available to insert complexes of OXPHOS. In most tissues, 1 cm^3 of mitochondria contains about 20–40 m^2 of cristae surface area.

The matrix, the innermost compartment of mitochondria, is a fluid in which the various metabolites associated with the TCA and OXPHOS are dissolved. The composition of mitochondrial matrix is very different from that of the cytoplasm and intermembrane space. It is very rich in proteins, including the enzymes of the TCA cycle. In fact, proteins are so abundant that most of the water within the matrix is bound to the proteins to form their hydration shells. Without much free water within the matrix, it has been suggested that many of the reactions within the TCA cycle involve substrate channeling from one enzyme to the next. The matrix also contains the numerous circles of mitochondrial DNA (mtDNA). They are collected together in bunches that are associated with specific integral membrane proteins of the inner membrane.

Mitochondrial Biogenesis

Over the course of eukaryote evolution, there was a transfer of power between the organelle and the host cell. In animals, most of the proteins needed by

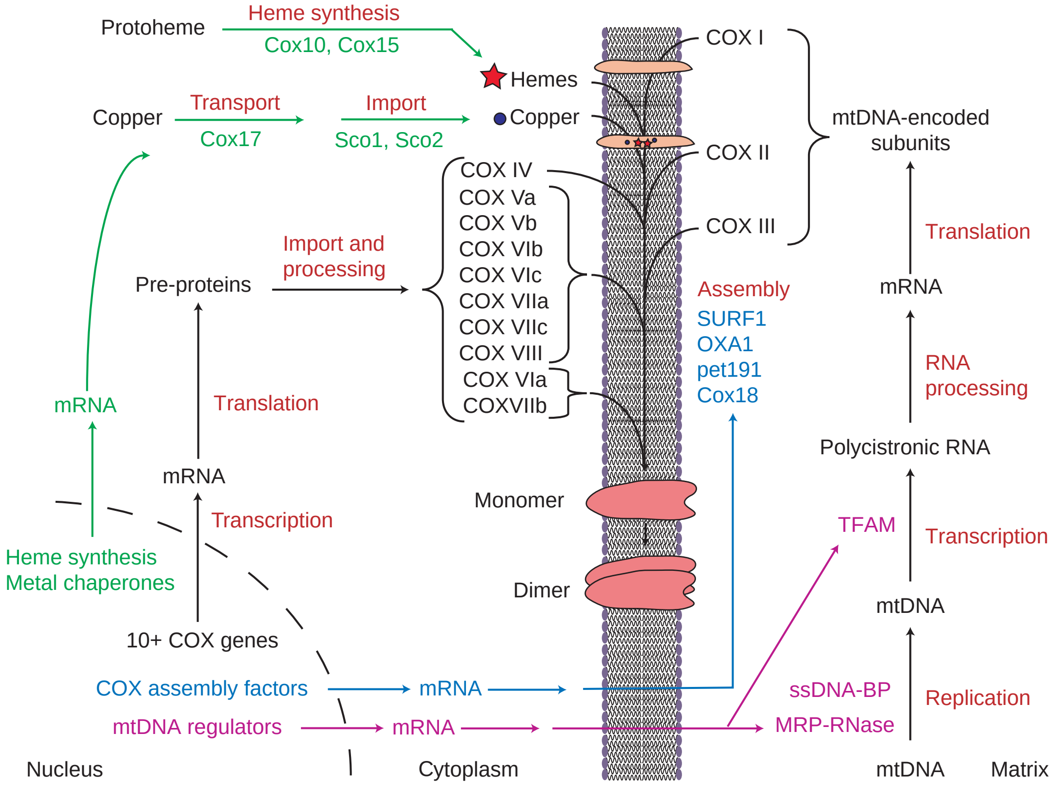

Figure 3 COX synthesis. Diagram includes COX subunit genes (black) encoded by nucleus (IV–VIII) and mtDNA (I, II, III), as well as proteins involved in metal and heme transport (green), transcriptional regulators (pink), and assembly factors (blue). Modified from Moyes CD and Hood DL (2003) Origins and consequences of mitochondrial variation. *Annual Reviews of Physiology* 65: 177–201.

mitochondria are encoded by nuclear genes. However, there is a core group of 13 proteins that are encoded by mtDNA. In addition to the protein-coding genes, mtDNA encodes the ribosomal and transfer RNA necessary for translation within the organelle. The organization of the mitochondrial genome is more similar to that of bacteria than a eukaryote nucleus. This bigenomic location presents a formidable problem for cells that want to alter their mitochondrial quantitative or qualitative properties. For example, consider the complexity of producing a single enzyme of the ETS (**Figure 3**). Cytochrome *c* oxidase (COX) is a 13-subunit metalloprotein that is produced from three mtDNA-encoded genes and 10 nuclear-encoded genes. When the cell needs to change the content of COX, it must produce the individual subunits in the correct proportions. For many of the nuclear-encoded subunits, there are multiple isoforms; so, in reality, the nucleus must control the expression of almost 20 distinct genes. Once the proteins are made in the cytoplasm, they need to be imported into the mitochondria, along with the metals and heme needed to produce the metalloprotein. While these events are happening outside the mitochondria, inside the mitochondria mtDNA-encoded genes are being regulated to produce the right amount of the three remaining subunits. Once all of the precursors are in place, the enzyme is assembled in a stepwise manner, a complex process mediated by suites of assembly proteins.

Coordination of the nucleo-cytoplasmic and mitochondrial processes of mitochondrial biogenesis is mediated in large part at the level of transcription. The hundreds of nuclear genes encoding mitochondrial proteins are regulated by a small suite of transcriptional regulators. These proteins bind onto promoters of individual genes and control expression as networks of genes. The most prominent of these transcriptional regulators are nuclear respiratory factor-1 (NRF-1), NRF-2, and their common regulator peroxisome proliferator-activated receptor gamma coactivator 1 (PGC1). The role of these regulatory factors is best studied in mammals, where increases in the levels of one or more of these proteins parallel increases in mitochondrial enzyme content.

Basic Features of OXPHOS

The process by which mitochondria use oxygen and make ATP is a combination of two independent pathways. These pathways, oxidation and phosphorylation, are functionally coupled through shared sensitivity to the electrochemical gradient across the mitochondrial inner membrane.

Oxidation by the ETS

The ETS accepts electrons from reducing equivalents, passes them down a chain, ultimately to oxygen to form water (**Figure 4**). The first step in this process is the oxidation of a reducing equivalent, NADH or $FADH_2$. NADH is produced in a number of mitochondrial reactions, but the most important sources are the pyruvate dehydrogenase complex (PDC) and the three TCA cycle dehydrogenases: isocitrate dehydrogenase, 2-oxoglutarate dehydrogenase, and malate dehydrogenase. The NADH from these reactions is oxidized by complex I, a large complex composed of more than 40 subunits encoded by both the nucleus and mtDNA. Electrons are transferred within the complex and donated to ubiquinone, the first mobile electron carrier of the ETS. Ubiquinone is also an electron acceptor for other dehydrogenases that use flavin nucleotides as internal electron acceptors. Complex II, or succinate dehydrogenase, is a flavin adeninine dinucleotide (FAD)-linked enzyme that donates electrons arising from succinate oxidation. The fatty acid oxidation enzyme fatty acyl CoA dehydrogenase is a flavin mononucleotide (FMN)-linked enzyme that is another source of electrons for ubiquinone. Regardless of the source of electrons for ubiquinone, the reduced ubiquinone (ubiquinol) is oxidized by complex III, which transfers electrons to the second mobile electron carrier, the heme protein cytochrome *c*. Reduced cytochrome *c* transfers its electrons to complex IV (cytochrome *c* oxidase, or COX). Finally, complex IV transfers electrons to oxygen to form water.

This basic pattern of electron transport is similar among all animals and its purpose is to provide energy to pump protons into the intermembrane space from the matrix.

Proton Motive Force

During electron transport through the chain of complexes, some of the energy that is released from oxidation of reducing equivalents is used to pump protons out of the mitochondrial matrix. Complexes I, III, and IV each pump protons; complex II and the other flavin-linked dehydrogenases do not. The resulting proton gradient is a source of energy that can be used for various purposes. There is chemical energy associated with the pH gradient (delta pH) as the proton concentration is higher outside the mitochondria. There is also an electrical energy associated with the membrane potential (delta psi) with the inside of the mitochondria being more electronegative. This electrochemical gradient, known as the proton motive force (PMF), drives many transport processes but perhaps the most important is ATP synthesis.

Phosphorylation

The PMF is the driving force for ATP synthesis by the mechanoenzyme complex V, or F_1F_o ATPase. When protons flow through a channel in the enzyme, the movement spins the protein, much like wind drives a turbine. The mechanical movement of this rotor provides the energy to add an inorganic phosphate group to adenosine diphosphate (ADP) to form ATP. Like most enzymes, but unlike most ATPases, this enzyme can run backward within the cell; ATP hydrolysis can

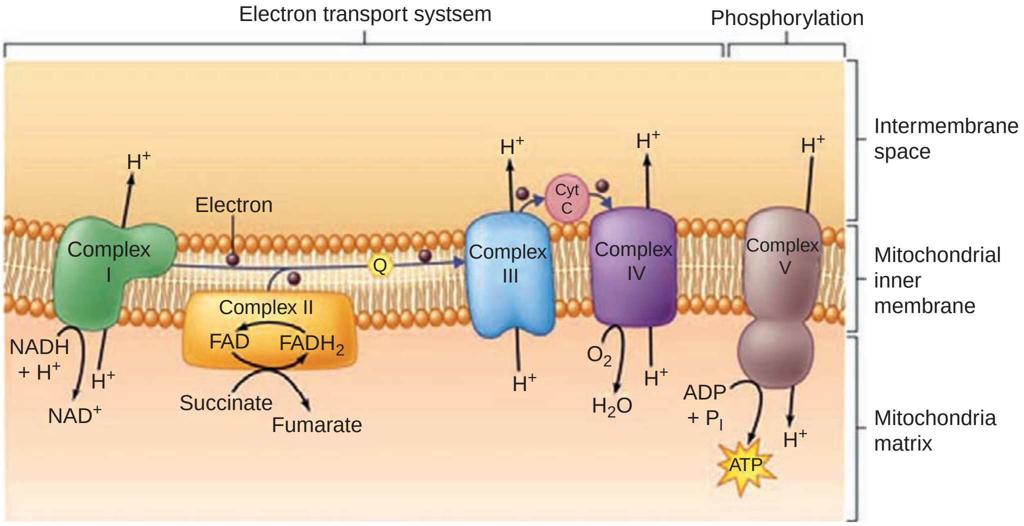

Figure 4 Electron transport and OXPHOS. Reproduced from Moyes CD and Schulte PM (2008) *Principles of Animal Physiology*. San Francisco, CA: Pearson/Benjamin Cummings.

be the driving force to cause the enzyme to eject protons out of the mitochondria. This capacity enables depolarized mitochondria to regenerate their PMF. ATP synthesis by this enzyme is possible only when both substrates (phosphate and ADP) are available and the mitochondria possess sufficient PMF to drive the reaction.

Coupling and Uncoupling

The PMF is produced by the oxidation–reduction cycles of the ETS and it is utilized in the phosphorylation of ADP by the F_1F_o ATPase. These two processes – oxidation and phosphorylation – may involve separate proteins but they share sensitivity to the PMF. One can think of the PMF as a product of the ETS, and when this product is high, it inhibits the ETS, leading to a low rate of oxygen consumption regardless of the availability of the reducing equivalent substrates. When mitochondria synthesize ATP, the PMF is diminished, allowing greater rates of electron transport and oxygen consumption. Thus, oxidation by the ETS is coupled to phosphorylation. This relationship is the main reason why animals consume less oxygen at rest and more oxygen during activity.

In mitochondria that are well coupled, oxygen consumption reflects the rate of ATP synthesis. However, there are instances where respiration occurs independently of ATP synthesis, that is, uncoupled respiration. Uncoupled mitochondria consume oxygen but produce less ATP. If, for example, mitochondria sustain damage such that there is a loss in the integrity of the inner membrane, protons flow freely down their concentration gradient. In such circumstances, a lower PMF permits ETS activity but is insufficient to drive ATP synthesis.

On the surface, uncoupling respiration would seem to have no upside. It is a waste of chemical energy because fuels are consumed but less ATP is produced. However, in some circumstances this can be beneficial because the chemical energy that would have been transferred from reducing equivalents to ATP is instead lost as thermal energy. In other words, uncoupled mitochondria generate heat. In endotherms, such as mammals and birds, the inner mitochondrial membrane is inherently leaky, and their mitochondria are less coupled. For a given amount of ETS activity (oxygen consumption) less ATP is produced than would be in mitochondria from ectotherms, like fish. This membrane leakiness is an important source of heat for endothermy. Mammals are also capable of inducing uncoupling through synthesis and activation of a specific uncoupling protein (UCP) known as thermogenin. This protein would appear to be a mammalian invention, and though all eukaryotes possess their own UCPs, nonmammalian UCP homologs do not generate significant heat. Though several species of fish are able to generate and retain metabolic heat, none of the pathways appear to involve uncoupling of mitochondria. For example, tuna and lamnid sharks generate heat through muscle activity, and billfish heater organs produce heat through futile cycling of Ca^{2+} (**see also Pelagic Fishes**: Physiology of Tuna and Endothermy in Tunas, Billfishes, and Sharks).

Regulation of Mitochondrial Respiration Rate

The regulation of mitochondrial ATP production is complex because so many different substrates and products can influence OXPHOS. In muscle, most of the control of respiration probably resides in the substrates and products of the ATPase. In resting trout white muscle, mitochondria respire at very low rates due to a high ratio of ATP/ADP. Though there is a need for some mitochondrial ATP to support diverse cellular activities, the low respiration rate under these resting conditions results from both basal ATP demands and the effects of mitochondrial proton leak. Both processes dissipate the PMF and permit ETS activity, although only the former results in ATP synthesis. With high-intensity exercise, ATP must be hydrolyzed by the actinomyosin ATPase, increasing both ADP and phosphate levels in muscle. The increases in these substrates stimulate ATP synthesis, which dissipates the PMF and permits the consumption of oxygen by the ETS. In this way, muscle cells can regulate the rates of ATP production in response to ATP demand.

Although regulation of oxygen consumption by the substrates and products of the ATPase is the most common scenario, there are situations where OXPHOS is regulated by other substrates, such as NADH and $FADH_2$. The importance of redox control has been best studied in mammals but it is likely that redox regulation of OXPHOS can play a role in respiratory control of some fish tissues. Under some circumstances, the desired rate of respiration can be suppressed by oxygen limitations within the cell. This has two main effects on mitochondria. First, with a deficiency in this important substrate, ETS activity is reduced and the PMF suffers, reducing the rate of ATP synthesis. Second, the reduction in electron flow through the ETS accelerates the spontaneous production of reactive oxygen species (ROS). In impairing ETS activity, complexes spend more time in the reduced state, and under these conditions, molecular oxygen can steal electrons to form superoxide. This ROS initiates a cascade of free radical production that damages DNA, lipids, and proteins.

Fuel Selection

At the level of the whole animal, the choice of which fuels to burn for energy is controlled at multiple levels and involves hormones, the gastrointestinal tract, energy stores, and enzyme regulation at the storage and target tissues (**see also Tissue Respiration**: Cellular Respiration). Thus, much of the regulation of fuel selection occurs prior to mitochondrial exposure to its carbon substrates. At the level of mitochondria, the main factors that affect fuel selection are fuel availability and regulation of one main enzyme that affects the choice between fatty acids and pyruvate, PDC. Low energy levels are reflected in reductions in NADH/NAD, acetyl CoA, and ATP/ADP. These metabolites and metabolite ratios regulate PDC activity both allosterically and covalently, through effects on PDC kinases (inhibition) and PDC phosphatases (activation).

Conclusions

Many aspects of mitochondrial structure and function are broadly similar among diverse species because of the origins of mitochondria in a common ancestor shared by eukaryotes more than a billion years ago. Mitochondria, in muscle, exist as a dynamic organelle network, with regional specializations that distinguish mitochondria in subsarcolemmal and interfibrillar regions of the myofiber. Regulation of mitochondrial rate in response to physiological energy demands occurs largely through substrates and products of the OXPHOS. Probably, the most important regulatory step in regulation of mitochondrial rate under changing environmental and physiological conditions is the F_1F_o ATPase, particularly through effects of the concentration of ADP. Under some conditions, oxygen limitations impair mitochondrial respiration, compromising ATP synthesis and exacerbating ROS production. When oxygen levels are insufficient to support metabolism, the membrane potential is lost. Thus, animals and tissues use complex pathways (**see also Hypoxia**: Anaerobic Metabolism in Fish, Metabolic Rate Suppression as a Mechanism for Surviving Hypoxia, and The Expanding Hypoxic Environment) to ensure that oxygen uptake at the respiratory epithelium and oxygen delivery by the cardiovascular system are sufficient to permit tissues to use OXPHOS to generate the ATP required for cell survival.

Glossary

Coevolution The parallel evolutionary change of structurally or functionally related proteins.

Complex I The first enzyme of the electron transport system (ETS) when oxidizing reduced nicotinamide adenine dinucleotide (NADH). Electrons taken from NADH are transferred to ubiquinone. It is also known as NADH dehydrogenase.

Complex II The first enzyme of the ETS when oxidizing succinate. Electrons taken from succinate are transferred to FAD within the enzyme. The resulting reduced flavin adeninine dinucleotide ($FADH_2$) is oxidized, with the electrons transferred to ubiquinone. It does not pump protons. It is also part of the tricarboxylic acid cycle and, when considered in this role, is called succinate dehydrogenase.

Complex III A proton-pumping complex that accepts electrons from ubiquinol (reduced ubiquinone) and transfers them to cytochrome *c*.

Complex IV The final enzyme of the electron transport system. It accepts electrons from cytochrome *c* and transfers them to oxygen, forming water. Similar to complexes I and III, this is a proton-pumping complex. Also known as cytochrome *c* oxidase, or COX.

Complex V The multiprotein mechanoenzyme that uses the energy of the proton motive force to generate ATP within the mitochondria. It is also known as the F_1F_O ATPase.

Creatine phosphate An energy store alternative to ATP. Also known as phosphocreatine.

Electron transport system A series of four multiprotein complexes (I, II, III, IV) and two mobile electron carriers (ubiquinone and cytochrome *c*) embedded in or associated with the inner mitochondrial membrane that transfer electrons from reducing equivalents to molecular oxygen to form water, and in so doing forms an electrochemical gradient. Previously called the electron transport chain, or ETC.

Mitochondrion A cellular organelle that acts as the 'powerhouse' of the cell and produces the chemical energy source adenosine triphosphate, using oxygen as the final electron acceptor.

mtDNA The mitochondrial genome composed of circular DNA-encoding critical subunits of oxidative phosphorylation and the tRNA and rRNA required for translation within the organelle.

Oxidative phosphorylation (OXPHOS) The coupling of oxidation in the ETS and phosphorylation by the F_1F_O ATPase.

Positive selection The rapid accumulation of mutations in the sequence of a gene that can translate into changes of the structure and function of the resulting protein.

Proton motive force (PMF) The electrochemical gradient across the inner mitochondrial membrane, produced by the ETS and used by the F_1F_O ATPase.

Reducing equivalents Molecules derived from vitamins that transfer electrons in redox reactions, mainly NADH and $FADH_2$.

Introduction

The basic features of mitochondrial metabolism are shared among eukaryotes are discussed in **Tissue Respiration**: Cellular Respiration. However, all species have some specializations that modify the basic unit of a mitochondrion to build an organelle that is better suited to its role in those species. Thus, in fish there are many examples of peculiarities in mitochondrial structure and function that fine-tune mitochondrial properties in ways that are better suited to their lifestyle. In some cases, the differences are quantitative. For example, a fish might possess more of an otherwise-unremarkable enzyme, conferring greater enzymatic capacity. In other cases, the differences are qualitative, where a fish might have a distinctly different approach to mitochondrial structure or function. In this article, we discuss the many ways that mitochondria from a fish differ from the basic plan shared by eukaryotes. In some cases, these are traits of individual taxa of fish, and can be attributed to the adaptive radiation among fishes. In other cases, fish as a group demonstrate differences from other vertebrates that arose as a result of the evolutionary history of vertebrates. Although mitochondria are essential to diverse cellular systems and organismal functions, most research in this area has been conducted on muscle tissue because of the critical role of mitochondria in supporting animal locomotion.

Genetic and Genomic Variation

Diversification of fish over evolutionary time has led to variation in the primary sequence of genes encoding mitochondrial enzymes and regulators of genes encoding mitochondrial products. Such variation can be used to infer evolutionary relationships, and test specific hypotheses in biogeographics and population genetic, making the important assumption that most substitutions are selectively neutral or nearly so and do not have significant consequence for mitochondrial function. In an increasing number of cases, however, genetic differences among lineages have important consequences for mitochondrial function.

Bigenomic Evolution

Mitochondrial DNA (mtDNA) sequence data have played a central role in animal molecular phylogenetics. Such data have proved particularly useful in inferring relationships among relatively closely related groups because mtDNA evolves, on average, faster than comparable nuclear genes. All of the oxidative phosphorylation (OXPHOS) complexes (except complex II) are composed of subunits derived from the nucleus and mtDNA as described in **Tissue Respiration**: Cellular Respiration. If nuclear and mtDNA-encoded subunits for a given complex evolve at different rates, there is the greater potential for mtDNA mutations to disrupt the enzyme assembly and function. Defects in complex structure and function will incur a heavy selective penalty, and thus divergence in DNA sequence of these genes is predicted to be modest and comprised of synonymous substitutions (i.e., those not resulting in a change in the amino acid residue encoded by a codon). This is called purifying selection. However, there are numerous recent examples of groups of taxa where mtDNA sequences have diverged much more than expected (accelerated evolution) or have a preponderance of mutations that are nonsynonymous, resulting in amino acid substitutions.

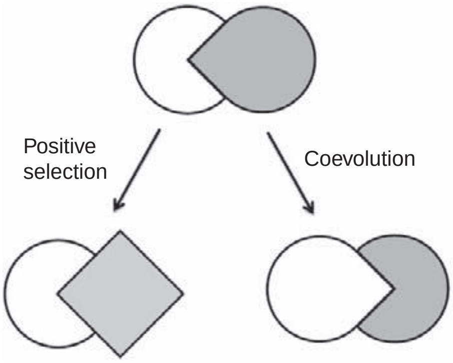

Figure 1 Positive selection and coevolution of multimeric proteins. When separate genes encode subunits of a multimeric protein, there is the potential for different types of structural evolution. In coevolution, both interacting subunits experience changes in structure, but the effects counteract and there is no net change in structure. In positive selection, one subunit experiences a significant change in structure, altering the enzyme global structure and function.

Accelerated mitochondrial evolution and such nonsynonymous mutations have been described for a number of taxonomic groups that have evolved unusual patterns of energy metabolism: snakes, primates, and scombrid fish (tunas and their relatives). Some mutations might change protein sequence, but do so in a way that is functionally neutral. However, amino acid substitutions typically result in one of two situations (**Figure 1**). Positive selection might change the structure in a way that alters assembly, stability, or kinetics of the protein. In many cases, a mutation occurs in one part of a protein (that in isolation would have important structural consequences for the complex), but a second gene also experiences a significant mutation that negates the impact of the first mutation. The net effect of these two compensatory mutations is maintenance of the structure and function of the whole complex. This pattern of coevolution is seen in many of the genes of cytochrome *c* oxidase (COX) in a variety of animals.

Though there is abundant sequence information of mitochondrial genes, an experimental challenge has been to assess the functional consequences of the genetic variation. The impact of mtDNA variation has been difficult to test directly because it is not currently technically feasible to perform site-directed mutagenesis studies on mitochondrial proteins; however, the availability of crystal structures of mitochondrial proteins and related analytical work can give insight on the impact of genetic changes.

Gene and Genome Duplication

Many aspects of metabolism are fine-tuned through the use of isoforms of enzymes (isozymes). For example, tissues can express different lactate dehydrogenase isozymes; one form is well suited to oxidize lactate while the other isoform is better suited to produce lactate. Though different versions of enzymes can arise through alternative splicing of the mRNA from a single gene, it is more common for isozymes to arise from different genes within the same genome (paralogs). The repertoire of paralogs in a given animal arises from ancient duplications of individual genes or entire genomes. Thus, many of the differences between fish and other vertebrates are a reflection of a combination of gene and genome duplications, shortly followed by a division of tasks of the duplicated isoforms (subfunctionalization), diversification of duplicates where one acquires new functions (neofunctionalization), or the loss of a duplicated gene (pseudogenization).

Early in vertebrate evolution, two genome duplication events are thought to have occurred (**Figure 2**). The first duplication (1R) probably occurred in an early agnathan ancestor around the origin of lamprey and hagfish. The second genome duplication (2R) occurred prior to the divergence of chondrichthians. After these duplications, the common ancestor to sharks, fish, and tetrapods shed some duplicate genes, as did the ancestors to individual lineages. A third large-scale duplication event occurred early in teleost evolution (3R), such that most teleosts possess more copies of select genes than do ancient bony fish, cartilaginous fish, and tetrapods. Finally, select lineages of teleosts (e.g., salmonids) have experienced additional genome duplications (4R) resulting in various degrees of polyploidy.

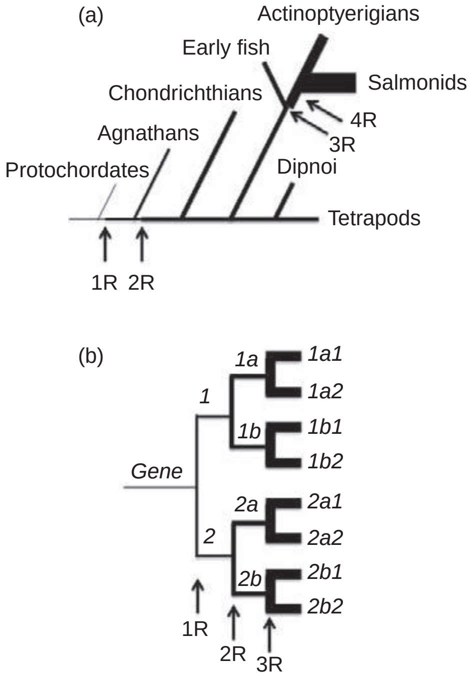

Figure 2 Gene and genome duplications in fish. (a) It is thought that whole-genome duplications (R) have occurred repeatedly over vertebrate history, beginning just prior to the origins of agnathans. (b) These genome duplications increase the number of paralogs of enzymes, giving rise to genes that are usually expressed in tissue-specific patterns.

As a consequence of these events,

1. lamprey and hagfish generally have more copies of genes that are single genes in invertebrates;
2. cartilaginous fish, bony fish, and tetrapods have more gene copies than extant agnathans;
3. derived teleosts have more gene copies than basal teleosts; and
4. select teleosts have more genes than their sister taxa.

Though many studies have explored the impact of these gene duplications on processes such as embryonic development and muscle formation, the significance of genome duplications on metabolism is largely unexplored. For example, most of the genes encoding enzymes of the glycolytic pathway show a pattern of diversity that is consistent with the 1R/2R/3R/4R series of gene duplications. In many cases, the extra copies have evolved to be tissue-specific isoforms. The importance of gene and genome duplications on mitochondrial function has only recently been studied, and like the glycolytic pathway there is an underlying influence of the 1R/2R/3R events on gene families for mitochondrial proteins.

Most of the subunits of tricarboxylic acid cycle enzymes are encoded by single genes, which clearly contrasts with most glycolytic enzymes/enzyme subunits that have multiple isoforms. For whatever reasons, duplicated genes for most mitochondrial proteins have been lost after genomic duplication events. In contrast, there are many examples of isoforms of subunits of OXPHOS complex genes. Many of the duplicates have been retained, with divergence, from the 1R and 2R genomic events. In addition, fish have retained many of the gene duplicates arising from the 3R genome duplication and subsequent lineage-specific genomic events. The functional consequences of the fish OXPHOS subunit variants have yet to be established.

Mitochondrial Structure and Function

In any particular fish, almost every cell possesses a nearly identical genome. Nonetheless, each tissue builds its mitochondria with tissue-specific properties. This developmental plasticity is an important component of mitochondrial function. Thus, it is not surprising that when comparing different species, structural and functional differences accrue. Many important differences in mitochondrial structure and function are obvious when comparing different groups of fish or comparing fish with other vertebrates.

Fuel Selection

One unusual aspect of mitochondrial function in fish, relative to other vertebrates, is fuel selection in muscles. Tetrapod muscles oxidize a range of substrates but, in most circumstances, they rely on some combination of fatty acids (from triglyceride) and pyruvate (from carbohydrates). Under starvation conditions, glucose levels decline and the liver converts some fatty acid to ketone bodies (acetoacetate, beta-hydroxybutyrate) to enable the vast lipid stores to be utilized by tissues such as brain. Under these circumstances, peripheral tissues such as muscle also rely on ketone bodies. In bony fish, however, muscles have little capacity to use ketone bodies as oxidative fuel. The circulating levels of ketones in the blood change little even during prolonged starvation, and mitochondria from fish muscle do not seem to use ketones to any significant extent (**see also Tissue Respiration**: Cellular Respiration).

Like bony fish, chondrichthians (e.g., sharks, rays, and skates) also have an unusual muscle fuel preference. Though muscles of bony fish rely on fatty acids for energy production, shark muscles cannot oxidize fatty acids. Instead, mitochondria from chondrichthian muscle rely on ketone bodies as their lipid source. Ketone bodies are higher in shark blood and change little with starvation. Furthermore, little fatty acid is carried in shark blood and their heart quickly succumbs in experiments where isolated hearts are given fatty acids.

Inner Membrane Surface Area

The inner mitochondrial membrane is the home for the proteins of OXPHOS, and within the membrane the proteins are very closely packed. Proteins constitute almost 80% of the mass of the inner mitochondrial membrane, which has important implications for mechanisms by which evolutionary and developmental mitochondrial specializations arise. For example, if a fish could benefit from an increase in maximal mass-specific mitochondrial OXPHOS capacity (adenosine triphosphate (ATP) produced per minute per gram tissue), then it would need to increase the OXPHOS specific activity within the tissue. Because the inner mitochondrial membrane is densely packed with OXPHOS complexes, there is little potential to increase OXPHOS capacity by increasing the amount of OXPHOS protein in a given amount of inner membrane. Thus, an increase in OXPHOS specific activity can arise through (1) an increase in the amount of inner mitochondrial membrane contained within a volume of mitochondria or (2) an increase in the volume of mitochondria within a volume of tissue (**Figure 3**). The two strategies can be distinguished through mitochondrial morphometric analysis. Mitochondrial images are taken using transmission electron microscopy and ultrastructural features measured directly on the images. The results of the morphometric analyses lead to measures of inner mitochondrial membrane surface area per mitochondrial volume (Sv(im,mt)) and mitochondrial volume per volume of muscle fiber (Vv(mt,mf)).

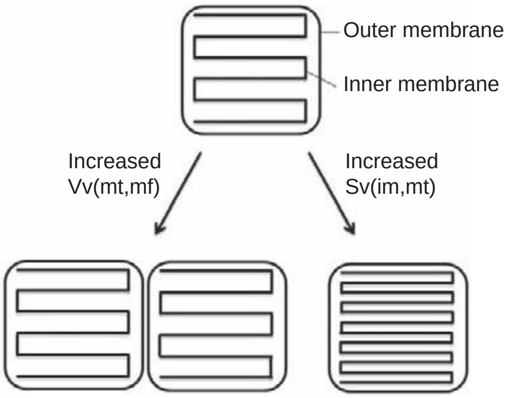

Figure 3 Strategies for changing mitochondrial capacity. Mitochondrial cristae content (surface area) is tightly packed within a volume of mitochondria. Some strategies for increasing mitochondrial inner membrane in a volume of tissue rely upon increasing mitochondrial content (Vv(mt,mf)). Other strategies increase the surface area of mitochondrial inner membrane contained within a given volume of mitochondria (increased Sv(im,mt)).

Most vertebrate muscles have Sv(im,mt) values between 20 and 40 m^2 of inner mitochondrial membrane per cubic centimeter of mitochondria. The reason for this is probably related to constraints on intramitochondrial dimensions and diffusion distances. When inner membrane is packed this tightly, there is barely enough room for a couple of enzyme molecules between opposing layers of inner membrane. The fact that this basic design feature of muscle mitochondria is similar across broad taxa infers that the main way animals alter OXPHOS capacity is by changing the volume of mitochondria within the fiber. However, there are a few high-performance species of vertebrates – tuna, hummingbird, and pronghorn antelope – that have been shown to possess mitochondria with surface area to volume ratios that are twice as high, in the 60–70 $m^2\ cm^{-3}$ range. It is thought that this elevated surface area is an important mechanism by which these species increase OXPHOS capacity within the muscle. Conversely, some polar fish have very low inner-membrane surface area ($<20\ m^2\ cm^{-3}$), though mitochondrial content is relatively normal. Recall that mitochondria in muscle occur as a reticulum and it is thought that this arrangement of mitochondria – abundant mitochondria with relatively few cristae – facilitates diffusion of oxygen into the depths of the muscle.

Mitochondrial Content of Muscle

Even in those species where mitochondrial surface area is within the typical range, differences in OXPHOS capacity can arise through changes in mitochondrial content, typically assessed as Vv(mt,mf). Differences are seen in development, where muscle fibers achieve a mitochondrial content that is appropriate for their fiber type. Thus, slow-twitch (i.e., red) muscle has a higher mitochondrial content than fast-twitch (i.e., white) muscle. This difference in mitochondrial content between fiber types of an animal is seen in all vertebrates. However, while the mitochondrial enzyme activities of tetrapod muscle fibers differ only about two- to threefold between locomotor muscle fiber types, fish red and white muscle mitochondrial enzyme activities differ by much more, 5- to 10-fold.

The main reason for the disparity in mitochondrial enzyme capacities between red and white fibers is a difference in mitochondrial volume per fiber. In most fish species, about 25–30% of the volume of red muscle is occupied by mitochondria, while in the same species white muscle mitochondria typically occupy less than 5% of myofiber (**see also Design and Physiology of the Heart**: Cellular Ultrastructure of Cardiac Cells in Fishes).

Interestingly, there is little difference in the mitochondrial content of red muscle among fish species. The mitochondrial volume in red muscle of the fastest and slowest species is consistently between 25% and 30% of the myofiber volume. The main difference in oxidative muscles between species appears to be the relative proportion of the red muscle itself. In active fish species, red muscle constitutes a much greater proportion of total muscle mass than in inactive species. Fish red muscles generally have higher mitochondrial volumes than do tetrapod locomotor muscles, which have Vv(mt,mf) values that are typically less than 5%.

A paradigm where differences in mitochondrial content are seen in diverse animals is the effect of body mass. Allometric scaling of metabolism, first identified more than 100 years ago by Rubner, reflects the effects of body size on aerobic respiration. Larger animals have greater rates of oxygen consumption (milliliter of O_2 per minute per animal), but less than would be expected if the parameters increased in direct proportion. Thus, larger animals have lower mass-specific metabolic rates (milliliter of O_2 per minute per kilogram). It has also been shown that the mitochondrial enzyme activities also show scaling, though to a lesser extent than metabolic rate. In the case of fish, the data are more complex. Meta-analysis of scaling of respiration suggests no single pattern of the effects of body size on metabolic rate. Likewise, there are complex patterns of size-dependent muscle enzyme activity. In general, however, many fish show evidence of scaling of respiration and muscle mitochondrial enzymes (**see also Energetics**: Physiological Functions that Scale to Body Mass in Fish).

The underlying mechanisms that cause muscles of different-sized fish to produce their appropriate metabolic phenotype remain uncertain. There are questions about how a muscle cell regulates its genes in a coordinated manner to ensure that all of the required gene products are at the required levels. The size-dependent patterns seen within a species as it grows (ontogenetic scaling) and between species differing in mass (phylogenetic scaling) may arise through different mechanisms. However, it is likely that the factors that determine the expression of mitochondrial genes in an individual also play a role in manifestation of the differences seen between species.

Control of Mitochondrial Biogenesis

Like other metabolic pathways, mitochondria respond to environmental and physiological challenges to maintain energy homeostasis. In many cases, fish experience the same type of remodeling responses seen in mammals. For example, changes in muscle-mitochondrial content and fuel selection are seen in response to exercise training and diet. Perhaps the best-studied response is the muscle remodeling that occurs in response to temperature. This process is reviewed in more detail in **Temperature**: Mitochondria and Temperature but, in brief, acclimation to cold temperature and acclimatization to winter conditions both induce mitochondrial proliferation in the locomotor muscles of many fish species. Cold acclimation in striped bass (*Morone saxatilis*) and goldfish (*Carassius auratus*) induces a near doubling of mitochondrial content in white muscle, and a lesser increase in red muscle. While salmonids show a similar but attenuated pattern, centrarchids (bass and sunfish) do not appear to exhibit the typical cold-induced mitochondrial proliferation seen in other species. The reasons for the species-specific responses are not yet known.

Changes in mitochondrial content in response to environmental and physiological challenges appear to be driven by the same family of transcriptional regulators that have been implicated in mammals: nuclear respiratory factor 1 (NRF1) and NRF2. A role for peroxisome proliferator-activated receptor-gamma coactivator 1α (PGC1α), a master regulator of mitochondrial content in mammals, is less clear in fish. In goldfish, NRF1 mRNA levels are a good predictor of mitochondrial gene expression and enzyme levels in different tissues and in response to changes in diet and temperature. Such a finding would be predicted from studies on mammals, but the same studies would also predict that PGC1α mRNA would change in parallel. In contrast, in the goldfish study, PGC1α did not change in parallel to NRF1 (**Figure 4**), suggesting that it is playing a different role in fish than mammals. The reason for this difference may be related to the structure of PGC1α. The region of the protein that interacts with NRF1 in mammals appears to have a series of insertional mutations in fish that may disrupt the interaction. In contrast to PGC1α, a different member of the gene family, PGC1β, may play the role of master controller in fish. The levels of PGC1β mRNA are much better predictors of mitochondrial gene expression in goldfish tissues.

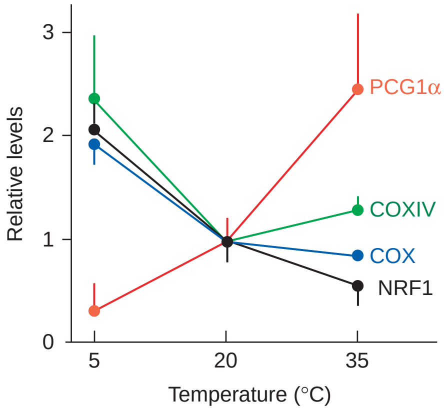

Figure 4 Patterns seen in expression of mitochondrial genes. Cold acclimation of goldfish leads to mitochondrial proliferation in white muscle, as indicated by elevations in cytochrome *c* oxidase (COX) specific activity. This change is paralleled by changes in mRNA for nuclear-encoded subunit COXIV, and by mRNA for nuclear respiratory factor 1 (NRF1), a putative regulator of COX gene expression. The expression of PGC1α, another putative regulator of mitochondrial gene expression in mammals, decreased in the cold when other elements of mitochondrial biogenesis increased. Data from LeMoine CM, Genge CE, and Moyes CD (2008) Role of the PGC-1 family in the metabolic adaptation of goldfish to diet and temperature. *Journal of Experimental Biology* 211: 1448–1455.

Membrane Properties

Though most studies of mitochondrial function focus on enzyme levels, many aspects are influenced by the membrane properties. Integral membrane proteins often have structural relationships with membrane lipids, and changes in the lipids can influence protein function. For example, the electron transport system enzyme COX has cardiolipin molecules that are fully integrated into its structure. Removal of the lipid moiety dramatically affects COX enzymatic properties and it has been presumed that changes in cardiolipin structure would more subtly affect its kinetics. Cold acclimation and winter acclimatization also affect the profile of phospholipids in the membrane. Such changes influence membrane fluidity much like the effects seen in the plasma membrane. Unlike the plasma membrane, the inner mitochondrial membrane is devoid of cholesterol, which has important influences on membrane fluidity and permeability in response to temperature.

Conclusions

Many aspects of mitochondrial structure and function are broadly similar among diverse species. Whether comparing mitochondria between fish and other animals, between fish species, or in a single species in response to environmental or physiological challenges, the main differences are usually qualitative; some species or tissues have more of otherwise similar mitochondria. However, important qualitative differences do exist. For example, bony fish and cartilaginous fish differ from each other and from tetrapods in fuel selection. Most teleosts also possess the remnants of repeated duplication events, leading to the presence of many gene duplicates with still undiscovered consequences to mitochondrial metabolism. Regulation of mitochondrial rate in response to physiological energy demands occurs largely through substrates and products of the F_1F_O ATPase, particularly the concentration of adenosine diphosphate. Under some conditions, oxygen limitations impair mitochondrial respiration, compromising ATP synthesis and exacerbating reactive oxygen species production.

Glossary

Action potential A small and transient change of voltage across the cell membrane when the negative resting potential momentarily becomes nearly zero volts and quickly returns to the original level in a few milliseconds. The action potential is possible because of the activity of ion channels, embedded in the cell membrane, selectively allowing certain inorganic ions to pass through their pore.
Artery A blood vessel leading away from the heart.
Capillary A vessel that connects the arterial and venous systems, whose wall is composed of endothelial cells and connective tissue.
Cardiac output Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.
Diastole A period of the cardiac cycle when cardiac muscle is relaxed or relaxing. It is associated with filling the heart with blood.
Excitation–contraction coupling The term used to describe the progression from membrane excitation with an action potential to the rise of the calcium transient to cell contraction.
Heart A valved, muscular pump that propels fluid, usually blood or lymph, around the circulatory system.
Medulla oblongata Hindmost portion of the brainstem that contains the vagal motor and sensory areas, the respiratory rhythm generator, and cardiovascular control center.
Resistance The sum of the impediments to fluid flow, resistance is increased by vessel length and fluid viscosity, and decreased by increased vessel radius.
Rete Structure consisting of densely packed blood vessels, mostly with a countercurrent blood flow scheme, arranged to facilitate the exchange of, for example, heat or oxygen.
Secondary circulation A system of blood vessels in fishes that originate as arterio-arterial connections and which normally supplies tissues such as the skin, scales, and gills with blood containing very few red blood cells.
Stroke volume The volume of blood ejected into the ventral aorta by a single contraction of the ventricle(s).
Systole A period of the cardiac cycle when cardiac muscle is contracted or contracting. It is associated with the ejection of blood from the heart.
Vein A blood vessel leading toward the heart.

A Historical Perspective on Circulatory Systems

Anyone who attempts to write on the circulatory system, especially that of fishes where the diversity extends to over 25 000 species of fishes, should do so with some trepidation. In addition to this enormous diversity, intellectual giants have been writing on the circulatory system for over two millennia, dating back to the sixth century BC. These writers reveal the progression of scientific discovery, which was supported by careful, often meticulous observation and experimentation. As new discoveries emerged, ideas necessarily changed, but sometimes reluctantly.

The written records on the circulation date back to Greek philosophers concerned with the four elements (air, fire, water, and earth) and the 'natural, vital, and animal spirits'. At that time, the idea of two types of blood vessels (phlebos: arteries and veins) first emerged, as did the Hippocratic document entitled *On the Heart*. However, blood was viewed as moving back and forth in blood vessels by tides and pulsations until Galen, a second-century physician and philosopher, correctly identified the importance of one-way cardiac and vascular valves, which directed the flow of blood from arteries to veins. Even so, how blood moved between the arterial and venous blood vessels remained a mystery for over a millennium. Furthermore, Galen's idea of the heart as the center of our being and the source of 'vital spirit' withstood scientific and theological challenges for 14 centuries. In fact, the unorthodox view of the heart's meaning and function contributed to Michael Servetus, a sixteenth-century theologian, being burned at the stake! Today, nearly two millennia later, Galen's central tenet for the heart still retains some metaphorical currency given that only love can break your heart!

During the centuries following Galen, the anatomy of the heart and blood vessels was detailed using the naked eye, as exquisitely illustrated by Leonardo da Vinci. The seventeenth century, however, saw the emergence of a new age where new technologies propelled scientific discovery. For example, Malpighi's lenses, followed by Leeuwenhoek's more powerful ones, allowed capillaries to be finally visualized. These observations solidified the idea that circulatory system comprised a closed system of blood vessels. The physical connections between arteries and veins had been proposed nearly two millennia earlier by Erasistratos, but the technology to see these connections did not exist. Harvey, often referred to as the founding father of the modern-day experimental circulatory physiology and who had performed experiments to show that blood did indeed flow from arteries to veins, dispelled the Galenian idea of a vital spirit. Harvey's work was remarkable and extensive. He performed experiments on over 80 species, measuring blood pressure and the output of blood from the heart, as well as aspects of its control. Hales' treatise, entitled *Haemastaticks,* followed in the eighteenth century. It contains details of blood pressure, cardiac output, and blood viscosity measurements. Poiseuille then provided a mathematical equation to predict the flow of viscous fluids in narrow tubes. Ludwig's kymograph appeared in the nineteenth century, paving the way to continuously record mechanical events such as contractions of the heart and blood vessels. The working life of kymographs as a teaching and research tool extended to the undergraduate days of the author in the 1970s!.

The turn of the twentieth century saw Frank's and Starling's discovery of the remarkable intrinsic mechanical property of the heart: the heart can empty with sufficient blood pressure to propel blood around the circulatory system by greatly amplifying the stretch of its walls caused by the small amount of energy in the venous circulation. However, this intrinsic property remained without a mechanistic explanation for several decades. At the same time, Krogh and his wife were breaking new ground in their examination of the relationship between capillaries and tissues. They clearly showed that oxygen moved into and out of capillaries by diffusion and, in doing so, rejected Bohr's theory of oxygen secretion. Around the same time, the first physiological experiments were being made on blood pressure in fishes, building on an extremely rich history of anatomical studies of their hearts and blood vessels, which had amassed in the German, French, and English literature. In 1904, Greene reported the first measurements of arterial blood pressure in a fish, showing that it was about half of that in humans. The first measurements of cardiac output in fishes had to await the inventiveness of Hart, who tied two sutures around the heart, pulling them tight after systole or diastole to determine cardiac stroke volume as the difference of the two volumes.

Circulatory Systems in Fishes Today

The series of articles in this section provides a synthesis of current knowledge concerning circulatory design and function of fishes. It begins with an introductory article (**see also Circulation**: Circulatory System Design: Roles and Principles) that describes the roles of a circulatory system. Principles of hydrodynamics and circulatory design are explained alongside the equations that predict the movement of blood through blood vessels.

The powerhouse of the circulatory system is the heart, which serves as a muscular organ that rhythmically contracts with each heartbeat. The gross anatomy (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes) and the variations in form of fish hearts are explained, as is with the cellular structure of cardiac muscle (**see also Design and Physiology of the Heart**: Cellular Ultrastructure of Cardiac Cells in Fishes). Fish hearts have their own neurons and neurotransmitters (**see also Design and Physiology of the Heart**: Intracardiac Neurons and Neurotransmitters in Fish), and some have a coronary circulation (**see also Design and Physiology of the Heart**: The Coronary Circulation). The heart works as a pump, generating blood pressure and hence blood flow. The basic physiology of cardiac function (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping) is accompanied by details on how the cardiac action potential is generated (**see also Design and Physiology of the Heart**: Action Potential of the Fish Heart). The action potential an electrical event generated by an orchestrated, highly controlled series of ion movements across cardiac cell membranes that ultimately produce a contraction of all cardiac muscle cells – termed excitation–contraction coupling. Central to excitation–contraction coupling is the movement of calcium into the cytoplasm (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux) and then the binding of calcium to troponin C to initiate contraction of the contractile proteins (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element), namely actin, myosin. As it turns out, the fish heart is exquisitely sensitive to stretch when its chambers are filled (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping) and cellular mechanism for this is explained (**see also Design and Physiology of the Heart**: Cardiac Cellular Length-Tension Relationship).

The heart pumps blood around a closed system of blood vessels. The varied patterns and forms of the circulatory system in fishes are described (**see also Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns), while noting the important phylogenetic differences that exist for the major groupings of fishes, namely the cyclostomes, the primitive fishes, the elasmobranchs, and the teleosts. Special consideration is given to the major types of blood vessels, the outflow vessels from the heart (**see also Design and Physiology of the Heart**: The Outflow Tract from the Heart), the resistance vessels (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels), the capillaries (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis), and the veins (**see also Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels), because their form is closely allied to their function. While the circulatory system of fishes is termed closed, describing the fact that capillaries connect the arterial and venous system, the capillaries are designed to facilitate fluid and gas exchange with tissues (**see also Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels). This fluid exchange must be carefully controlled and balanced (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange).

The gastrointestinal circulation of fishes receives at least a quarter of cardiac output even in nondigesting fish and therefore is given separate attention (**see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation). Special consideration is also given to the anatomy of the branchial circulation (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy) and gill morphometrics (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics), which are responsible for gas and ion exchange with water. Air-breathing fishes have specialized circulatory adaptations to permit dual breathing of air and water (**see also Air-Breathing Fishes**: Respiratory Adaptations for Air-Breathing Fishes).

The cellular composition of blood is described (**see also Blood**: Cellular Composition of the Blood), along with information on how the primary cell type in blood, the red blood cell, is produced (**see also Blood**: Erythropoiesis in Fishes). More detail on gas transport in the circulatory system, which is the primary role of the red blood cell, is found in **Gas Exchange**: Respiration: An Introduction. Beyond gases (oxygen, carbon dioxide, and ammonia), the circulatory system plays critical roles in distributing hormones and then removing them from the circulation (**see also Integrated Control and Response of the Circulatory System**: Hormone Metabolism in the Circulation).

A circulatory adaptation apparently unique to fishes is the secondary circulation (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy), which supplies certain tissues with blood largely devoid of its cellular components (**see also Blood**: Cellular Composition of the Blood). Associated with the secondary circulation and the lymphatics (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy) are additional pumps. These so-called accessory hearts (**see also Design and Physiology of the Heart**: Accessory Hearts in Fishes) impart additional potential energy to blood to help return it back to the central heart. A special arrangement of arteries and veins, called rete, promotes highly efficient gas and heat exchange between the arterial and venous vessels (**see also Design and Physiology of Arteries and Veins**: The Retia).

Obviously, fine control of the circulatory system is an essential requirement for a life support system. This control occurs through autonomic neural control of the heart (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes) and resistance vessels (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). The autonomic cardiovascular control centers are located in the medulla oblongata of the brain (**see also Integrated Control and Response of the Circulatory System**: Central Control of Cardiorespiratory Interactions in Fish). These centers are ultimately responsible for integrating circulatory control (**see also Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System), which then allows fish to appropriately respond to the circulatory demands of digestion (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion), exercise (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming), hypoxic environments (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia), and changes in temperature (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature). As might be expected, there is intimate interaction between the control of respiration and circulation with the brain (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish), especially during hypoxia (**see also Hypoxia**: Respiratory Responses to Hypoxia in Fishes).

We have a solid foundation of knowledge on the function and anatomy of the circulatory system of fishes. However, much remains to be discovered beyond the few dozen species studied so far in any detail. Indeed, remarkable circulatory adaptations are still likely to emerge as more research is performed. Beyond this attraction, discoveries for fish may find applications in medicine.

When trying to understand circulatory form and function, there may be wisdom in stepping back from the complexities of a Ferrari sports car (humans) and temporarily considering a model T Ford (fishes). For example, a comparative approach to the debate surrounding "the mixing of pneuma and blood in the left ventricle to create the vital spirit", which lasted nearly 1000 years, might have advanced much faster than it did by considering the simpler, single circulatory design of fishes rather than the deluxe, double circulation of mammals.

Glossary

Baroreceptors Receptors in the walls of blood vessels that monitor blood pressure.

Compliance The ability of a blood vessel to stretch. Compliance is defined mathematically as the slope of the change in volume of the vessel divided by the change in pressure, i.e., $\Delta V/\Delta P$.

Convection Bulk movement of a medium, e.g., gas, water, or blood.

Diastole The condition of the heart at rest; diastolic pressure is the lowest blood pressure.

Fahraeus effect The observation that hematocrit in small vessels is significantly lower than that in large vessels.

Fahraeus–Lindqvist effect The condition in small blood vessels where viscosity becomes less dependent on hematocrit.

Hematocrit The percentage of packed red blood cells contained in a volume of blood after centrifugation.

Hydraulic pressure Pressure imparted on a solution by a piston or pump. Blood pressure is a form of hydraulic pressure.

Hydrostatic pressure Pressure due to the height of a column of fluid directly above the reference point. This pressure exists in both static and flowing fluids and can be either added to, or subtracted from, the hydraulic pressure, where the reference point is the heart.

Newtonian fluid A fluid such as water whose viscosity remains constant at all flow rates.

Non-Newtonian fluid A fluid such as blood whose viscosity changes with flow rate.

Oncotic pressure Unique form of osmotic pressure created by unequal protein concentrations across a membrane or capillary, also called colloid osmotic pressure.

Osmotic pressure The hydrostatic pressure produced by the different concentrations of two solutions on opposite sides of a semipermeable membrane.

Portal circulation An anatomical condition where there are two resistance networks in parallel.

Resistance The sum of the impediments to fluid flow; resistance is increased by increased vessel length and fluid viscosity, and decreased by increased vessel radius.

Suction pump A pump that creates negative pressure and pulls fluid into it.

Sump pump A pump that fills passively and only pumps when fluid flows into it.

Systole The condition of the heart during contraction; systolic pressure is the maximum arterial blood pressure.

Transmural pressure The pressure difference between the inside and the outside of a vessel.

Viscosity The ease with which a liquid will flow under an applied pressure; molasses is more viscous than water.

Function of the Cardiovascular System

Molecules move from one location to another three ways – diffusion, carrier-mediated transport, and convection. Diffusion is a random process capable of moving many molecules but it is only efficient over short distances, typically no further than several cells. Furthermore, the net movement of molecules can only occur down a concentration gradient. Carrier-mediated transport is similar to diffusion in that it is for only short distances, typically across cell membranes or epithelia, and serves to move molecules across otherwise impermeable barriers or allow them to be concentrated against an electrochemical gradient. Convection is the movement of molecules in a current and is the only efficient way to move molecules over considerable distances.

The purpose of the cardiovascular system is the convective movement of molecules over the considerable distances that separate the different cells of the body. The best-known activity of the cardiovascular system is the movement of nutrients from sites of uptake such as the respiratory organs (gills) or gastrointestinal (G.I.) tract to the cells, or removal of metabolic wastes and delivery of these excretory products to the gills, kidney and liver. However the cardiovascular system is also used for other functions. These include the body's signaling system through transport of hormones, the body's defense mechanism through transport of immune response elements, and the dissipation, or retention, of heat from the animal's core to the environment. Because blood is a liquid, the body must also have mechanisms to prevent it from leaking out when a vessel is cut (clotting mechanisms) and counter-mechanisms to prevent excessive or spontaneous clotting.

Operating Principles of the Cardiovascular System

In very general terms the operation of the cardiovascular system is quite analogous to the water supply of many cities. A pump (or heart) pumps water (or blood) from an underground reservoir, usually an aquifer, to an elevated reservoir such as a water tower that is higher than the houses. In this process the mechanical energy of the pump is converted into potential energy in the water tower. The pressure that is generated by the difference in height between the reservoir and the buildings (a hydrostatic pressure) ensures that under normal circumstances the water pressure supplied to all houses is the same. Thus, each house has the opportunity to use water depending upon its need, that is, drinking, washing, watering the lawn, etc. As long as there is adequate water in the reservoir, the pressure will remain constant and intermittent water usage by one house will not affect water supply or delivery pressure to the other houses. However, in times of crisis such as drought or excess demand, there also has to be a higher authority empowered to prioritize water use and reduce water use by less critical applications such as washing the car or watering the lawn. This ensures adequate water supply for critical organizations such as the fire department, hospitals, and for drinking water.

The cardiovascular system operates by analogous principles. The heart pumps blood into the aorta and major arteries and this arterial pressure is the potential energy supplied to all organs (houses). Each organ has the opportunity to regulate its own blood flow based on its immediate need, usually metabolic demand, and can do so as long as the arterial pressure remains adequate. This is termed local regulation. A crisis can occur if the pump (heart) becomes weak (after a heart attack) or if there is not enough blood coming to the heart to pump (venous return: e.g., excessive loss of blood and high gravitational forces), or if the demand by one of the tissues becomes excessive. In any one of these situations the higher authority (central nervous system) has the power to restrict blood flow to less critical organs such as the gastrointestinal tract, skin, or skeletal muscle in order to ensure that blood flow to the organs most vital to immediate survival, the heart and brain, and sometimes exercising skeletal muscle, is not compromised. This is termed remote regulation and the central nervous system makes these decisions based largely on information it receives from pressure receptors (baroreceptors) located in the walls of the arteries, veins and heart. However, unlike the water pump in a city, the fish heart is not a very good suction pump and must therefore depend on blood pressure in the veins to ensure adequate filling of the heart (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping). This entails additional control mechanisms that regulate blood volume and venous pressure.

Hemostatics and Hemodynamics

In order to understand the principles of the cardiovascular system, it is important to first understand some basic properties of fluids at rest (hemostatics) and in motion (hemodynamics).

Fluids at Rest: Hemostatics

Unlike many molecules that have specialized proteins to help them move across membranes or epithelia, there are no known carriers for water and the only way water moves from one location to another is down a pressure gradient. There are three forms of pressure – hydrostatic, hydraulic, and osmotic.

Hydrostatic pressure

Hydrostatic pressure is determined by the weight of fluid directly above a point of reference; the latter depends on the distance between the top of the water and the reference point and the density of the fluid (**Figure 1**(**a**)). The pressure at the reference point (P) is then $P = \rho g h$, where ρ is the density of the fluid (in g L^{-1}), g is the gravitational acceleration constant (9.8 m s^{-2}), and h is the height (in m) from the reference point to the top of the water. There is an interesting dichotomy here, however, because as fish descend deeper into water, the hydrostatic pressure on the outside of the fish is offset by the hydrostatic pressure in the fish's cardiovascular system (**see also Design and Physiology of Arteries and Veins:** Physiology of Capacitance Vessels). Thus, actual blood pressure in a fish (and in physiological experiments) is always measured relative to the surface of the water. Furthermore, the only time hydrostatic pressure is important in fish is

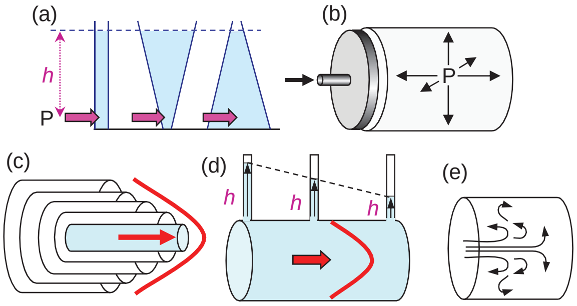

Figure 1 Pressure and flow in the cardiovascular system. (a) Hydrostatic pressure is determined by the height (*h*) of a column of water above a reference point (arrow) irrespective of the container shape. The hydrostatic pressure is the same at all arrows. (b) Hydraulic pressure (*P*) is exerted by a piston or pump and at any point in a fluid is the same in all directions. (c) Newtonian fluids flow through a tube in concentric cylinders with the flow through the outer cylinder the slowest due to frictional drag on the walls of the tube. (d) Hydraulic pressure in fluid flowing down a tube decreases due to the frictional loss of energy. At any point along the tube, the hydraulic pressure is equivalent to the hydrostatic pressure (*h*) which would force fluid up a vertical standpipe. (e) Turbulent flow results when lamellar flow is disrupted such as branch points in vessels and around the heart valves; this may increase viscosity but is not normally a feature of the peripheral circulation.

when they are out of water (except at depths of greater than 1000 m; (**see also Deep-Sea Fishes**).

Hydraulic pressure

Hydraulic pressure is pressure supplied by a pump, in this case the heart. Hydraulic pressure is exerted in all directions in a blood vessel (**Figure 1**(**b**)). Hydraulic pressure will be examined in greater detail in subsequent sections.

Osmotic and oncotic pressure

Osmotic pressure is the pressure caused by water at different concentrations due to the dilution of water by dissolved molecules (solute), notably salts and nutrients. Osmotic pressure is very important in bony fish where the difference in osmotic pressure between the body fluids (typically 300 milliosmoles per liter; mosm L^{-1}) and the environment (<1 mosm L^{-1} in freshwater and 1000 mosm L^{-1} in saltwater) can create substantial forces that, if otherwise uncontrolled, can cause volume overload in the former and dehydration in the latter. For instance, a difference of 10 mosm across the membrane can create a pressure difference of 190 mmHg, which is approximately 6–8 times the arterial blood pressure of a fish. A unique form of osmotic pressure called oncotic or colloid osmotic pressure is presumed to exist across the capillaries. This pressure is due solely to the difference in protein concentration between plasma and interstitial fluid because proteins are presumed to be the only solute molecules that do not freely cross capillaries. While oncotic pressure is important in maintaining fluid balance across mammalian capillaries, its importance in transcapillary fluid balance in fish is controversial.

Blood pressure definitions

Blood pressure can be measured anywhere in the circulation and usually the location is specified, that is, arterial pressure, venous pressure, etc. Arterial pressure is not constant but varies with the cardiac cycle (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping). Systolic pressure is the maximum pressure and occurs with ejection of blood from the heart (systole). Diastolic pressure is the minimum pressure and occurs when the heart is at rest (diastole). Pulse pressure is the difference between systolic and diastolic pressure, and mean blood pressure is the average pressure. In many fish the oscillations in arterial pressure take on a sawtooth pattern and the mean pressure is the arithmetic average of systolic and diastolic pressure (i.e., mean pressure = (systolic + diastolic) 2^{-1}). In other fish the diastolic period is longer than systolic and mean pressure is the time-integrated average pressure weighted toward the diastolic. The formula derived for mammals, mean = (systolic + 2 diastolic) 3^{-1}, is often used in these instances.

Fluids in Motion: Hemodynamics

Perfect Newtonian fluids

The movement of fluid down a tube (flow) is directly related to the pressure gradient (ΔP) along the tube and inversely related to the resistance (R) to flow (i.e., $F = \Delta P R^{-1}$). This is Darcy's law, which is the hemodynamic equivalent of Ohm's law for electricity. The ΔP is the difference between the input and output pressures and is an absolute requirement for fluid to flow down a tube or blood vessel. Newtonian fluids flow down a tube as concentric cylinders, the outermost cylinder moves at the slowest rate due to friction against the wall, and the innermost cylinders move progressively faster as they slide along their neighbors (**Figure 1**(**c**)). This is called laminar flow and it has a parabolic profile (red lines in **Figures 1**(**c**) and **1**(**d**)). Resistance is due to the fractional energy loss as fluid interacts with the wall of the blood vessel which in turn results in a progressive decrease in pressure (**Figure 1**(**e**)). Resistance encompasses all of the factors that impede flow and, for a Newtonian (i.e., 'pure' fluid such as water), can be described by the relationship

$$R = \frac{\eta l}{r^4}\frac{8}{\pi}$$

where η is the viscosity of the fluid, l is the length of the tube, r is the radius of the tube, and $8\ \pi^{-1}$ is a geometric constant. Substituting these values for resistance back into Darcy's law produces the Hagen–Poiseuille equation

$$F = \frac{\Delta P r^4}{\eta l}\frac{\pi}{8}$$

Because length and viscosity do not normally vary substantially, it is clear from this equation that the major determinants of flow through a tissue are the vessel radius and pressure gradient. The considerable effect that a change in vessel radius has on flow is evident from a simple calculation: a twofold increase in vessel radius will cause a 16-fold decrease in resistance, and therefore increase flow 16 times. Turbulent flow results when lamellar flow is disrupted (**Figure 1**(**e**)) and it will increase the apparent viscosity. Turbulence may be found around vascular branch points or the heart, but is not a common feature of the peripheral circulation.

Imperfect non-Newtonian fluids

Blood is considered a non-Newtonian fluid primarily because the presence of red blood cells changes the viscous properties of blood. Hematocrit is the percent volume of blood occupied by the red blood cells, that is, if 100 ml of whole blood contained 35 ml of packed red blood cells, the hematocrit would be 35 (**Figure 2**(**a**); **see also Blood:** Cellular Composition of the Blood). In larger vessels such as arteries and veins, the viscosity of blood increases as hematocrit increases and at each hematocrit blood viscosity increases even more at very low flow (**Figure 2**(**b**)). **Figure 2**(**c**) shows the distribution of red cells in the blood vessel at different flow rates. At low flow (small arrow) the red cells mingle and bump into the walls of the vessel and each other, thereby increasing viscosity. At higher flow rates red blood cells become concentrated in the center of the vessel, a phenomenon known as axial streaming, and viscosity is reduced as blood flow becomes more laminar. In small blood vessels the red blood cells may have to deform to enter the vessel (**Figure 2**(**d**)) and any increase in red blood cell size or decrease in flexibility of the red blood cell membrane will increase the effective viscosity. Once inside small vessels, however, blood viscosity is far less dependent on hematocrit than it was in large vessels, a phenomenon known as the Fahraeus–Lindqvist effect. It is also interesting to note that the hematocrit in vessels ≤300 μm diameter is less than that found in large arteries and veins, often as low as 10. This phenomenon is known as the Fahareus effect.

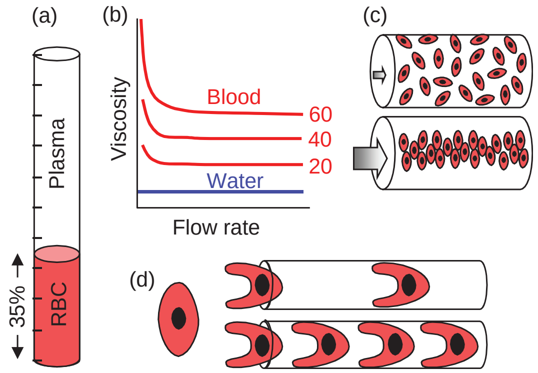

Figure 2 Non-Newtonian properties of blood. (a) The hematocrit is the percent volume of blood occupied by red blood cells (RBCs), in most fish around 35%. (b) The viscosity of blood increases as hematocrit increases and at each hematocrit viscosity increases at very low flow rates. The viscosity of water, a Newtonian fluid, is lower than that of blood and independent of flow rate. (c) At low flow rates red blood cells bump into the walls of the vessel disrupting laminar flow and increasing hematocrit. At higher flow rates, the red cells become concentrated in the center of the vessel (axial streaming) and viscosity is reduced. (d) Red blood cells must typically deform to enter smaller capillaries. An increase in the size of the red blood cell or decrease in flexibility of the red blood cell membrane will increase blood viscosity. Once inside small vessels, blood viscosity becomes considerably less dependent on hematocrit (the Fahraeus–Lindqvist effect).

Vascular Circuits: In-Series and In-Parallel Resistance

Vascular circuits such as electrical circuits can be found in series and in parallel (**Figure 3**). With in-series circuits, the total resistance of the system is equal to the sum of the individual resistances: $R_{\mathrm{T}} = R_1 + R_2 + R_3$. It is evident that as additional circuits are added, total resistance increases arithmetically. With in-parallel systems total resistance is calculated from: $1R_{\mathrm{T}}^{-1} = 1R_1^{-1} + 1R_2^{-1} + 1R_3^{-1}$. As additional circuits are added in parallel, total resistance decreases. In-series circuits are not as common in cardiovascular systems because of the increased pressure that must be generated to perfuse vascular beds in tandem. The most notable in-series circuit in the fish cardiovascular system is the gills and systemic circuit, although there

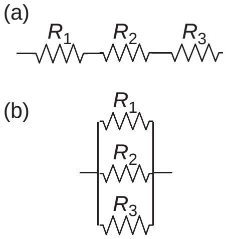

Figure 3 Resistance patterns in blood vessels. (a) Resistances in series. The total resistance (R_{T}) for vessels in-series is the sum of their individual resistances: $R_{\mathrm{T}} = R_1 + R_2 + R_3$. (b) Resistances in parallel. The total resistance for vessels in-parallel is $1R_{\mathrm{T}}^{-1} = 1R_1^{-1} + 1R_2^{-1} + 1R_3^{-1}$. Increasing the number of resistors in-series increases the total resistance, whereas increasing the number of resistors in-parallel decreases total resistance.

are other systems such as the hepatic portal, real portal, and pituitary.

Building a Cardiovascular System

A basic cardiovascular system can be constructed using the analogy of a simple bicycle tire as shown in **Figure 4**. For the moment the contribution of the respiratory circulation will be ignored and the arterial and venous components will be assigned to the left and the right side of the tire. When the tire is open (vented) to the environment (panel A), arterial pressure (P_a) equals venous pressure (P_v) and both pressures are equal to atmospheric pressure (P_{ATM}). Because arteries do not collapse, and veins are not completely collapsed, there will always be some blood remaining in the circulation. This volume of blood is called the unstressed volume (USV). Because the USV does not exert any pressure on the system, it is essentially hemodynamically inert. Remarkably, the USV in both fish and mammals is around 60% of the total blood volume.

In panel B, an air pump inflates the tire and now P_a and P_v are greater than P_{ATM} but still equal to each other because there is no flow. P_a and P_v are now equal to the mean circulatory filling pressure (P_{MCFP}), which by definition is the pressure that exists throughout the cardiovascular system when there is no flow and pressure has equilibrated throughout. The volume of air (or blood) that has been added to the system is called the stressed volume (SV). Compliance (C) is an index of how readily the walls of the tube can distend to contain more blood. Compliance is calculated from the ratio of the change in volume to a given change in pressure (i.e., $C = \Delta V \Delta P^{-1}$). In panel B, the increase in volume is the same as the stressed volume, and the increase in pressure is the same as the mean circulatory filling pressure, so compliance is equal to the ratio of the SV to the mean circulatory filling pressure (i.e., $C = \mathrm{SV}\ P_{MCFP}^{\ -1}$). Rearranging this equation it can be seen that the mean circulatory filling pressure is the ratio of SV to compliance, $P_{MCFP} = SVC^{-1}$.

In panel C, the bicycle tire becomes more like a cardiovascular system by modification of arterial and venous compliance and addition of a heart. In both fish and mammals, venous compliance (C_v) is approximately 20 times greater than arterial compliance (C_a). This allows more blood to be stored in the veins than in the arteries; in mammals approximately 80% of systemic blood is in the veins, 15% in arteries, and 5% in capillaries; however, these proportions are not known for fish. This also means that P_{MCFP} is far more dependent on C_v, and the equation can now be rewritten to reflect this: $P_{MCFP} = V_s\ C_v^{\ -1}$.

The vertebrate heart is more like a sump pump than a suction pump. That is, it is relatively inefficient in sucking blood into it and therefore cardiac filling and cardiac output are more dependent upon extracardiac factors that deliver blood to it, namely P_v, although the rigid pericardium in some fish assists in developing moderate cardiac suction. Because P_v is very close to P_{MCFP}, the most important determinant of cardiac filling and cardiac output is $V_s\ C_v^{\ -1}$. Any increase in this ratio (an increase in V_s or a decrease in C_v) will favor an in increase in cardiac output and vice versa. V_s is subjected to a variety of factors that can affect blood volume or flow into the venous

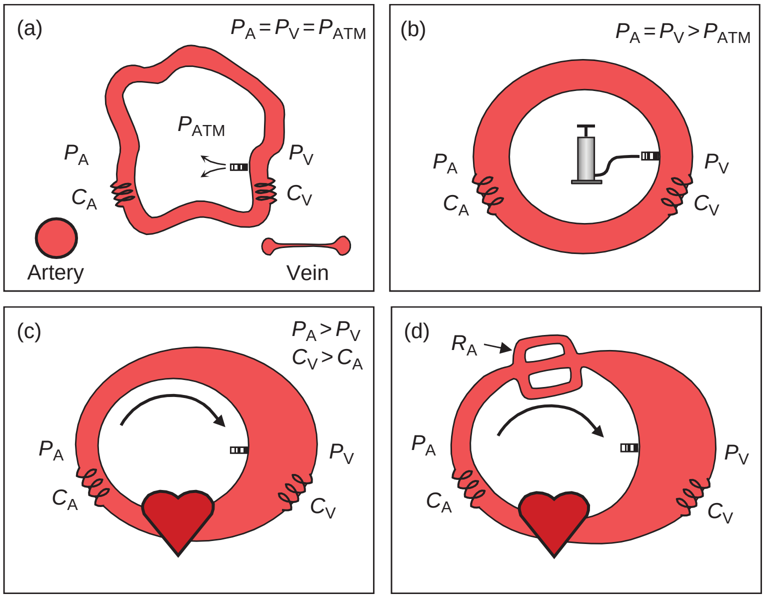

Figure 4 Development of a simple cardiovascular system using a bicycle tire. Abbreviations: C_A, C_V, arterial and venous compliance, respectively; P_A, P_V, P_{ATM}, arterial, venous, and atmospheric pressure, respectively; R_A, arterial vascular resistance. See text for details.

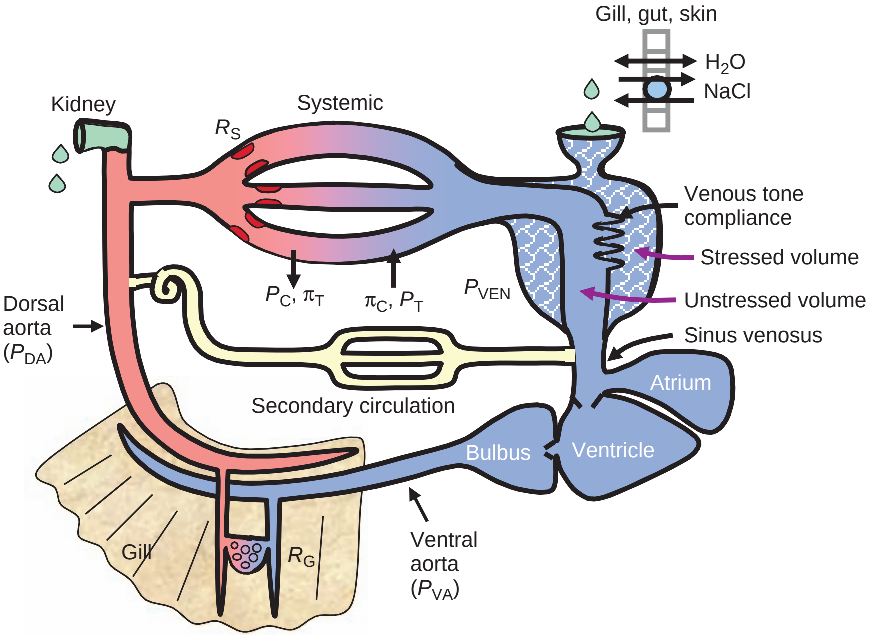

Figure 5 General features of the fish cardiovascular system. Abbreviations: P_{VA}, P_{DA}, P_{VEN}, hydraulic pressure in ventral aorta, dorsal aorta, and central vein, respectively; P_C, P_T, hydraulic pressure in capillary and tissue interstitial fluid, respectively; R_G, R_S, gill and systemic vascular resistance, respectively; π_c, π_T, oncotic pressure in capillary and tissue interstitial fluid, respectively. Boca Raton, FL: CRC Press.

circuit (see **Figure 5**) and C_v is dependent upon the elastic properties of the veins and can be further modified, increased, or decreased, by active dilation or constriction of these vessels. There is a simple axiom that the mammalian heart cannot be the direct cause of an increase in cardiac output, but when it fails it can be the direct cause of a decrease in cardiac output. This holds quite well for fish as well.

This simple cardiovascular system is completed by the addition of organs and their capillary networks (panel D). The major resistance to flow in the cardiovascular system resides in the small arteries and arterioles within the tissues (R_a) and these are all in-parallel circuits. Adding more tissues will decrease total resistance, not increase it. R_a can be controlled locally by the specific needs of the tissues or remotely by nerves and hormones in response to changes in blood pressure, analogous to the city water system (see above). This system also has some degree of intrinsic responsiveness in that a local decrease in R_a in response to a tissue's need to increase blood flow will send more blood into the venous circulation which in turn increases P_v, cardiac filling, and ultimately cardiac output.

Figure 5 shows the integrated fish cardiovascular system. Blood is pumped from a single ventricle into the ventral aorta and from there passes through the gill circulation before continuing on to the dorsal aorta and then to the systemic circulation. Because gill resistance (R_g) and systemic resistance (R_s) are in series, pressure in the ventral aorta (P_{VA}) and gill capillaries exceeds pressure in the dorsal aorta (P_{DA}) and systemic capillaries. Total blood volume (both stressed volume and USV) is determined by factors that affect the net exchange of water across the gill, gut, and skin, and by urinary output by the kidney, and by transcapillary fluid movement. In mammals, the factors that affect transcapillary movement of fluid include capillary and tissue hydraulic pressure (P_C and P_T, respectively) and capillary and tissue oncotic pressure (π_C and π_T, respectively). As described above, the importance of these factors in transcapillary movement in fish has not been established (**see also Design and Physiology of Capillaries and Secondary Circulation:** Circulatory Fluid Balance and Transcapillary Exchange). The secondary circulation is an alternative pathway, perhaps the progenitor of the lymphatics (**see also Design and Physiology of Capillaries and Secondary Circulation:** Secondary Circulation and Lymphatic Anatomy). Venous pressure and therefore filling of the heart are determined by the stressed blood volume, venous compliance, and, to a lesser extent, by fluid entering from the arterial side (inversely related to R_S) and ventricular suction.

Functional Definitions of Blood Vessels

Blood vessels are most commonly categorized according to their structure and location (i.e., arteries, arterioles, capillaries, venules, and veins), but they can also be categorized by their primary function. Compliance (aka elastance or windkessel) vessels dampen the arterial pulse. The intermittent ejection of blood from the heart stretches the elastic tissue in these vessels converting some of the potential energy of hydraulic pressure generated during systole into mechanical stretch. During diastole, when there is no blood flowing out of the heart the elastic recoil of these compliance of vessels transfer energy back into hydraulic pressure. This helps maintain a positive arterial pressure and blood flow down these vessels even when the heart is at rest. The bulbus (or conus in some fish) arteriosus is specifically designed for this function although the ventral aorta, dorsal aorta, and other vessels between the heart and systemic tissues also contribute (**see also Design and Physiology of the Heart:** The Outflow Tract from the Heart). Interestingly, this arterial pulse is not dampened out by the gills and is transmitted all the way through the dorsal aorta and into the systemic tissues. Conductance vessels, as their name implies, are conduits for blood transfer. Many of these serve dual roles as compliance vessels. Resistance vessels are the small arteries and arterioles that constitute the greatest impediment to flow. Active regulation of their diameter, by both local and remote mechanisms, is the primary means of regulating both tissue perfusion and arterial blood pressure. Exchange vessels are typically capillaries and small venules, although gas exchange may occur across small arterioles as well. The rest of the cardiovascular system exists for the sole purpose to deliver blood to these vessels. Capacitance vessels are the venules and veins and they conduct blood back to the heart, and through active contraction or relaxation, they are also the major determinants of the mean circulatory filling pressure, and ultimately cardiac filling.

Glossary

Anemia A state of reduced numbers of red blood cells, usually associated with bleeding.

Blood A tissue that moves around the body within blood vessels, serving many transport functions.

Erythrocyte The most abundant cell found in the blood of nearly all fish. It contains the respiratory pigment hemoglobin and is commonly called a red blood cell because of its color.

Granulocyte A medium-sized white blood cell with variously shaped nuclei and a cytoplasm-containing granules that can perform phagocytosis.

Hematocrit The percentage of packed red blood cells contained in a volume of blood after centrifugation.

Leucocrit The percentage of packed white blood cells contained in a volume of blood after centrifugation.

Leukocyte The name given to a blood cell that does not contain the respiratory pigment hemoglobin. It is commonly called a white blood cell because of its lack of color.

Lymphocyte A type of white blood cell involved in cellular defense and immunity. Granular lymphocytes are called natural killer cells and small lymphocytes produce immunoglobulins (B cells) or toxic granules to pathogens (T cells).

Mean cell hemoglobin concentration The average concentration of hemoglobin in red blood cells. It is usually estimated from the whole blood hemoglobin concentration divided by the proportion of red blood cells in the blood.

Monocyte The largest white blood cell, produced in the head kidney that will be mobilized as a response to inflammatory signals and mature to macrophages.

Plasma The extracellular fluid that often comprises the majority of blood. Its composition varies enormously among fishes.

Red blood cell The most abundant cell found in the blood of nearly all fish. It contains the respiratory pigment hemoglobin.

Thrombocyte The smallest white blood cell, often called a platelet, with an important role in blood clotting.

White blood cell The name given to a blood cell that does not contain the respiratory pigment hemoglobin.

Introduction

Blood is a tissue contained within the circulatory system that serves many transport functions. It has three major components: red blood cells (RBCs, erythrocytes), white blood cells (WBCs, leukocytes), and the extracellular space around these cells, the plasma (**Figure 1**). Blood differs from most of the other body tissues in that its extracellular volume (that occupied by the plasma) is typically twice as large the intracellular volume (that

occupied by the cells). While RBCs normally remain within the circulatory system, WBCs can routinely move from within the blood, across the endothelium, and into the interstitial space between cells to perform defense functions.

Blood is primarily a transport medium for gases and solutes that include oxygen, carbon dioxide, ammonia, nutrients, and hormones. Simply put, the concentrations of the various components of blood are regulated. Some that are tightly regulated (homeostatic roles) include electrolyte (ion) concentrations, pH, arterial oxygen and carbon dioxide tensions, and osmolarity. This tight regulation stems from the fact that blood composition influences most aspects of a fish's physiology. Consequently, plasma analysis is a routine diagnostic tool used to monitor a fish's physiological status in much the same way as physicians monitor the plasma of human patients. Changes in plasma composition can indicate a disturbed physiology (e.g., stress) or an excessive environmental challenge. Similarly, because RBC and WBC concentrations are also well regulated, changes to WBCs can indicate a pathological situation and anemic fish are not expected to perform well.

Blood composition, however, can vary within normal physiological limits. For example, nutrients (amino acids, fatty acids and lipids, and glucose) and wastes (ammonia) obviously become elevated during feeding. Similarly, certain hormones and yolk nutrients increase during reproductive development. Venous blood and arterial blood also differ considerably in certain respects, especially during exercise, when blood gases, pH, nutrients, and RBCs may change considerably. Such dynamic changes in blood composition are normally resolved within minutes, hours, or days. This article focuses only on the characteristics and variability of RBCs and WBCs.

Separating Blood Cells

The two primary blood cell types can be separated based on differences in cellular density. When a blood sample is centrifuged in a tube, the more dense RBCs (because of a higher iron content; **see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin) pack to the bottom of the tube as a red-colored layer (**Figure 1**). On top sits a thin, white, or buff layer of WBCs. WBCs are distinguished from RBCs by their lack of hemoglobin and lower cellular density. Above the cells lies the plasma, which may have on its surface droplets of fat that are less dense than water. The relative composition of blood is represented by the relative heights of the packed layers of RBCs, WBCs, and plasma. Hematocrit (Hct) is the term used for the percentage of the column of blood occupied by RBCs. Leucocrit (Lct) is the term used for the percentage of the column of blood occupied by WBCs. Typically, fish blood comprises 60–80% plasma, 20–40% RBCs, and 0.5–2.0% WBCs (**Figure 1**). However, in special cases, Hct can exceed 50% or RBCs can be completely absent (Hct = 0%).

Red Blood Cells

Fish RBCs are elliptical or ovoid. Like those of amphibians and reptiles, they have a nucleus, which not only contrasts with circulating mammalian RBCs but also results in a larger cell dimension. RBC dimensions vary among fish species, typically within a range of 10–20 μm for length and 6–10 μm for width. Fish lineages that have undergone gene duplication, and fish made triploid (**see also Cellular, Molecular, Genomics, and Biomedical Approaches**: Evolution of Fish Genomes, Physiology of Triploid Fish, and Transgenesis and Chromosome Manipulation in Fish), have proportionately larger nuclear and RBC sizes.

The most important role of RBCs is the transport of oxygen by the high concentrations of the respiratory pigment hemoglobin found in the cytoplasm. Hemoglobin (**see also Transport and Exchange of Respiratory Gases in the Blood**: O_2 Uptake and Transport: The Optimal P50) greatly increases the blood's capacity to transport oxygen, which is poorly soluble in the plasma. RBCs also play an important role in pH regulation (acid–base balance – **see also Transport and Exchange of Respiratory Gases in the Blood**: Carbon Dioxide Transport and Excretion, Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange, and Red Blood Cell Function) because hemoglobin binds hydrogen ions and carbon dioxide. The presence of the enzyme carbonic anhydrase (**see also Transport and Exchange of Respiratory Gases in the Blood**: Carbonic Anhydrase in Gas Transport and Exchange) in the cytoplasm is critical for effective carbon dioxide transport (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange). Clearly, the concentration (and type, **see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin) of hemoglobin in blood has an enormous impact on the blood's capability to transport gases and buffer blood pH.

The blood hemoglobin concentration is under the control of the hormone erthythropoietin, which regulates the regular replacement of old or damaged cells with the new ones through the process of erythropoiesis (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin Differentiation in Fishes and **Blood**: Erythropoiesis in Fishes). The main hematopoietic tissues in fish are the thymus, spleen and kidney, and erythropoiesis.

Across fish species, the routine concentration of both the RBCs contained in blood (as reflected by Hct), and the hemoglobin within a single RBC can vary substantially (**Figure 2**). Both phylogeny and other considerations contribute to this variability. Furthermore, blood hemoglobin concentration undergoes temporary and dynamic changes according to the fish's physiological state, largely through changes in Hct.

Hematocrit

Blood hemoglobin concentration is typically linearly related to Hct (**Figure 2(a)**). Hct varies enormously across fish species. Most fish have an Hct between 10% and 40%. The Hct of elasmobranch species tends to be at the lower end of this range (between 10% and 20%). Teleosts generally have a higher Hct (between 25% and 40%), and a value <20% would be considered anemic for say rainbow trout. With normal Hct varying from 0% to >50% among fishes, it is hardly surprising that factors other than phylogeny influence Hct. Athleticism and blood viscosity are very important in this regard. Temporary changes in Hct primarily involve RBC release from a storage site (the spleen) and secondarily involve fluid movements (**Figure 3**).

Athleticism

Athletic fishes are characterized by a circulatory system with a high Hct and cardiac output (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming). The high Hct of athletic fishes has likely been selected based on the high oxygen need for an active lifestyle since a higher Hct increases arterial oxygen concentration. In support of this idea, the Hct of benthic flatfishes can be half than found in athletic fishes. Also, experimentally induced anemia typically reduces swimming performance and maximum oxygen uptake (**Figure 4**). However, the fact that a higher-

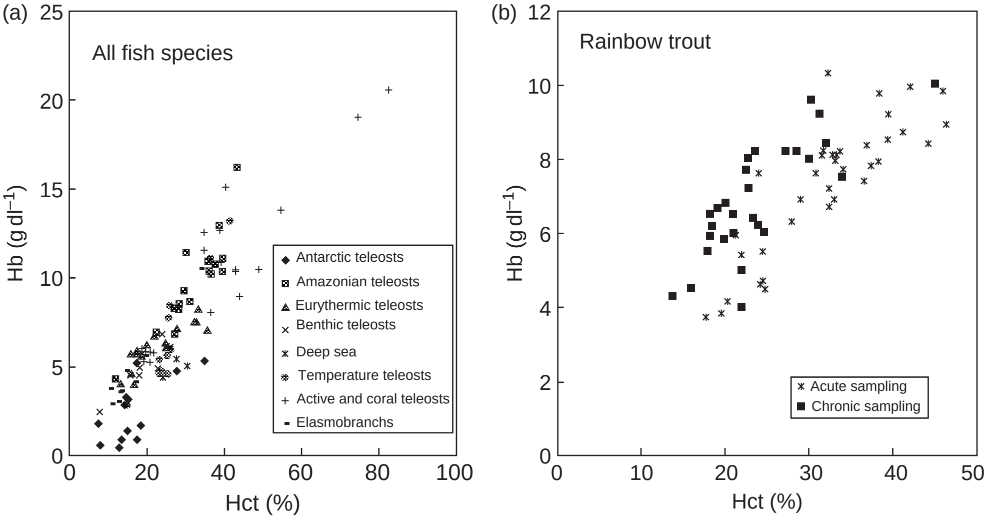

Figure 2 A meta-analysis of Hct values reported for (a) various fish species and (b) rainbow trout (*Oncorhynchus mykiss*). These relationships show the variability in Hct, the expected linear relationships between Hct and blood hemoglobin concentration, and systematic difference for Hct between two sampling methods; hemoglobin concentration at a given Hct in rainbow trout was typically higher for blood samples taken via venopuncture than via a cannula. Reproduced from Gallaugher P and Farrell AP (1998) Hematocrit and blood oxygen carrying capacity. In: Perry SF and Tufts B (eds.) *Fish Respiration, Fish Physiology*, vol. 17, pp. 185–227. San Diego, CA: Academic Press.

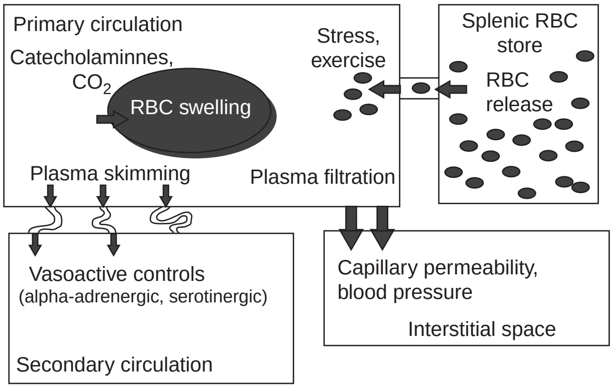

Figure 3 A schematic representation of some of the physiological factors that can influence hematocrit in fish blood. Reproduced from Gallaugher P and Farrell AP (1998) Hematocrit and blood oxygen carrying capacity. In: Perry SF and Tufts B (eds.) *Fish Respiration,* Fish Physiology, vol. 17, pp. 185–227. San Diego, CA: Academic Press.

than-normal Hct (35–45%) in rainbow trout does not improve swimming (**Figure 4**) suggests that functions in addition to oxygen transport during exercise play a role in setting Hct.

Blood viscosity

The heart generates blood pressure to overcome vascular resistance (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping) and blood viscosity directly affects vascular resistance (Poiseuille's law; **see also Circulation**: Circulatory System Design: Roles and Principles and **Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). Thus, the heart does more work with each and every heartbeat whenever blood viscosity is elevated. Since blood viscosity increases with Hct and decreases with temperature, it makes energetic sense to keep Hct to the minimum required for oxygen transport during locomotion, especially under cold conditions.

An extreme example of how the combined effects of Hct and low temperature on blood viscosity have resulted in wonderful adaptations involves Antarctic fishes. These extreme adaptations, which include a complete absence of RBCs as well as large, temporary increases in Hct, were likely possible only in the stable, cold (<1°C), and oxygen-rich water of Antarctica and with a lifestyle that was not highly active. Some Antarctic Nototheniids have survived the deletion of the gene for hemoglobin, which means their blood lacks RBCs and hemoglobin. These fishes pump extraordinarily high volumes of plasma around their circulatory system at low pressure using a very large ventricle adapted to accommodate an extraordinarily large cardiac stroke volume. Consequently, Hct and temperature are intimately linked to ventricular design through the effects of blood viscosity on cardiac work. (Interestingly, experimentally induced anemia and cold can trigger rapid ventricular growth in rainbow trout). Other Antarctic fishes, such as *Pagothenia borchgrevinki* and *Notothenia rossi*, have adapted to a very low routine Hct (14% and 6%, respectively) compared with other teleost species. These fishes, however, can double Hct, but only when it is absolutely necessary to temporarily boost oxygen transport (e.g., hypoxia, stress, and exhaustive exercise), because they routinely store an unusually large number of RBCs in their spleen.

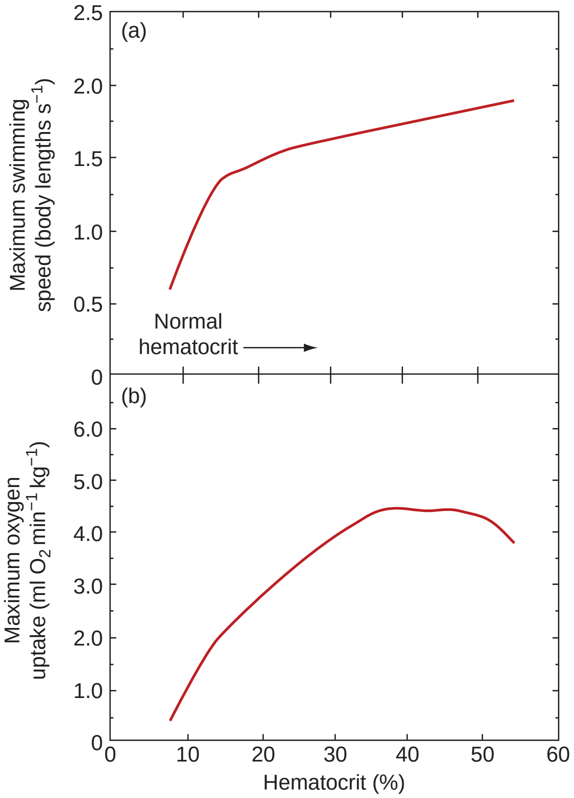

Figure 4 A. is supposed to be shaped a bit like a hockey stick B. is supposed to be shaped like part of a bell-shaped curve with a flattened top. The results of experimentally manipulating hematocrit in rainbow trout on maximum prolonged swimming performance and maximum oxygen uptake. Adapted from Gallaugher P, Thorarensen H, and Farrell AP (1995) Hematocrit in oxygen transport and swimming in rainbow trout (*Oncorhynchus mykiss*). *Respiration Physiology* 102: 279–292.

Temporarily changing Hct

Fish use rapid increases in Hct to temporarily increase oxygen transport during hypoxia, stress, and exercise. In these situations, RBCs stored in the spleen are released into the circulation under sympathetic nervous control (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes; **Figure 3**). While a few Antarctic fishes double Hct in this manner, most fish change Hct by just a few percent. RBCs are also released during anesthesia. Thus, when the spleen in anesthetized rainbow trout was surgically tied off, RBCs became trapped in the circulation, raising routine Hct by 8%. During exercise, the difference in Hct between these surgically treated fish and control fish disappeared because the exercise stimulated a similar 8% increase in Hct in control fish. Bleeding and blood sampling likely deplete the splenic store of RBCs before Hct decreases.

Minor changes in Hct occur when plasma, or some of its fluid, moves out of the primary circulation without any accompanying RBCs (**Figure 3**). Transcapillary fluid exchange, which is primarily influenced by capillary permeability and capillary blood pressure, is common to all vertebrates (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange, **Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels, and Secondary Circulation and Lymphatic Anatomy). However, a fluid movement unique to fishes is that through the convoluted arterial vessels that connect the primary and secondary circulations (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy). Normally, these narrow vessels preferentially allow plasma but not RBCs into the secondary circulation (termed plasma skimming). Consequently, the secondary circulation has a very low Hct (<<10%). Increased arterial blood pressure enhances plasma skimming, while vasodilation of the connecting vessels admits RBCs. RBCs, entry into the secondary circulation was first visualized in the gills of the European eel (*Anguilla anguilla*) and more recently in the skin of the zebrafish (*Danio rerio*) and the glasscatfish (*Kryptopterus bicirrhis*), two small fish species with relatively transparent bodies. Hypoxia stimulates RBC movement into the secondary circulation of the skin and under the control of nitric oxide release (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). The red flush of skin and scales of anesthetized and heat-challenged fish could also reflect RBCs accumulating in the skin. Whether such RBC movements just deplete splenic RBC stores or decrease Hct in the primary circulation as well is unknown.

These physiological adjustments to Hct can have implications for accurately measuring routine Hct in fish, even as simple as the Hct measurement technique is. For example, stressing rainbow trout while sampling blood (e.g., venopuncture without anesthesia) will overestimate normal Hct due to RBC swelling and/or splenic RBC release. Conversely while blood vessel cannulation techniques can avert stress, blood loss during or after the surgery becomes a possibility. As a result, Hct in rainbow trout is known to be systematically different using these two sampling methods, with Hct being typically higher for blood samples taken via venopuncture than via a cannula (**Figure 2(b)**).

RBC Hemoglobin Concentration

The concentration of hemoglobin within an RBC is usually expressed as mean cell hemoglobin concentration (MCHC). MCHC varies about twofold, between 170 and 340 g L^{-1}, over a wide range of fish species and conditions (physiological and environmental). MCHC in fish is lower than that in mammals, in part because the nucleus of a fish RBC takes up a considerable portion of the cell volume. MCHC estimated from the whole blood hemoglobin concentration divided by the proportion of RBCs in blood (i.e., Hct/100).

MCHC decreases temporarily for two primary reasons. One is that fish RBCs are prone to swelling. For example, RBCs can take on water when blood catecholamine concentrations rise during stress (**see also Transport and Exchange of Respiratory Gases in the Blood**: Red Blood Cell Function). Swelling can change Hct by ~5%, which means that in such situations an Hct measurement alone would overestimate MCHC to the same degree. RBC swelling is typically recognized when Hct increases but blood hemoglobin concentration does not.

The second reason for a decrease in MCHC is that fish release immature RBCs into the circulatory system during erythropoiesis (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin Differentiation in Fishes and **Blood**: Erythropoiesis in Fishes). Thus, a fish recovering from anemia will have a disproportionate number of younger RBCs and a lower MCHC. Young RBCs continue to manufacture hemoglobin while circulating, increasing MCHC over time. There are simple methods to isolate RBCs of different ages. Centrifugation packs older RBCs lower in the RBC layer than younger RBCs because of a higher hemoglobin concentration and density.

White Blood Cells

As in mammals, fish WBCs have primary roles in cellular defense and immunity. These roles result in WBCs being found in tissues outside of the blood, as well as their three primary production sites (thymus, spleen, and kidney). Here, the focus is on the WBCs routinely found in fish blood.

Fish regulate the number of circulating WBCs, despite their miniscule representation in fish blood (Lct = 0.3–1.0%). As a result, Lct is a relative coarse measure of any change in WBC abundance. Even so, an elevated Lct is often used as an indicator of pathology because it can easily double. Toxicants and stress can also depress Lct.

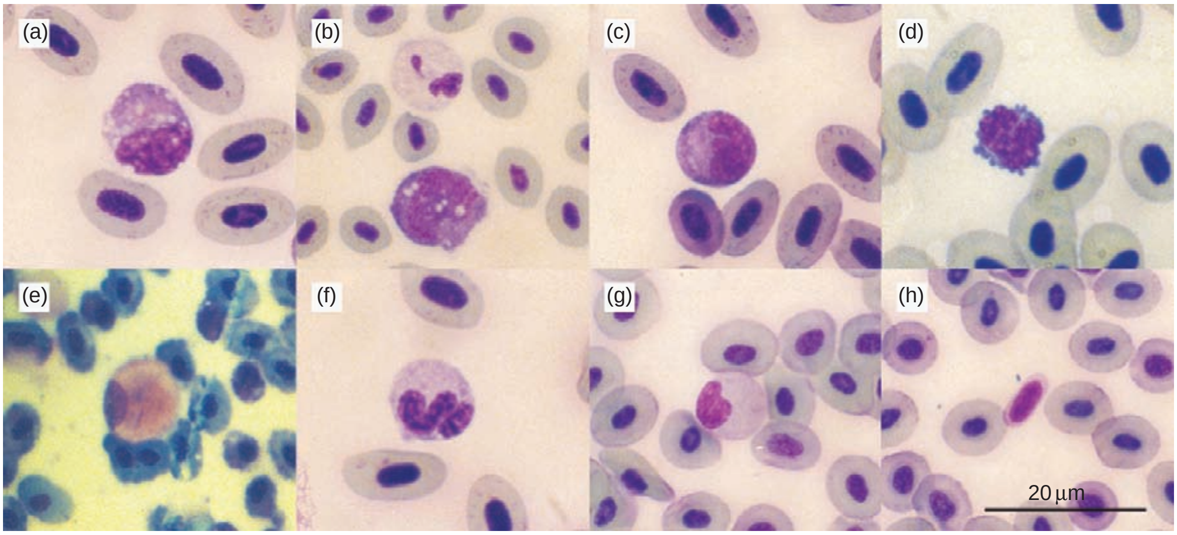

Figure 5 A selection of the types of leukocytes found in four different teleost fish (fathead minnow – *Pimephales promelas*, Pacific herring – *Clupea pallasi*, brook stickleback – *Culea inconstans*, and juvenile coho salmon – *Oncorhynchus kisutch*): (a) monocyte from coho salmon; (b) neutrophil (top) and monocyte (bottom) from Pacific herring; (c) basophilic staining cell from coho salmon; (d) lymphocyte from coho salmon; (e) eosinophilic staining cell from Pacific herring; (f) neutrophil from coho salmon; (g) neutrophil from fathead minnow; and (h) thrombocyte from fathead minnow. The more numerous elliptical cells are nucleated red blood cells. All cells stained with modified Wright–Giemsa and photographed at 1000. Reproduced from Tierney KB, Farrell AP, and Kennedy CJ (2004) The differential leucocyte landscape of four teleosts: Juvenile *Oncorhynchus kisutch*, *Clupea pallasi*, *Culea inconstans*, and *Pimephales promelas*. *Journal of Fish Biology* 65: 906–919.

Microscope counting chambers afford a more accurate measure of WBCs (the number per mm^3 of blood). Typically, there are thousands of WBCs per mm^3 compared with millions of RBCs per mm^3 of blood. Despite their low abundance, WBCs are about 20 times more metabolically active than RBCs (RBCs consume about $150\,\mu mol\,h^{-1}\,L^{-1}$ cells). Consequently, WBC metabolism will account for about 25% of the oxygen consumed by blood if Lct is 1% and Hct is 30%.

The four major WBC types in fish blood (**Figure 5**) are:

1. lymphocytes that play a role in immuno-competence;
2. thrombocytes that are involved in blood clotting;
3. granulocytes that have unknown functions; and
4. monocytes that are phagocytic.

Typically, lymphocytes and thrombocytes dominate over granulocytes, while monocytes are rare. The roles of the different WBC types, as well as their characteristics and proportions, are less well understood for fishes than mammals. Even so, WBCs can be more abundant in fish blood than in human blood.

The WBC types are distinguished in counting chambers and in dried blood smears after staining cells with dyes. Distinguishing features include overall cell size and the size and shape of the nucleus (**Figure 5**). A differential blood count assigns percentages to the proportions of WBC types in a blood sample. Expensive and automated electronic cell counting devices are also used. Criteria used to identify fish WBCs are based on those established for mammals. Even so, inconsistencies exist in the fish literature, partially because WBC appearance is confusing (e.g., small lymphocytes and thrombocytes have a nearly identical appearance), and partially because there are differences with mammalian WBCs.

Lymphocytes

Lymphocytes are small (5–8 μm) or large (12 μm). Regardless of size, about two-thirds of the cell is taken up by a purple-stained nucleus. They often have a serrated appearance due to folds in the membrane called pseudopodia. Lymphocytes are produced primarily in the thymus, and secondarily in spleen and kidney. As in mammals, fish have T-type and B-type lymphocytes. B-lymphocytes contain the antigen immunoglobulin (Ig) on their cell membrane, which is consistent with roles in antibody production and immuno-competence. Cortisol, which is released during stress, can depress lymphocyte numbers.

Thrombocytes

Thrombocytes, the smallest (5–8 μm) WBCs, take on different appearances (a spiked, spindle-cell, ovoid, and lone nucleus). Their cytoplasm stains lightly, whereas the nucleus stains dark purple and occupies the majority of the cell. Thrombocytes have a variable abundance (**Figure 6**). Great care is needed to distinguish

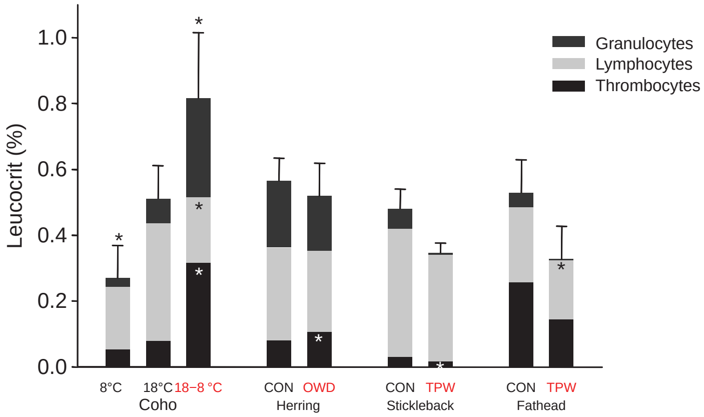

Figure 6 The white blood cell composition of fish expressed as a fraction of the total packed white cell volume (leucocrit). Control values for coho salmon acclimated to both 8 °C and 18 °C are compared with 18 °C-acclimated coho salmon exposed to an acute 96 h decrease in temperature (18–8 °C). Control Pacific herring held in seawater are compared with Pacific herring exposed to oil–water dispersion (OWD). Control stickleback and fathead minnows were sampled following wild capture and are compared with fish held for 48 h in the same tailings pond water (TPW). Lct values with asterisk are significantly different (t-test, á = 0.05). Reproduced from Tierney KB, Farrell AP, and Kennedy CJ (2004) The differential leucocyte landscape of four teleosts: Juvenile *Oncorhynchus kisutch*, *Clupea pallasi*, *Culea inconstans*, and *Pimephales promelas*. *Journal of Fish Biology* 65: 906–919.

thrombocytes with a lone or an ovoid nucleus from small lymphocytes, a mistake that could greatly elevate thrombocyte numbers. The lack of Ig on thrombocytes is perhaps their best distinguishing factor. Thrombocytes are involved in blood clotting (**Figure 7**).

Granulocytes

Granulocytes are 12–15 μm in diameter and can be confused with large lymphocytes. However, the nucleus occupies no more than about a third of the cell and can be mono-, bi-, or multi-lobed. The cells have circular or elliptical shapes and the stained cytoplasm takes on a variety of hues, textures, and shapes when stained, being sometimes referred to as heterocytes or neutrophils. The cytoplasm contains many vacuoles and stains from blue (basophilic) through transparent (neutrophilic) to red (eosinophilic); neutrophils are typically dominant. Depending on the species, eosinophils and basophils can be rare, or both subtypes can approach 10% of the WBC count. The roles of granulocytes are unclear, but reportedly they are phagocytic and respond to inflammation. An increased percentage of granulocytes in stressful situations results in part because lymphocyte numbers decrease. Granulocytes appear to be produced in the kidney and spleen.

Monocytes

Monocytes are infrequent (<1% of WBCs). If they account for 0.1%, of WBCs, on average, at least 1000 WBCs must be viewed just to observe just one monocyte. However, their large size (20 μm diameter) makes them easy to identify. The cytoplasm stains blue and contains vacuoles. The nucleus is typically kidney shaped and occupies more than half of the cell. Monocytes are phagocytic and chemotactic. They possibly mature to become the phagocytic tissue macrophages as part of a nonspecific defense. The respiratory burst activity

measured in kidney tissue macrophages is often used to diagnose a sick fish.

Each WBC type is present in variable amounts depending on the species, and according to a fish's physiological or pathological state, and even the season of the year. The variability of granulocytes and thrombocytes among species is particularly evident in **Figure 6**. These data show that Lct doubled by increasing lymphocyte numbers with warm acclimation of coho salmon (*Oncorhynchus kisutch*). In contrast, an acute cooling stress (18–8 °C) increased Lct even further, but this was because granulocyte and thrombocyte numbers increased whereas lymphocyte numbers decreased. High levels of the adrenocorticotrophic hormone and cortisol, typically found in blood during stress (**see also Hormonal Responses to Stress**: Hormone Response to Stress), are known to reduce lymphocyte numbers, leading to a low WBC count (leukopenia). **Figure 6** also illustrates that exposure to tailing water decreased Lct in both brook stickleback (*Culaea inconstans*) and fathead minnow (*Pimephales promelas*), but exposure to water-soluble oil fractions had no effect on either Lct or WBC composition of Pacific herring (*Clupea pallasi*). Furthermore, granulocytes, thrombocytes, and lymphocytes all decreased in brook stickleback, but only granulocytes and thrombocytes decreased in fathead minnow. Thus, we appear some distance from being able to characterize WBC responses across fish species.

In summary, the cellular composition of blood is regulated, dynamic, and multifunctional.

Glossary

Ectotherm (adj. ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Erythropoiesis Formation of red blood cells in the developing vertebrate embryo.

Evolutionary mutant model An organism naturally expressing a phenotype that mimics the clinical features of human diseases.

Hematopoiesis The process by which the cellular elements of the blood are formed.

Hematopoietic stem cells Responsible for production of all mature blood cells and including red cells, myeloid cells (neutrophils and macrophages), mast cells, megakaryocytes, and B- and T-lymphocytes.

Introduction

Here, we review erythropoiesis in fish and identify important questions yet to be addressed. Fishes account for approximately 50% of all vertebrate species and are suitable organisms for analyzing erythropoiesis. Complex genetic manipulations in zebrafish, an excellent model for studying development, have been important in the elucidation of erythropoiesis in fish. The similarities between erythropoiesis in fish and mammals are not limited to only conservation of genes. All major blood-cell types and the molecular signaling pathways are highly conserved between fish and mammals. Furthermore, analysis of evolutionary mutant models, such as the Antarctic icefish (devoid of hemoglobin and red blood cells (RBCs)), offers additional insights to tackle human disease and to identify novel genetic factors involved in erythropoiesis.

Hematopoiesis in vertebrates (including fish) occurs in two successive waves, that is, primitive (embryonic) and definitive (adult or even larval). Hematopoiesis invokes a hierarchy in which hematopoietic stem cells (HSCs) give rise to multipotential progenitors, which, in turn, generate precursors committed to differentiation along selected lineages.

The formation of RBCs in the developing vertebrate embryo becomes of vital importance as circulation is established and simple diffusion across the body can no longer satisfy increasing O_2 demand. Since RBCs are the first blood cells to appear during embryogenesis, the study of erythropoiesis is important for studying hematopoiesis. Moreover, analysis of the mechanisms by which proteins, such as globins, are highly and specifically expressed in developing RBCs has served as paradigm for transcriptional regulation in higher eukaryotes and has also shed light on the basis of inherited human disorders of hemoglobin production.

The process of hematopoiesis is generally conserved throughout vertebrate evolution, whereas, remarkably, the site of hematopoiesis is not conserved. For instance, the site of adult hematopoiesis in fish is the kidney and the thymus. The frog forms adult blood in the liver, and birds and mammals form blood in the bone marrow. In the frog, *Rana temporaria*, the site of hematopoiesis switches between liver and bone marrow, depending on the season.

Erythropoiesis

Erythropoiesis is the process whereby a fraction of primitive multipotent HSCs becomes committed to the red-cell lineage. Erythropoiesis involves highly specialized functional differentiation and gene expression. The main role of RBCs is to carry O_2 in the blood by the hemoglobin molecule. Therefore, erythropoiesis needs to be tightly regulated to maintain homeostasis and to meet changes in O_2 supply and demand.

The principal factor in the regulation of erythropoiesis is the hormone erythropoietin (Epo), essential for definitive erythropoiesis in all vertebrates studied to date. Epo binds the erythropoietin receptor (EpoR) on erythroid progenitors, stimulating a conserved intracellular signaling program that regulates vertebrate erythropoiesis. In fish, Epo and its receptor have low amino-acid sequence identity compared with mammalian species, and recombinant human Epo is inactive in fish. Even so, the critical functional residues and the physiological role in the regulation of erythropoiesis are well conserved.

The Zebrafish Model

Manipulation of animal models, such as mouse and zebrafish, has complemented and greatly extended studies of human hematopoiesis. The zebrafish (*Danio rerio*) has emerged in recent years as an exciting model for studying vertebrate organ development and heritable disorders. The combined genetic and embryologic advantages make zebrafish ideal for understanding the developmental biology of blood formation (hematopoiesis) in fish.

Although hematologic studies are being undertaken in other fish models, such as medaka (*Oryzias latipes*) and pufferfish (*Takifugu rubripes*), the genetic regulation of erythropoiesis is difficult to study in fish-model organisms other than zebrafish. However, several studies suggest that blood formation and its regulation are similarly widespread among fish.

Blood formation in the zebrafish is similar to that in mammals, but occurs more rapidly (**Figure 1(a)**). The zebrafish and most other fish do not form yolk-sac blood islands during early embryogenesis, but instead primitive hematopoiesis occurs at two intra-embryonic locations, that is, the anterior lateral mesoderm (ALM) and the posterior lateral mesoderm (PLM) that subsequently form the intermediate cell mass (ICM) of Oellacher (see below). The definitive hematopoiesis that contains long-term self-renewing HSC originates in the aorta-gonad mesonephros (AGM) region and caudal hematopoietic tissue (CHT). In zebrafish, the major site of definitive hematopoiesis in the larval period is the pronephros, whereas in the adult stage it takes place in the kidney as well as in the thymus, rather than in the bone marrow as in higher vertebrates.

Based on the expression patterns of blood-specific markers, erythroid, myeloid, and thromboid lineages are found in the CHT. Primitive myelopoiesis takes place in the ALM, whereas primitive erythropoiesis occurs in the ICM. The zebrafish spadetail mutant possesses regular myelopoiesis in the ALM, but fails to make erythroid cells in the ICM, suggesting distinct genetic regulations in these two regions. The ICM-forming fish have been regarded as exceptions to the general rule of yolk-sac hematopoiesis in vertebrates. However, some fish, such as killifish (*Fundulus* spp.), angelfish (*Pterophylum scalare*), and chondrichthyans, form blood predominantly in the yolk sac.

In the posterior ICM, some cells exhibit delayed maturation and may represent the HSCs or definitive progenitors. These may be analogous to definitive progenitors detected in cultures of mouse yolk sac. Hematopoiesis invokes a hierarchy in which HSCs give rise to multipotential progenitors, which, in turn, generate precursors committed to differentiation along selected lineages. HSCs are responsible for production of all mature blood cells, including red cells, myeloid cells (neutrophils and macrophages), mast cells, megakaryocytes, and B- and T-lymphocytes. HSCs may be considered as groups of cells with varying developmental potentials, dependent on intrinsic networks driven by transcription factors. All these networks confer great flexibility to the options of HSCs.

The first morphologically identifiable erythroid precursor cell is the proerythroblast, a cell characterized by a large nucleus and basophilic cytoplasm. The proerythroblast requires Epo for its survival and proliferation, and expresses small quantities of globin mRNA. The expansion, proliferation, and differentiation of erythroid progenitors into mature RBCs in response to exogenous Epo (Epo-injected zebrafish embryos) suggest that the signaling pathways regulated by Epo are functionally similar in mammals and fish. The regulation of Epo by O_2 concentration is functionally relevant to its role as modulator of erythroid cell mass for ensuring adequate O_2 supply. Activation of hypoxia-inducible factor (HIF-1), belonging to the family of basic helix–loop–helix transcription factors, increases the transcription rate of the *Epo* gene and Epo may influence RBC production in response to hypoxia, even if the role of hypoxia, HIF-1, and Epo in stimulating proliferation and differentiation of erythroid progenitor cells remain virtually unexplored in fish. However, evidence suggests that RBC production in fish is Epo sensitive.

Upon its differentiation, the proerythroblast matures progressively to the late normoblast stage, characterized by a condensed nucleus and hemoglobin-containing cytoplasm (**Figure 1(b)**). During primitive erythropoiesis in mammals, and throughout birds, amphibians, and fishes, the nucleus is retained, whereas in mammalian definitive erythropoiesis, mature RBCs become anucleate. The RBCs of all fish retain their nucleus and contain three filamentous systems: an actin/spectrin-based membrane cytoskeleton, intermediate filaments, and microtubules. In contrast, mammals RBCs lose intermediate filaments and microtubules during terminal differentiation and enucleate prior to entering the bloodstream. Thus, adult mammals RBCs are enucleated and contain only one filamentous system, a membrane cytoskeleton. Enucleation is a normal developmental/differentiation process in mammals. Together with the acquired biconcave shape, this lack allows maximal diffusion of O_2 and CO_2 within the cell. The number of molecules of hemoglobin is higher than that of a typical sphere containing a huge nucleus, conferring an important advantage for O_2 transport.

Once mature, RBCs in fish develop a characteristic flattened elliptical shape. Similar to humans, ectotherm RBCs exhibit high metabolic activity, due to the presence

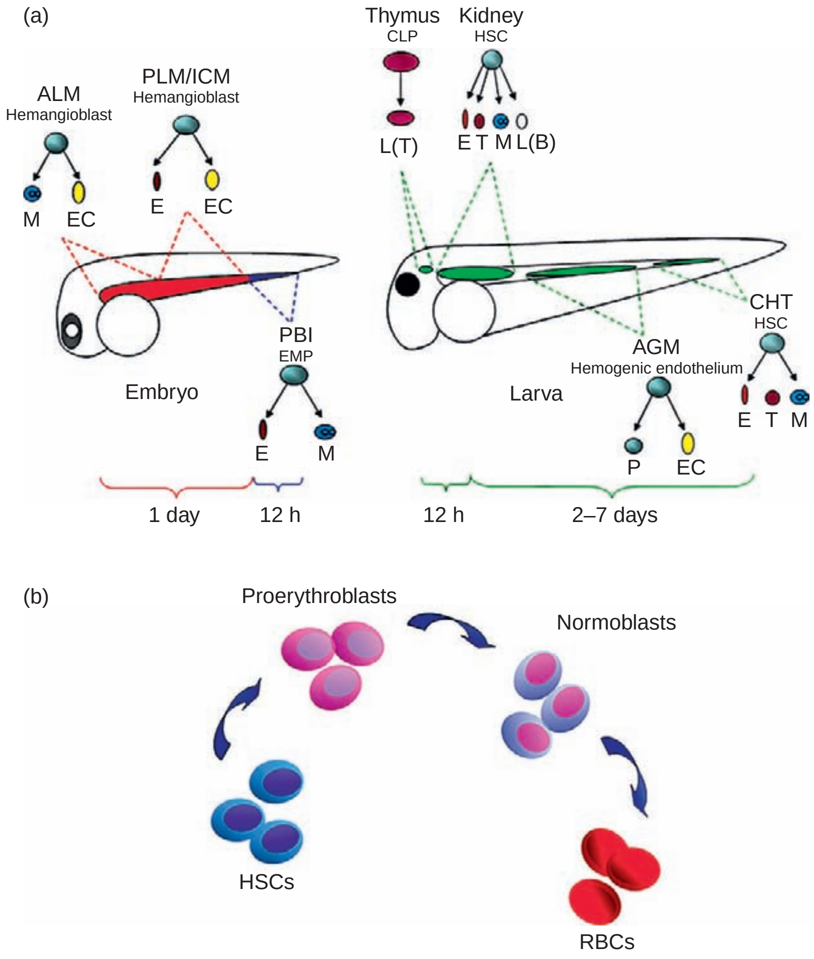

Figure 1 (a) Hematopoiesis in the zebrafish. The first step of hematopoiesis (in red) starts in the embryo with hemangioblasts. (Hemangioblast was hypothesized to be the common progenitor of blood and vascular cells on the basis of intimate association of these lineages in the blood islands of the yolk sac. The presence of hemangioblasts has also been addressed in zebrafish and current studies support the existence of these cells, although it is important to redefine the potential of these cells in the future. It is likely that, phylogenetically, hemangioblasts originated as bi- or pluripotent cells populating the coelomic epithelium of an ancestral invertebrate.) These hemangioblasts give rise to myeloid (M) and endothelial cells (EC) in the anterior lateral mesoderm (ALM), and to erythroid (E) and ECs in the posterior lateral mesoderm (PLM), which later become the intermediate cell mass (ICM). In the posterior blood island (PBI) (in blue), erythromyeloid progenitors (EMPs) originate erythroid and myeloid cells in a transient definitive wave. The next step of hematopoiesis (in green) occurs in the larva with the formation of hematopoietic stem cells (HSCs) in the aorta-gonad-mesonephros (AGM). In AGM, the hemogenic endothelium gives rise to ECs and hematopoietic progenitor cells (P) that migrate to and colonize other sites of definitive hematopoiesis. The AGM progenitor cells seed the caudal hematopoietic tissue (CHT), an intermediate site of definitive blood development, and the kidney that later becomes the primary site of hematopoiesis. The kidney contains all the different blood lineages, including the lymphoid B cell L(B) lineage. Erythroid, myeloid, and thromboid (T) lineages are found in the CHT. The common lymphoic progenitors (CLP) mature into lymphoid T cells L(T) in the thymus. The time of expression of blood-specific markers in different sites is indicated by curly brackets with different colors.. (b) Erythropoiesis during the progressive differentiation from the initial HSCs to the RBCs.

of a complex cellular apparatus (including nucleus, mitochondria, and endoplasmic reticulum). Mature RBCs play a key role in vertebrate and human metabolism. Besides their role in transporting O_2 to the tissues, RBCs interact with many factors (protons, chloride, and organic phosphates) for modulating tissue O_2 supply either by changing the equilibrium between the tense (low-affinity structure) and relaxed (high-affinity structure) states of hemoglobins or by regulating RBC rheology and tissue perfusion. Oxygenation–deoxygenation transitions appear to induce a cascade of tyrosine and serine/threonine phosphorylation reactions involved in O_2 signaling and may lead to the reorganization of the cytoskeleton in fish RBCs.

Definitive Erythropoiesis

Multipotent HSCs capable of self-renewing and producing all blood cells arise during definitive hematopoiesis. In zebrafish, these HSCs are initially found in the CHT and then in the kidney. A subset of HSCs also migrates to the thymus for lymphopoiesis. Definitive erythropoiesis begins at 3.5 days post-fertilization (dpf), as shown by expression of embryonic globins and GATA1 (see below). In zebrafish, the globin switch from embryonic to adult occurs between 15 and 30 dpf. As in other teleost fishes, the zebrafish globin loci are very complex, encoding many α and β chains for hemoglobin switching. The zebrafish embryonic and adult globins display high homology to the human globin genes early expressed during human embryogenesis. It may be postulated that embryonic globin genes in humans and fish are the most evolutionary conserved ones and that their differentiation in embryonic and adult subtypes, in relation to the developmental stage, might have occurred about 450 million years ago after the divergence between teleosts and the ancestors of mammals.

As in mammals, the zebrafish spleen functions as a reservoir for RBC storage and destruction. Erythroid maturation is reflected by changes in cytoplasmic shape, staining, nuclear size, and chromatin density. As in mammals, RBCs in fish are involved in metabolic regulations and blood rheology. Defects in enzymatic and/or metabolic activities produce RBCs abnormalities that, despite the presence of nuclei in fish, mirror human RBC-disease phenotype. Similar to other vertebrates, fish express hemoglobins displaying quaternary structure (α_2/β_2) that undergo globin switching from the embryonic stage to the adult one.

Genes Required in Erythropoiesis: The GATA-Family Example

Vertebrate embryonic hematopoiesis involves critical transcriptional regulation of coordinated gene expression, such as those encoding globins and cell-surface receptors. Several genes are required at the proerythroblast stage to permit or guide terminal erythroid differentiation. These include components of the Epo-signaling pathway and many transcription factors. For the sake of conciseness, only few examples are discussed here. For full description of all components involved in the process of hematopoiesis, the reader is addressed to the section Further reading at the end of the chapter.

The GATA family consists of six transcription factors, GATA1 to GATA6; they all bind to the DNA consensus sequence (A/T)GATA(A/G) by two characteristic (Cys-X2–Cys-X17–Cys-X2–Cys) zinc-finger motifs specific to the GATA family. GATA1 is fundamental for primitive erythropoiesis. It is expressed in primitive and definitive RBCs, megakaryocytes, esinophils, mast cells, and in the Sertoli cells of the testis. In mice, disruption of the GATAl or GATA2 gene leads to severe hematopoietic defects, demonstrating requirement of these factors for normal erythroid maturation. GATA1 and GATA2 are initially expressed during gastrulation, and GATA1 expression is restricted to hematopoietic cells during embryogenesis. GATA2 is expressed in early ventral ectoderm and hematopoietic cells, and is later expressed in the central nervous system. In each vertebrate species studied thus far, GATA1 levels increase and GATA2 levels decrease during erythroid differentiation (**Figure 2**). For instance, GATA1 is highly expressed in megakaryocytic/erythroid progenitors (MEPs) that give rise to megakaryocyte and RBC precursors. GATA2 is required at the level of multipotential progenitors for the proliferation/survival of multipotential progenitors.

In zebrafish, after 12 h post-fertilization (hpf), GATA1 is expressed in a subset of cells expressing the stem-cell leukemia (*scl*) gene encoding a basic helix-loop helix transcription factor. These cells give rise to the first circulating blood cells. Approximately 300 proerythroblasts (*GATA1+*) in the ICM enter circulation around 24 hpf and mature into RBCs. These primitive RBCs are morphologically different from adult zebrafish RBCs endowed with less cytoplasm and a large elongated nucleus. Blood cells of primitive hematopoiesis appear in circulation 1 week after fertilization.

The transcription factors critical for hematopoiesis virtually encompass all classes of DNA-binding proteins. Remarkably, the majority of transcription factors working in the hematopoietic system are also involved in chromosomal translocations or in somatic mutations in human hematopoietic malignancies. The coexistence of transcription factors of different lineages within a common cell (the HSC or immature progenitor) offers the potential for immediate information exchange at the molecular level. The requirements and functions of the principal transcriptional regulators are context dependent. The key lineage-specific factors may promote their own lineage differentiation, and may simultaneously act against factors favoring other choices in lineage programming. At each critical point, genes

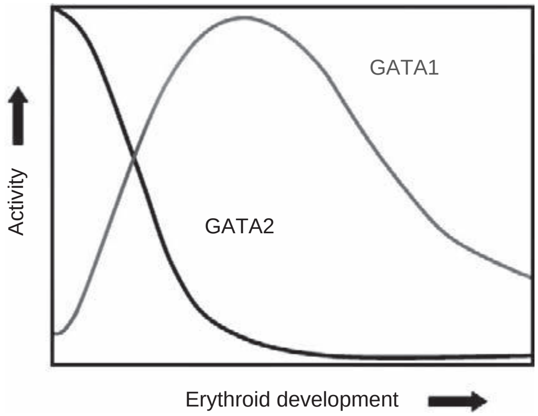

Figure 2 During RBC differentiation, GATA1 is downregulated by an autonomous cell signalling mechanism.

associated with the pertinent pathways are upregulated while the genes linked to lineages not chosen are silenced. The coordination of the silencing of some genes with the activation of others is the mechanism by which cells choose a differentiation pathway.

GATA1 and PU.1 (myeloid-specific transcription factor) promote erythroid/megakaryocytic/esinophil and myeloid differentiation, respectively. The balance between primitive erythroid and myeloid cell production is a delicate one, being mainly governed by the equilibrium between GATA1 and PU.1. Expression of PU.1 and GATA1 are mutually exclusive, suggesting antagonism between these two transcription factors via direct physical interaction. PU.1 is co-expressed with GATA1 in the ICM from 16 hpf to 20 hpf and the equilibrium between these two factors regulates production of primitive erythroid and myeloid cells. *In vivo* confirmation of the different roles of GATA1 and PU.1 exists for zebrafish. Inhibition of GATA1 expression shifts hematopoietic progenitors to a myeloid fate, whereas the opposite occurs upon inhibition of PU.1 expression. The involvement of multiprotein complexes in the action of hematopoietic transcription factors suggests that their relative concentrations influence the choice of lineage in the programming mechanisms. Experiments with zebrafish, in which the pattern of erythroid versus myeloid development is affected by inhibition of expression of GATA1 or PU.1, are consistent with this model. GATA1 also activates structural genes required in RBCs such as globins.

The Icefish Model

The variety of adaptations underlying the ability of modern Antarctic fish to survive at freezing temperatures represents the extreme of low-temperature adaptations in vertebrates. The Antarctic sea, perennially at or near freezing, has a higher O_2 concentration than other waters. In these environments, the selection pressure for O_2-binding hemoproteins was relaxed, and hemoglobin expression was lost in icefishes (family Channichthyidae) (**Figure 3**). Antarctic icefishes do not express the developmental program for RBC formation. The loss of hemoglobin exploits the high O_2 solubility and low metabolic rates in frigid water. The delivery of O_2 to tissues occurs by transport of the gas physically dissolved in the plasma.

The loss of hemoglobin is a derived character shared by the 16 species of the family. Fifteen out of 16 genomes lack most of the adult $\alpha\beta$-globin gene complex and retain only a fragment of the α gene. There is strong evidence that the $\alpha\beta$-globin complexes were also deleted in juveniles.

Therefore, they are a useful evolutionary mutant model for studying hemoglobinopathies and thalassemias found in humans.

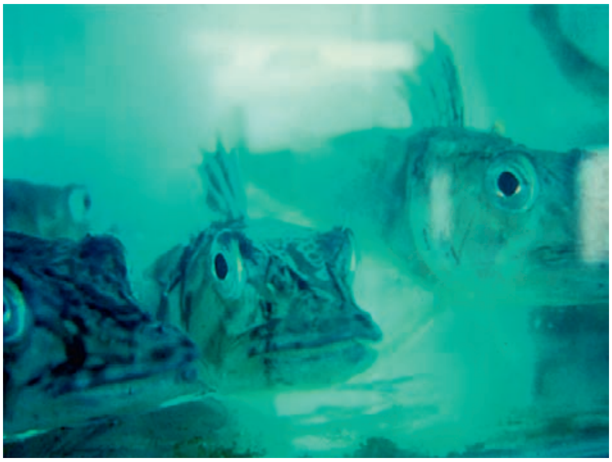

Figure 3 *Chionodraco hamatus* (icefish, family Channichthyidae, suborder Notothenioidei). Photograph by G. di Prisco.

Icefish are natural knockouts of the RBC lineage and therefore may be considered excellent models for erythroid gene discovery by comparative genomics. In fact, they could be paired with closely related, but red-blooded, notothenioids to discover novel erythropoietic genes by subtractive genomic strategies. How hemoglobin loss may influence the terminal erythroid differentiation from the proerythroblast progenitor remains a fascinating question yet to be explored.

Glossary

Atrium A thin-walled chamber of the heart that is primarily comprised of cardiac muscle tissue.
Cardiac Pertaining to the heart.
Ductus Cuvier A pair of horn-shaped vessels that lie outside the pericardium, which are connected to the sinus venosus and collect venous blood from central veins.
Endocardium Inner part (infolding) of the pericardial sac, and is the inner lining of the cardiac chambers.
Ostial valves Flap-like connective tissues that extend one side of an opening (ostium), in this case the opening connecting cardiac chambers, which serve to prevent blood from flowing back through the opening when a chamber contracts.
Outflow tract A general term for the vessel through which blood leaves the ventricle. In fish, this is the bulbus arterious, the conus arteriosus, or the ventral aorta.
Pericardium A cellular membrane that creates a sac to surround and enclose the heart, and which contains a small amount of pericardial fluid. This sac is closed in teleost fishes, but in sharks there is a pericardio-peritoneal canal that allows regulated exchange of fluid between the pericardial and peritoneal cavities.
Sino-atrial node A region of the heart near the junction of the sinus venosus and atrium, where the specialized cardiac fibers that initiate the heartbeat (pacemaker cells) are located.
Sinus venosus A thin-walled chamber of the heart that contains little cardiac muscle but is the site of the cardiac pacemaker.
Trabecula(ae) A bundle of cardiac muscle fibers, which is the most common arrangement for the cardiac muscle in the walls of the atrium and ventricle.
Ventricle A thick-walled chamber of the heart that is primarily comprised of cardiac muscle tissue.

Introduction

The heart is the powerhouse of the cardiovascular system. It propels blood (blood cells and plasma) around the circulatory system by imparting potential energy (blood pressure) and, to a lesser degree, kinetic energy (velocity) to the blood. This article considers the anatomy of the heart in fish.

Cardiac anatomy varies closely with cardiac function, which in turn varies considerably among fish. Nevertheless, some generalities apply to most fish. These generalities are considered first. Then, the anatomical diversity among fish is presented for each cardiac chamber. The cellular aspects of the fish heart are covered in **Design and Physiology of the Heart:** Intracardiac Neurons and Neurotransmitters in Fish.

The General Anatomical Structure of a Fish Heart

Overview

The fish heart is located ventrally, in front of the pectoral fins and peritoneal (gut) cavity, but generally behind the gill structures (**Figure 1(a)**). The heart is also referred to as the branchial heart or systemic heart because it pumps blood first to the gill and then to the systemic circulations that lie in series. This arrangement is called a single circulatory system because a red blood cell that leaves the heart passes through both the respiratory and systemic circulations before returning to the heart. This nomenclature distinguishes the branchial heart from the accessory hearts also found in some fish (**see also Design and Physiology of the Heart:** Accessory Hearts in Fishes) and that assist in the pumping of fluid around the circulatory system.

The heart is positioned within a membranous sac, the pericardial cavity, which is created by a layer of mesothelial (epithelial-like) cells in addition to connective and fat tissue, called the pericardium. The epicardium represents the inner part (infolding) of the pericardium and is often directly attached to the cardiac chambers (see below). The pericardium separates the heart from the rest of the body. The pericardium is variably stiff and may be fused with other body tissues. For example, the peritoneum and pericardium are fused on the posterior wall of the pericardial cavity, and the dorsal wall is fused with esophageal tissue. The pericardial cavity contains a small amount of pericardial serous fluid that bathes the heart and provides lubrication as the heart moves with each heartbeat.

Within the pericardium, there are four distinct chambers that comprise the fish heart: the sinus venosus, the atrium, the ventricle, and an outflow tract (**Figure 1(b)**). Each chamber plays a key, but different role in the overall function of the heart. Consequently, fish are generally considered to have a four-chambered heart, with the chambers arranged in series to support a single circulation and so a red blood cell is pumped twice by the heart before reaching the systemic tissues, that is, a red blood cell leaving the heart normally returns to the heart after a single circuit through the body. In contrast, the mammalian heart, which is also considered to be four chambered, possesses two atria and two ventricles, with one pairing of an atrium and a ventricle being arranged in parallel with the other to form a double circulatory system, that is, a red blood cell leaving the heart would normally return to the heart after first passing through the pulmonary circulation. However, because only the atrium and the ventricle contribute appreciably to the generation of blood pressure, fish hearts are sometimes referred to as being two-chambered.

Figure 1 (a) A ventral view of a rainbow trout with a mid-line incision to reveal the anatomical organization and shape of the cardiac chambers. The pericardial cavity was opened for this view. Note the coronary artery visible on the white surface of the bulbus arteriosus. (b) A schematic diagram of the cardiac chambers as seen from a lateral view.

From a lateral view, the chambers of the fish heart have an S-shaped appearance (**Figure 1(b)**). The sinus venosus is connected to the ductus Cuvier, a pair of horn-shaped collecting vessels lying outside the pericardium.

The outflow tract is connected to ventral aorta, which lies outside the pericardial cavity and takes blood to the gill vessels. Blood returning from the venous system collects in the ductus Cuvier and flows freely into the sinus venosus as no valves protect these connections. Similarly, there are no valves in the outflow tract and the ventral aorta except in elasmobranchs and other primitive fish lineages (**see also Design and Physiology of the Heart:** The Outflow Tract from the Heart).

The sino-atrial (SA) canal, which connects the sinus venosus to the atrium, has a one-way ostial valve. This valve prevents blood from back flowing into the sinus venosus when the atrium contracts. Similarly, the atrioventricular canal, which connects the atrium to the ventricle, has a one-way ostial valve serving a similar purpose. The ventricle then connects to an outflow tract (either the bulbus arteriosus (**see also Design and Physiology of the Heart:** The Outflow Tract from the Heart) or conus arteriosus via another one-way ostial valve (**Figure 2**)).

Cardiac muscle is the predominant tissue type in the walls of the atrium and ventricle and is mainly composed of connected muscle cells (the so-called cardiomyocytes). When this muscle contracts, the pressure of the blood contained with the lumen of these chambers rises appreciably. The ventricle contains more cardiac muscles than the atrium and therefore contributes most to the generation of blood pressure. Even so, relative ventricular mass varies over an order of magnitude, representing anywhere from 0.03% to 0.40% of the fish's body mass among fish species. Atrial mass is about one-tenth to one-fifth of the ventricular mass. The atrium has a thinner wall and a greater internal distended volume than the ventricle.

The single arterial outflow tract is also thick walled. Wall thickness, which is needed to contain and store blood pressure energy, varies among species. In teleosts, the wall is comprised mainly of vascular smooth muscle and connective tissues, containing for the most part fibroblastoid cells and extracellular matrix material such as elastin and collagen. It is called the bulbus arteriosus. In elasmobranchs and other primitive fish, the outflow tract has an additional outer layer of cardiac muscle and is called the conus arteriosus.

All cardiac chambers are lined with endothelial cells, the endocardium, similar to the remainder of the cardiovascular system in fish. The outside of the heart has a layer of epithelial cells and connective tissue called the epicardium, embryologically representing the inner part (infolding) of the pericardium. Therefore, the atrial and

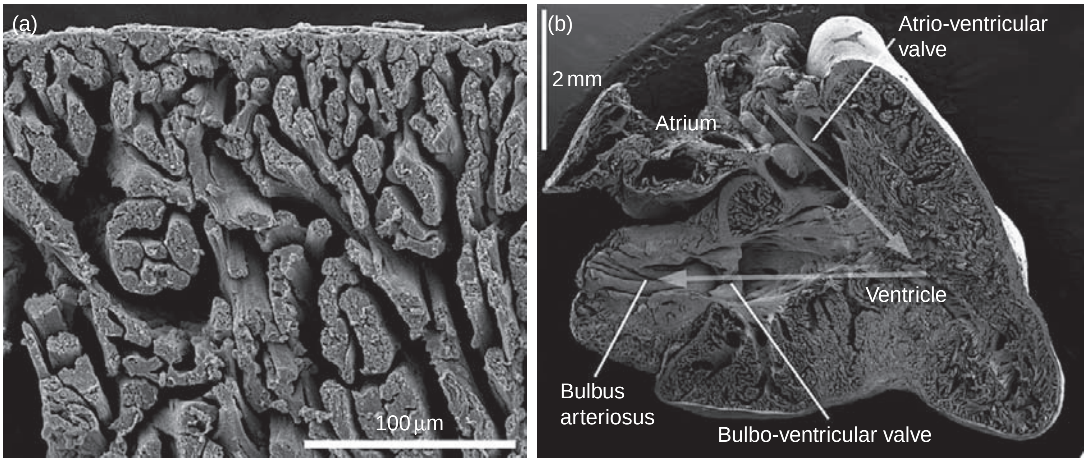

Figure 3 Scanning electron micrographs of (a) part of the atrium and (b) the ventricle and the outflow tract in a saggital section to reveal the interior architecture of the cardiac chambers of a sockeye salmon. The blood flow direction is indicated by the arrows.

ventricular cardiac muscle is sandwiched between endocardial and epicardial tissues. Interstitial cells and extracellular collagen and elastin fibers are also sparsely dispersed in between the interconnected cardiac muscle fibers.

The epicardium has a variable thickness (10 to more than 100 µm) depending on the age of the fish (**Figures 3(a)** and **3(b)**). It also contains blood vessels, nerve fibers, and adipocytes; in addition, a subepicardial layer of loose connective tissue contains predominantly collagen and elastin fibers. The blood vessels (part of the coronary circulation) either can be entirely epicardial (i.e., they do not penetrate the cardiac muscle) as found in the plaice (*Pleuronectes flesus*), or they can penetrate the cardiac muscle and form capillaries within the cardiac muscle, as found in rainbow trout (*Oncorhynchus mykiss*) (**Figure 2(c)**). Some of these superficial vessels are coronary veins and venules that coalesce toward the atrioventricular region, which is where the coronary vein drains into the lumen of the heart (**see also Design and Physiology of the Heart:** The Coronary Circulation).

Sinus venosus and ductus Cuvier

All systemic veins terminate in either the ductus Cuvier or the sinus venosus. There are no one-way valves associated with the termination of these veins. The thin-walled (5–100 µm thick) ductus Cuvier and sinus venosus contain smooth muscle, which can contract to alter their volume. The sinus venosus has the thinnest wall of all the cardiac chambers and its volume can be larger or smaller than that of the ventricle, depending on the species. The sinus venosus also contains a sparse and variable arrangement of bundles of cardiac muscle. An exception is the continuous, vascularized layer of cardiac muscle seen in the sinus of the common eel (*Anguilla anguilla*).

The cardiac muscle in the sinus venosus is spontaneously active and the electrical events associated with the contractions are seen as the V-wave preceding the P-wave of the electrocardiogram (ECG) (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping). V-waves are not reported for all fish, perhaps because so few cardiomyocytes cannot produce a detectable ECG signal. Contraction of the sinus venosus, in the absence of a valve guarding the entrance of the sinus venosus, is just as likely to propel blood away from as well as toward the atrium.

Some of the cardiomyocytes in the basal region of the SA canal are specialized and spindle shaped. They act as pacemaker or conductive tissue. Electrophysiological recordings from cells in this region have revealed the typical pacemaker potentials that initiate the heartbeat (**see also Design and Physiology of the Heart:** Action Potential of the Fish Heart). This region is often called the SA nodal tissue and often forms a ring around the SA canal. It may be functionally analogous to the mammalian SA node in the right atrial wall. In contrast, the existence of a well-defined conduction system in fish is still controversial.

The cardiac branch of the vagus nerve, which is present in all fish except the hagfishes (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes), joins the wall of sinus venosus after following the tract of the ductus Cuvier. The SA node is richly innervated with myelinated and unmyelinated nerve fibers, and includes nerve ganglions (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes and **Design and Physiology of the Heart:** Intracardiac Neurons and Neurotransmitters in Fish). The density of the innervation in this region is so high that it is often referred to as a plexus. Cardiac control of pacemaker activity is possible through the vagus nerve. The distribution of autonomic nerves and intracardiac nerves throughout the entire heart is detailed in **Design and Physiology of the Heart:** Intracardiac Neurons and Neurotransmitters in Fish.

The density of collagen in the sinus venosus increases toward the SA canal. This is likely related to the structural support needed for the SA valve. The SA valve is typically comprised of cells that may be similar to the mammalian valvular interstitial cells, which build up huge amounts of extracellular matrix material (mainly collagen bundles). They act like the cuspid valve of other vertebrates in preventing blood from flowing backward when the atrium contracts.

Atrium

The SA canal connects to the middle of the posterior wall of the atrium. There are no layers to the atrial cardiac muscle. Instead, the cardiac muscle is arranged in bundles (trabeculae) of variable diameter (10–30 μm).

Although thin walled, the atrium is not simply a sac-like structure (**Figure 2**). Trabeculae crisscross the atrial wall, creating a mesh-like arrangement without generally traversing opposing walls. Instead, the trabeculae create shorter arcs that form small lobular or cava-like structures within the atrial chamber. Therefore, the atrium has a well-defined, tissue-free lumen.

The trabecular length (especially in the ventricle) greatly exceeds that of an individual cardiomyocyte, which rarely reaches 200 μm. This means that many cardiomyocytes must be longitudinally arranged to form a single trabecula. While mammalian cardiomyocytes are branched and connect end-on-end, the tapered shape of fish cardiomyocytes likely leads to an overlapping pattern to ensure that each cardiac cell is robustly connected with its neighbor. Since individual cardiomyocytes are typically 3–6 μm in diameter in fish (**see also Design and Physiology of the Heart:** Cellular Ultrastructure of Cardiac Cells in Fishes), each trabeculum likely contains no more than about 10 cardiomyocytes side by side.

Innervation of the atrial cardiac muscle is extensive (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes and **Design and Physiology of the Heart:** Intracardiac Neurons and Neurotransmitters in Fish) with one study suggesting about one axon for every two cardiomyocytes.

Ventricle

The atrio-ventricular canal connects to the middle of the dorsal wall of the ventricle (**Figure 3**). For most fish, the ventricle has only one architectural arrangement of the cardiac muscle (**Figures 2(b)** and **2(d)**). Similar to the atrium, trabecular bundles crisscross the ventricle, but unlike the atrium the density is much higher and some trabeculae span to opposing walls of the ventricle. This is more clearly seen for trabeculae spanning almost the full length of the ventricle, from the apex to the base at the bulbo-ventricular junction. As a result of the extensive trabecular network, the lumen of the ventricle may be taken on an obscure, sponge-like appearance, more so in some species than others – hence the term spongy myocardium or spongiosa. However, scanning electron microscope images reveal a much more sophisticated structure to the trabeculae (**Figure 3**). The trabeculae can form sheet-like structures, which may assist the directional flow of blood within the ventricle. These sheet-like trabeculae also increase the cross-sectional area of a trabecula (the force that is generated by a muscle is proportional to its cross-sectional area) without greatly increasing the shortest diffusional distance to the center of a trabecula. In such cases, a trabecular muscle sheet can be over 100 μm wide, but only 30 μm deep. A narrow sheet like this has an advantage for myocardial oxygen delivery; venous blood can have a low oxygen partial pressure during exercise because the systemic tissues have already stripped blood of most of its oxygen (**see also Design and Physiology of the Heart:** The Coronary Circulation) and the diffusion rate for oxygen is determined principally by the venous oxygen partial pressure and the diffusion distance, which is set by the trabecular cross-sectional dimensions. A coronary vessel can be located inside of trabeculae of elasmobranchs and large pelagic teleosts, perhaps reducing the need for a sheet-like arrangement.

The ventricle has a second layer of cardiac tissue in those fish that have a coronary circulation that penetrates the ventricle (**see also Design and Physiology of the Heart:** The Coronary Circulation). The layer of cardiac muscle, which is richly invested with coronary capillaries (**Figures 2(a)** and **2(c)**), is sandwiched between the epicardium and the spongy myocardium, and envelops the spongy myocardium. This outer layer of cardiac muscle is referred to as the compact myocardium or compacta because the individual fibers are densely packed circumferentially around the ventricle. The compact myocardium can have 2–4 sublayers, each having a different fiber orientation. Depending on the fiber orientation, these sublayers can variously create an apically directed contraction, contraction that constricts the chamber and reduces the height and length of the ventricular walls. In contrast, when trabeculae contract, their crisscross arrangement across the ventricular walls tends to pull the walls of the ventricle inward. Also, the caudal apex toward the arterial outflow vessels if the trabeculae extend from the apex of the ventricle to the bulbo-ventricular junction can be pulled.

Innervation of ventricular muscle is far less extensive than in the atrium (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes and **Design and Physiology of the Heart:** Intracardiac Neurons and Neurotransmitters in Fish), with one study suggesting about one axon for every 25 cardiomyocytes. While some of this innervation may reach the ventricle via the atrium, there is also a possibility that axons arrive along the coronary artery, which typically lies on the arterial outflow tract (**see also Design and Physiology of the Heart:** The Outflow Tract from the Heart). The presence of adipocytes in the epicardium is likely to be related to the fish's nutritional status. Over-fed farmed salmon have excessive cardiac fat deposits near the bulbo-ventricular region and around coronary vessels.

Arterial outflow vessels

The ventricle ejects blood into either a bulbus arteriosus or a conus arteriosus. The former is comprised mainly of vascular smooth muscle and connective tissue, whereas the latter has an outer coating of cardiac muscle. In addition, the valves are arranged differently. The anatomy and functions of the conus arteriosus and bulbus arteriosus are considered in detail in **Design and Physiology of the Heart:** The Outflow Tract from the Heart.

Comparative Cardiac Anatomy

With over 25 000 species of fish, it is impossible to do justice to the range of diversity that exists for cardiac anatomy. The following sections, therefore, simply discuss some of the more general differences and then discuss features that are unique to certain vertebrate groups.

Cardiac shapes and sizes

The shape and size of the cardiac chambers reflects two influences: fit and function. Foremost, the heart must fit within a fish, but body shape varies enormously among fish. Consequently, a fish with an elongated body shape tends to feature an elongated heart. Second, the heart must perform its job appropriately. Higher blood pressures demand a thicker ventricular wall (compact myocardium) and higher stroke volumes demand a larger chamber volume (**Figure 4**).

The atrium has a variable shape and size. One extreme is where the most anterior part of the atrium almost completely envelops the outflow vessels and laterally extends over the wall of the ventricle. The other extreme is where sides of a small atrium are barely in contact with the ventricle (**Figure 4**).

There are three primary ventricular shapes, in part, determined by that of the fish: tubular, sac-like, and pyramidal (**Figure 4**). However, tubular and sac-like shapes are not always associated with an elongated body shape. Anguillid eels have a pyramidal heart, as do salmonids and tunas. The pyramidal heart appears to be associated with a coronary circulation and compact myocardium.

The relative mass of the ventricle varies by almost an order of magnitude. At one extreme are sluggish fish that live on the bottom and invest only 0.05% of their body mass into a sac-like ventricle. These fish have spongy myocardium and a low-blood-pressure generating capability. At the other extreme are the tunas with up to 0.4% of their body mass invested in their ventricle. Their pyramidal heart can generate arterial blood pressures approaching those found in mammals. Relative ventricular mass is more typically 0.1% or less in most fish; a larger ventricle is associated with athletic fish, presumably to support a higher arterial blood pressure. An exception to this generality exists for certain cold-water species. These fish compensate for the weaker cardiac muscle contraction at cold temperature by enlarging their ventricle, either through an adaptation or by phenotypic modification during cold acclimation. As a result, they have a relatively larger ventricle. For example, rainbow trout acclimated to cold conditions can almost double relative ventricular mass compared to warm acclimation. An extreme example of ventricular enlargement

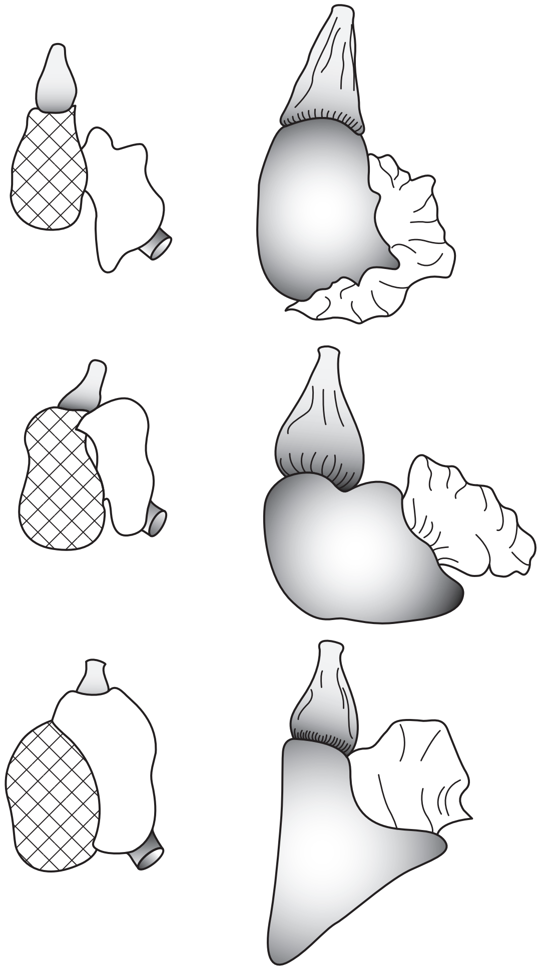

Figure 4 Illustrations of three different ventricular shapes (right column) and atrial arrangements relative to the ventricle (left column) in fish. These illustrate that the morphology of the heart is influenced by the fish's physiology (e.g., how hard does the heart work) and anatomy (e.g., into what body shape must the heart fit). Adapted from Santer RM (1985) Morphology and innervation of the fish heart. *Advances in Anatomy, Embryology and Cell Biology* 89: 1–102.

has evolved in Antarctic icefish, which have no red blood cells and live in water typically below 0 °C. Their relative ventricular mass is 0.4%, which is as large as the ventricle in the more athletic tunas. However, unlike that of the tuna, the icefish ventricle is thin walled, has a large internal luminal volume, and lacks a coronary circulation. Sexual development in male rainbow trout as well as anemia in rainbow trout and zebrafish (*Danio rerio*) can produce ventricular remodeling and enlargement.

The proportion of compact myocardium also varies widely among fish. This can reach 75% in some tuna species, but is commonly less than 30%. Some elasmobranchs have 10% or less compact myocardium. Since the compact myocardium is always associated with a coronary circulation, it is not surprising to find a high percentage of compact myocardium in athletic fish with their high blood pressures and cardiac oxygen needs (**see also Design and Physiology of the Heart:** The Coronary Circulation). Habitat may also influence the development of compact myocardium. However, while the hypoxia-tolerant common eel has a compact myocardium, not all hypoxia-tolerant fish do so. Thus, phylogenetic considerations may override the roles of athleticism and hypoxia in terms of the presence and abundance of compact myocardium. For example, no cyclostome heart has compact myocardium; all elasmobranchs and only some teleosts have compact myocardium.

Cyclostomes

A number of anatomical features are specific to the cyclostome heart. Hagfish have a modified pericardial cavity, which communicates fully with the peritoneum via an enlarged pericardio-peritoneal canal (**see also Hagfishes and Lamprey:** Hagfishes). Further, the pericardium terminates anteriorly at the junction of the ventricle and the ventral aorta. As such, hagfish do not have an outflow tract inside of the pericardium and so there is no true conus or bulbus arteriosus. The ventral aorta is very thin walled, reflecting the low blood pressure within. In lampreys, the pericardium is closed, as in teleost species.

Adult cyclostomes possess a single ductus Cuvier. The left duct is retained during development in hagfish, whereas the right duct is retained in lampreys. Lampreys, but not hagfish, also have a high relative ventricular mass.

The hagfish heart lacks innervation, whereas the lamprey heart has rudimentary vagal innervation (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes and **Design and Physiology of the Heart:** Intracardiac Neurons and Neurotransmitters in Fish). Hagfish have specialized chromaffin cells that contain varying quantities of adrenaline and noradrenaline, and may have paracrine effects on the heart. The chromaffin cells predominate in the sinus venosus and decrease in abundance from the atrium to the ventricle.

Elasmobranchs

The pericardium of elamobranchs tends to be thicker, more fibrous, and more rigid than that of teleosts (**see also Chondrichthyes:** Physiology of Sharks, Skates, and Rays). The pericardium communicates with the peritoneum via a narrow pericardio-peritoneal canal, which allows pericardial fluid to move between the pericardium and the peritoneum. Adjusting the volume of pericardial fluid within a rigid pericardial cavity can greatly alter the pressure exerted on the outside of the heart. This transmural pressure then influences the ease with which the heart is filled by venous blood pressure. The intra-pericardial pressure is normally subambient, in part, because of the relatively stiff nature of the pericardium, but becomes more negative if pericardial fluid moves out of the pericardium.

All elasmobranches possess a conus arteriosus within the pericardium (**see also Design and Physiology of the Heart:** The Outflow Tract from the Heart). Branchial arteries are formed immediately anterior to the pericardium without there being a ventral aorta prior to these branches, as is the case for most teleosts. The conus arteriosus is invested with circumferentially arranged cardiac muscle and is contractile. Longitudinally arranged cardiac fibers have been found in the conus arteriosus of large sharks. Superficial coronary vessels, clearly visible on the surface of the conus arteriosus, deliver blood from the gills to the cardiac muscle of the conus arteriosus and ventricle. The longitudinal coronary vessels supply blood to the heart and the lateral branches supply blood to the conus arteriosus (**see also Design and Physiology of the Heart:** The Coronary Circulation). The conus arteriosus has multiple tiers of valves, which vary in number from 2 to 6 among species (**see also Design and Physiology of the Heart:** The Outflow Tract from the Heart) and its own ECG, as noted above.

Coronary arterioles and capillaries supply the ventricular trabeculae as well as the compact myocardium of elasmobranchs. The trabecular coronary vessels have been seen to communicate with, and therefore likely drain to, the lumen of the heart. Sometimes, the atrial trabeculae have capillaries. This means that the oxygen supply of the spongy myocardium of the elasmobranch heart is not restricted to the venous blood, as in most teleosts (**see also Design and Physiology of the Heart:** The Coronary Circulation). This anatomical feature may increase the hypoxia tolerance of elasmobranch heart. In contrast, capillaries in the ventricular trabeculae have been reported only for the highly athletic swordfish and tuna.

Air-breathing fish

Some of the most diverse cardiac anatomy is seen in air-breathing fish, but this is detailed in (**Air-Breathing Fishes:** Respiratory Adaptations for Air-Breathing Fishes.

Glossary

A-band Dark region of the myofibril. It mainly consists of the protein myosin.

Acclimation Physiological and/or biochemistry adjustments made by an organism in response to a prolonged change in their environment, e.g., temperature.

Area composita Specialized very strong junction connecting adult mammalian cardiomyocytes. It consists of typical desmosomal and adherens junction components.

Cardiomyocyte Fundamental contractile cell of the working fish myocardium.

Caveolae Small (150 nm in diameter), flask-like invaginations of the cell (sarcolemmal) membrane which increases the cell's surface area-to-volume ratio and plays an important role in cell-signaling pathways.

Costamere Lateral attachment structure connecting the Z-bands of striated muscle cells to extracellular matrix material.

Cristae Invaginations of the inner membrane of a mitochondrion.

Desmosome A plaque-like structure on the surface of a cell that functions in adhesion with adjacent cells.

Ectotherm (adj. ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioral mechanisms to regulate body temperature.

Endotherm An animal that uses its own metabolism as the major source of heat to maintain its body temperature greater than that of the surrounding environment.

Fascia adheren junction Involved in cell-to-cell connections. It connects two membranes of adjacent cardiomyocytes and is usually attached to actin filaments of myofibrils.

Free sarcoplasmic reticulum Sarcoplasmic reticulum that is not closely associated with either the sarcolemmal membrane or the t-tubular network.

Gap junction A connection between two neurons that allows electrical signals to pass directly between them.

Hemoglobin An iron-containing oxygen-transport protein in the red blood cells of vertebrates and the tissues of some invertebrates.

Hyperplasia An increase in the number of cells of an organ or tissue. In this article, it refers to an increase in cardiomyocyte number.

Hypertrophy An increase in the cell size of an organ or tissue. In this article, it refers to an increase in cardiomyocyte size.

I-band Region of the myofibril that stains lightly. It mainly consists of the protein actin.

Invagination The folding of a cell membrane.

Junctional sarcoplasmic reticulum Sarcoplasmic reticulum that is closely associated with either the sarcolemmal membrane or the t-tubular network.

M-band Central region of the myofibril that forms a broad, dense band in the center of the A-band.

Mitochondrion A cellular organelle that acts as the 'powerhouse' of the cell and produces the chemical energy source adenosine triphosphate, using oxygen as the final electron acceptor.

Myofibrils Bundles of protein filaments that contain the contractile elements of the cardiomyocyte. They are the machinery, or motor, that drives contraction and relaxation.

Myoglobin An oxygen-binding protein in muscle that resembles hemoglobin in function, and enhances the rate of oxygen diffusion.

Organelle An intracellular component of a cell, for example, mitochondria, nucleus, and myofibril.

Ryanodine receptor It mediates the release of Ca^{2+} from the sarcoplasmic reticulum.

Sarcolemmal membrane The lipid bilayer that surrounds the cardiomyocyte, forming a barrier between the intra- and extracellular environments.

Sarcomere The functional contractile unit of the myofibril. The sarcomere is found between two Z-lines.

Sarcoplasmic reticulum A specialized form of endoplasmic reticulum that acts as a storage site for Ca^{2+}.

Sarcoplasmic reticulum Ca^{2+}-ATPase (SERCA) An energy-consuming Ca^{2+}-pump located on the sarcoplasmic reticulum membrane that concentrates Ca^{2+} inside the sarcoplasmic reticulum.

Thick filament Protein filament in the myofibril that is made up of myosin.

Thin filament Protein filament in the myofibril that is made up of actin.

T-tubular network Deep invaginations of the sarcolemmal membrane that bring the external environment in close contact with the center of the cell.

Working myocardium The regions of the heart that contract and propel the blood when excited via excitation-contraction coupling. These muscular regions are made up of the contractile myocytes of the atrium and ventricle.

Z-line Narrow dark bands in the myofibril that define the length of a sarcomere.

Introduction

Contraction and relaxation of the working fish myocardium is a result of the complex interaction of many individual cells connected together by specialized adhesion structures. It is these cells that allow the heart to beat and generate pressure to pump blood around the body. The fundamental contractile cell of the working fish myocardium is called a cardiomyocyte. As with other cells that constitute organs, the structure of a cardiomyocyte is specially adapted for its function. In the case of fish cardiomyocytes, they are adapted to function under highly variable conditions, including fluctuating temperatures, oxygen, and pH. In fact, the ultrastructure of the fish cardiomyocyte is malleable and can both adjust (acclimate) and be adapted to its environment, making it an excellent example of how cellular structure can fit perfectly to its function.

Fish Cardiomyocyte Ultrastructure

Cardiomyocyte Dimensions

The dimensions of vertebrate cardiomyocytes differ greatly between vertebrate species (endotherms or ectotherms), tissue type (atria or ventricle), cell type (muscle or pacemaker), and even between different regions of the same tissue (outer or inner layer of the ventricle). **Table 1** shows the dimensions of cardiomyocytes from a range of different fish species and, for comparison, from a mammalian ventricle. Typical images of a fish and mammalian ventricular cardiomyocyte (**Figure 1**) reveal the obvious dimensional differences. Fish cardiomyocytes appear long, thin, and spindle shaped (**Figure 1**(**a**)), while mammalian cardiomyocytes are rectangular (**Figure 1**(**b**)). The width and depth of the fish cardiomyocyte is much smaller, leading to a lower volume, and greater surface area-to-volume ratio (S/A ratio), while lengths may be comparable (**Table 1**). Fish atrial myocytes are similar in length to ventricular myocytes, but are slightly thinner, leading to a smaller cell volume and S/A ratio (**Table 1**). The large S/A ratio in fish has important implications for Ca^{2+} movement into the cardiomyocyte during excitation–contraction coupling (**see also Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux and Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element).

Cardiomyocyte dimensions among different fish species are quite similar, even though body size and heart mass vary enormously (**Table 1**). Remarkably, cardio myocytes of a 0.55 g zebrafish (*Danio rerio*, heart mass = 0.001 g) are only marginally smaller than a 1400 g bluefin tuna (*Thunnus orientalis*, heart mass = 52 g) (**Table 1**). Thus, the fish heart grows larger primarily by increasing the number of cardiomyocytes (hyperplasia) in the myocardium, rather than the cardiomyocyte size (hypertrophy).

Cardiomyocyte hypertrophy does occur as fish grow, but most notably when a fish enters cold water for long periods of time (termed 'cold acclimation'). Under this circumstance, cardiomyocyte size is enlarged, mainly as an adaptation to the cold. Similarly, under pathological

Table 1 Cardiomyocyte dimensions in fishes compared with mammals

Dimensions	*Rat V*	*Trout V*	*Trout A*	*Carp V*	*Tuna V*	*Mackerel V*	*Zebrafish V*
Length (μm)	141	180	197	110	186	167	100
Width (μm)	32	8	5	6	8	5	5
Volume (pL)	34	3	2	1	3	2	2
Surface area-to-volume ratio (pF/pL)	8	18	15	19	14	22	12

Cell length, width and volume was measured by analysis of confocal or light microscopy images of cardiac myocytes. Rat, *Rattus norvegicus*; trout, *Oncorhynchus mykiss*; carp, *Carassius carassius*; mackerel, *Scomber japonicus*; zebrafish, *Danio rerio*. V = Ventricular myocytes, A = artrial myocytes.

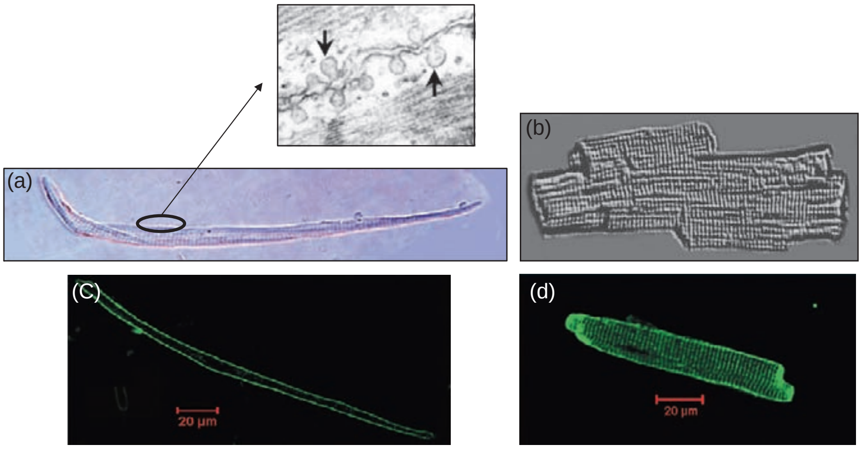

Figure 1 Morphology of live ventricular cardiomyocytes from adult Pacific bluefin tuna, *Thunnus orientalis* (a), adult rabbit, *Oryctolagus cuniculus* (b), trout, *Oncorhynchus mykiss* (c), and rat, *Rattus norvegicus* (d) Myocytes from (a) and (b) are not drawn to scale. The average dimensions of bluefin tuna, trout, and rat ventricular myocytes are given in **Table 1**. The average adult rabbit ventricular myocyte is approximately 100–150 µm in length and 20µ*m* in width. Light microscopy images are shown in (a) and (b). Inset of (a) = ultrastructure of the sarcolemmal membrane of a trout ventricular myocyte. Arrows point to flask-like structures, or invaginations of the membrane, known as caveolae. (c, d) Confocal microscopy images of ventricular myocytes labeled with di-8-ANEPPS (fluorescent dye). Images are from *x–y* planes taken near the center (*z–y*) of the myocyte. Notice the absence of T tubules in trout (c) and the presence in rat (d). Rat and trout images are adapted from Shiels HA and White E (2005) Temporal and spatial properties of cellular Ca^{2+} flux in trout ventricular myocytes. *American Journal of Physiology* 288: R1756–R1766, with permission from American Physiological Society. Rabbit images are taken from Xu L (1999) Ontogeny of Myocardial Excitation–Contraction Coupling. MSc. Thesis, Simon Fraser University. Bluefin tuna image is taken from Shiels HA, Blank JM, Farrell AP, and Block BA (2004) Electrophysiological properties of the L-type Ca^{2+} current in cardiomyocytes from bluefin tuna and Pacific mackerel. *American Journal of Physiology* 286: R659–R658, with permission from American Physiological Society. Caveolae image adapted from Vornanen M, Shiels HA, and Farrell AP (2002). Plasticity of excitation–contraction coupling in fish cardiomyocytes. *Comparative Biochemistry and Physiology* 132: 827–846, with permission from Elsevier.

situations, such as anaemia, the *D. rerio* ventricle undergoes myocyte hypertrophy to counteract the extra demand placed on the heart. This is an example of how the fish cardiomyocyte responds to its environment.

The Cardiomyocyte Membrane

The cardiomyocyte is enclosed by a lipid membrane, called the sarcolemmal membrane, which provides a barrier between the inside (intracellular) and outside (extracellular) spaces of the cell. Embedded in the membrane are numerous ion channels, pumps, and exchangers that allow the movement of ions (e.g., Ca^{2+}) into and out of the cardiomyocyte.

Figures 1(**c**) and **1**(**d**) show the sarcolemmal membrane of a trout (*Oncorhynchus mykiss*) and rat cardiomyocyte that has been stained with a fluorescent red dye and visualized using confocal microscopy. The sarcolemmal membrane of the rat cardiomyocyte has folds (invaginations) into the cell interior – the ‘t-tubular network’ (**Figure 1**(**d**)). T-tubules allow the extracellular space to be bought into close contact with more central regions of the cardiomyocyte. Fish lack a t-tubular network (**Figure 1**(**c**)), likely because their small width makes this membrane system unnecessary. Instead, smaller (150 nm in diameter), flask-like invaginations of the membrane (caveolae) are present, which increase the cell S/A ratio (**Figure 1**(**a**) inset). Caveolae are more abundant in atrial versus ventricular cardiomyocytes and are thought to be important in cell signaling.

Myofibrils

Myofibrils are bundles of protein filaments that contain the contractile elements of the cardiomyocyte, that is, the machinery or motor that drives contraction and relaxation. Myofibrils have a characteristic banding pattern, refereed to as striations, where repeating light and dark transverse bands can be observed under a light microscope (**Figure 2**, labeled MF and **Figure 3**). The myofibrils are located peripherally, forming a single cylindrical shaped layer directly below the sarcolemmal membrane (**Figure 3**, labeled MF), a location that contrasts with mammals, which have numerous layers of myofibrils arranged longitudinally throughout the cell.

The contractile functional unit of the myofibril is called the sarcomere, which is approximately 1.6–2.0 µm in length. The different regions of the sarcomere are classified according to their ability to polarize light. A cross section of the fish sarcomere is shown in **Figure 3**.

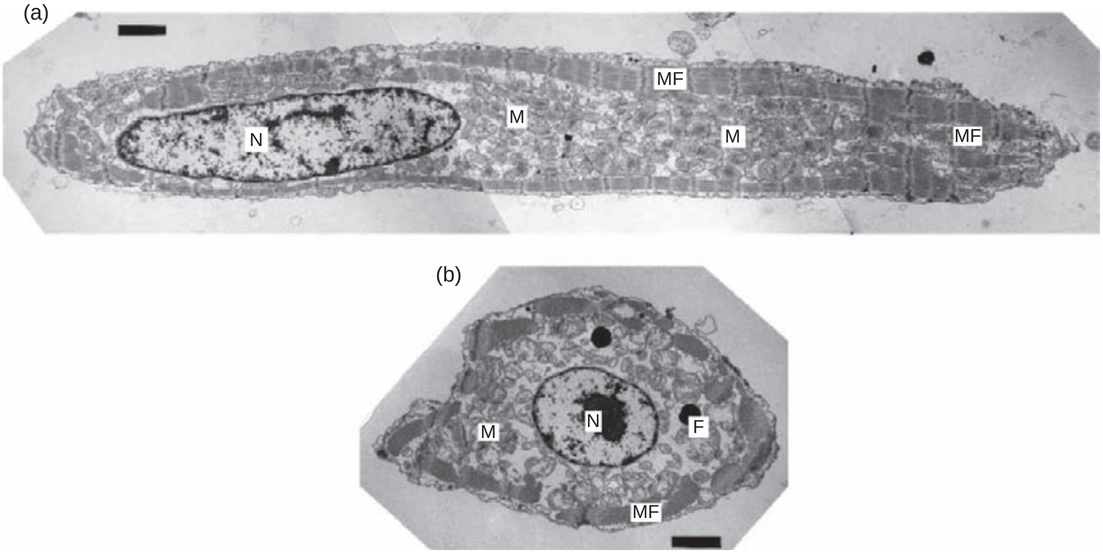

Figure 2 Electron micrographs of enzymatically isolated ventricular myocytes of rainbow trout (*Oncorhynchus mykiss*) heart. (a) A longitudinal section through a small part of a ventricular myocyte. (b) A cross section of a ventricular myocyte. M, mitochondria; MF, myofibrils; N, nucleus; F, fat. Scale bars, 2 μm. Reproduced from Vornanen M (1998) L-type Ca^{2+} current in fish cardiac myocytes: Effects of thermal acclimation and beta-adrenergic stimulation. *Journal of Experimental Biology* 201: 533–547, with permission from American Physiological Society.

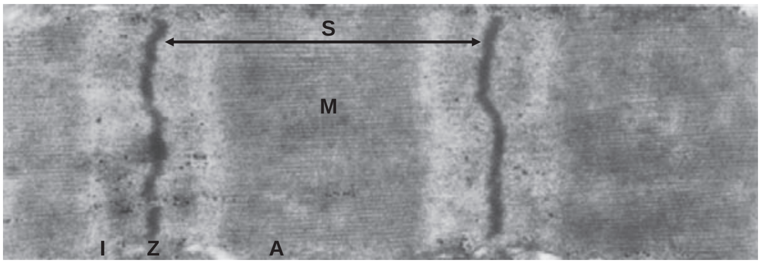

Figure 3 Longitudinal section of sturgeon atrium, showing the sarcomeric banding, Z-, I-, and A-band are clearly seen. The M-line (M) is more diffuse. Magnification = × 35 700. The sarcomere (S) is the distance between two Z-lines. Reproduced From Myklebust R and Kryvi H (1979) Ultrastructure of the heart of the sturgeon *Acipenser stellatus* (Chondrostei). *Cell Tissue and Research* 202: 431–438, with permission from Springer.

The more darkly staining bands are called A-bands (**Figure 3**, labeled A), while the lighter areas are called I-bands (**Figure 3**, labeled I). Each I-band is bisected by a narrow dark band, named the Z-line (**Figure 3**, labeled Z) and a broader dense M-band (**Figure 3**, labeled M) is found in the center of the A-band. The distance between two Z-lines is designated as one sarcomere.

A schematic diagram of a single sarcomere shows a relaxed state (**Figure 4**(**a**)) and a contracted state (**Figure 4**(**b**)), as well as the two types of filaments in sarcomeres, a thin filament (made of the protein actin) and a thick filament (made up of the protein myosin). During myocyte contraction, the thick and thin filaments slide across each other to form cross-bridges between the actin and myosin heads (**Figure 4**(**b**)).

The percentage of cell volume that myofibrils occupy in cardiomyocytes is rather uniform in most fish species, being approximately 40%. However, there are important

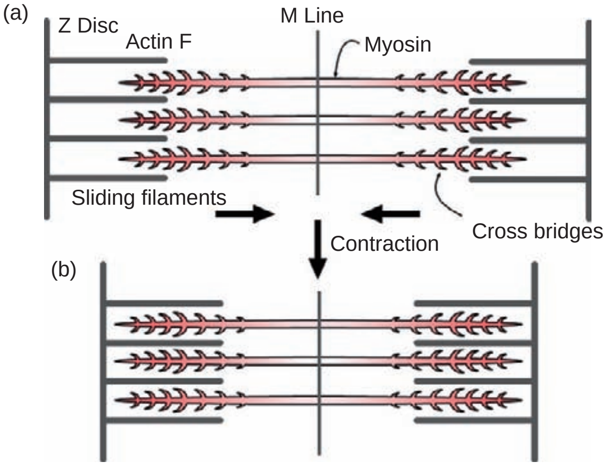

Figure 4 A schematic diagram of a single sarcomere during relaxation (a) and contraction (b). The illustration shows a shift in the amount of cross-bridges formed by actin and myosin during contraction. Illustration drawn by Gina Galli and Jake Rigby.

exceptions to this rule. The burbot (*Lota lota*), which usually inhabits very cold environments during the winter (1–4 °C), has an exceptionally high myofibrilar density (65%), and possesses very long sarcomeres (2.6 μm). These myofibrillar adaptations are characteristic of a slow contraction rate and large force production. The adaptation likely relates to the cold-dependent increase in blood viscosity and decrease in cardiac contractility.

At the other end of the spectrum, certain species of icefish have very low volumes of myofibrils (29%). Although this may seem disadvantageous for the icefish (which also has to tolerate exceptionally cold temperatures), as we shall see in later sections, the icefish sacrifices myofibrillar volume to increase the density of another important cellular constituent, the mitochondria, and correspondingly has a very low cardiac power output.

The Mitochondria

Mitochondria are centrally located just under the myofibrils (**Figure 2**, labeled M), which differs from the uniform distribution throughout the cell between the myofibrils in mammals. As with other cell types, the cardiomyocyte mitochondrion contains an outer and inner membrane (**Figure 5**(**a**)), with invaginations (cristae) that greatly increase the surface area of the inner membrane. The inside of the mitochondria, or matrix, contains all of the enzymes and proteins necessary for cellular respiration (**see also Temperature:** Mitochondria and Temperature).

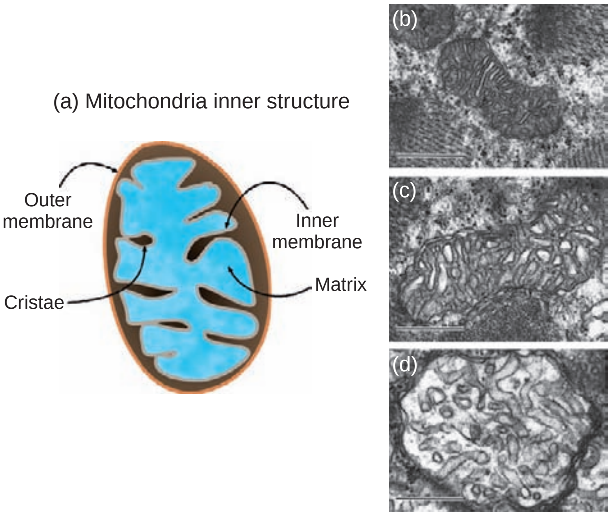

Figure 5 (a) Schematic diagram of the inner structure of mitochondria. (b–d) Electron micrographs of mitochondria from cardiac muscle of three species of Antarctic fishes. Mitochondria differ in both the density of the inner mitochondrial membrane and the surface-to-volume ratio according to the expression of oxygen-binding proteins, myoglobin, and hemoglobin. (b) *Gobionotothen gibberifrons* (has both myoglobin and hemoglobin); (c) *Chionodraco rastrospinosus* (has just myoglobin); (d) *Chaenocephalus aceratus* (neither myoglobin nor hemoglobin). Scale bar = 0.5 μm. Schematic illustration drawn by Gina Galli and Jake Rigby. (b–d) Reproduced from O′Brien KM and Sidell BD (2000) The interplay among cardiac ultrastructure, metabolism and the expression of oxygen-binding proteins in Antarctic fishes. *Journal of Experimental Biology* 203: 1287–1297, with permission from Company of Biologists.

Mitochondrial volume (compared to total cardiomyocyte volume) ranges between 15% and 45% in fish. The enormous variation between species is a good example of how the cell is modified to fit its need. In general, active species that generate high heart rates and blood pressures tend to contain more mitochondria to support a higher rate of energy utilisation. For example, the *T. orientalis* contains 10–15% more mitochondria than a more sedentary fish species, such as the cichlid, and generates heart rates and blood pressures that greatly exceed those in most teleosts. An important exception to this rule is the Antarctic icefish. Mitochondrial volume can be exceptionally high (41%) in some icefish species, or exceptionally low (15%) in others, with this variability apparently directly proportional to the expression of oxygen binding proteins. Mitochondrial volume is higher in species that lack hemoglobin or myoglobin (**Figures 5**(**b**)–**5**(**d**)). Interestingly, the high mitochondrial density is not related to cellular aerobic capacity, but may reduce the diffusion distance for oxygen to reach mitochondria, thereby compensating for the lack of intracellular oxygen-binding proteins.

Mitochondrial volume is altered by the environment. Cold acclimation causes similar increases in both mitochondrial volume and myofibril density in the stripped bass as well as a hypertrophy of the cardiomyocyte. These changes are thought to compensate for the kinetic constraint of cold temperature.

The Nucleus

The nucleus of the fish cardiomyocyte (**Figure 2**, labeled N) is also centrally located near the mitochondria, taking up approximately 25% of cell volume in the trout ventricular myocyte. Most fish (90%) possess only one nucleus, but on rare occasions fish cardiomyocytes with two nuclei have been observed. As with other cells, the nucleus contains most of the cells genetic material, organized as DNA to form chromosomes. Triploid fish are genetically engineered to have an additional copy of their DNA (3N) and the nucleus is correspondingly one-third large, but the cell size is not.

Fat and Glycogen Deposits

Glycogen clusters, in the form of β-particles, and fat droplets are found in the spaces between the myofibrils and mitochondria. They vary in density between species, according to feeding status, energy stores, and season. For example, *O. mykiss* have sparse glycogen reserves but large fat droplets, while crucian carp (*Carassius carassius*) and *T. orientalis* contain huge glycogen clusters, but no fat droplets.

The Sarcoplasmic Reticulum

The sarcoplasmic reticulum (SR) is a specialized form of endoplasmic reticulum (ER) found in most cells, which forms a system of intracellular membranes. The SR is separate from the sarcolemma and T-tubules. Unlike the ER, which is primarily involved in protein synthesis, the SR lacks ribosomes (the machinery required to make proteins) and is primarily involved in controlling Ca^{2+} concentrations inside the cardiomyocyte. There are two proteins embedded in the SR membrane that permit this function – a Ca^{2+} pump (termed the SR Ca^{2+} ATPase, or SERCA) and a Ca^{2+}-release channels (termed ryanodine receptors, or RyRs). Ca^{2+} is stored in the SR, moving into the cytoplasm via the RyR and being removed from the cytoplasm by SERCA. Therefore, Ca^{2+} is moved back and forth from the inside of the cell to the SR as part of E–C coupling.

There are two types of SR in fish cardiomyocytes: junctional SR (jSR) and free SR (fSR) (see **Figure 6**). jSR forms peripheral couplings with either the sarcolemmal or t-tubular network (**Figure 6**(**a**), double arrows). In these peripheral couplings where the jSR profile aligns with the sarcolemma or t-tubule, rows of proteins known as 'feet' are visible between the two membranes (**Figure 6**(**b**), inset). These proteins are the Ca^{2+}-release ryanodine receptor channels. fSR is not closely associated with any other membrane system, and can be found throughout the cardiomyocyte (**Figure 6**(**a**), arrows).

Quantitative measurements of SR volume (relative to total volume) have only been made for two fish species: the perch (*Perca fluviatilis*; 4.5–6.5%) and the *T. orientalis* (2–3%). In mammals, SR density is on average much greater, but ranges between 1% and 12%. The highly active *T. orientalis* possesses both fSR and jSR that contribute significantly to overall Ca^{2+} regulation. In this species, atrial cardiomyocytes have a greater proportion of SR (3.2%) in comparision to ventricular cardiomyocytes (2.2%). Lastly, fish species that inhabit cold environments and those that acclimate to the cold seasonally enhance SR density. The warm-acclimated *P. fluviatilis*, for example, increase SR density from 4.5% to 6.5% when acclimated to the cold. Presumably, this adaptation allows Ca^{2+} levels within the cell to remain normal in the cold, which would usually slow down the rates of protein and ion channel activities.

Balancing the Volumes of Cellular Constituents

One may ask, if increasing mitochondrial or myofibrillar volume has the potential to dramatically increase energy and force production, respectively, in a fish cardiomyocyte, then why don't they all do it? The fact is that an alteration in the volume of one cardiomyocyte constituent or organelle must come at a cost to another. For example, if cardiomyocyte volume remains constant, then an increase in mitochondrial density will require a decrease in some other component of the cell. In most cases, myofibril density will suffer. This is shown in **Table 2**, where the volume of various fish cardiomyocytes that is occupied by mitochondria is generally inversely related to myofibrillar volume. Thus, although aerobic capacity may increase with a higher mitochondrial density, contractile force may suffer, or vice versa. This trade-off is delicately

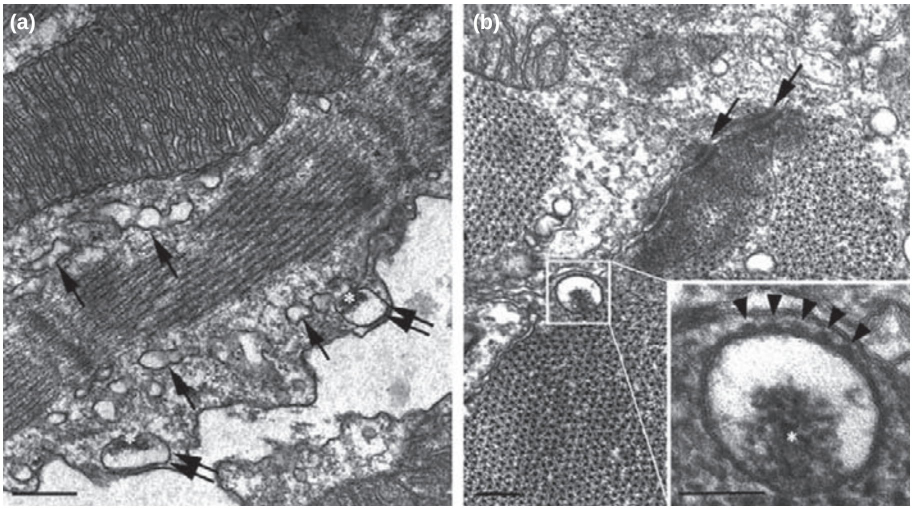

Figure 6 Distribution of the junctional SR (jSR) in peripheral couplings in the ventricle of the Pacific bluefin tuna (*Thunnus orientalis*). (a) Longitudinal thin section. The jSR appears as wide cisternae containing calsequestrin (white asterisk) and is located only at the periphery of the cells (double arrows). The extensive internal fSR network (arrows) is also visible throughout the cytoplasm. (b) Transverse section. The form and shape of the jSR do not change. Note that in peripheral couplings ((b), inset) formed by the apposition of the jSR profile with the plasmalemma, rows of feet (ryanodine receptors, RyRs) are visible between the two membranes ((b), arrowheads). Bars = 0.3 μm (a), 0.2 μm (b), 0.1 μm (inset). Table 2 Percentage of cell volume that mitochondria and myofibrils occupy in ventricular muscle from various fish species

Volume	*Trout*	*Carp*	*Icefish (CA)*	*Icefish (NN)*	*Icefish (GG)*	*Burbot*
Mitochondrial (%)	45	22	41	25	15	27
Myofibrils (%)	40	40	29	47	40	65

Percentage of volume (compared to total cell volume) that the mitochondria and myofibrils occupy in ventricular muscle from various fish species. Three species of Antarctic icefish are given; CA = *Chaenocephalus aceratus*, NN = *Neglecta nototheria*, GG = *Globionotothen gibbenifons*. Trout, *Oncorhynchus mykiss*; carp, *Carassius carassius*; burbot, *Lota lota*.

balanced in many fish species according to their environment, highlighting another example of the cardiomyocyte structure–function relationship.

Cell–Cell Connections

Cardiomyocytes are connected to each other by three main structures found at the sarcolemma: (1) fascia adherens, (2) desmosomes, and (3) gap junctions. These specialized structures provide strong mechanical linkages between cardiomyocytes as well as a low electrical resistance pathway that facilitates conduction of the cardiac impulse and electrophysiological coupling.

Fascia adherens and desmosomes are composed of the two sarcolemmal membranes of adjacent cardiomyocytes. The thin actin filaments and intermediate filaments of the myofibrils protrude to the sarcolemmal membrane and bind tightly to either side of the fascia adherens and desmosomes, respectively. In contrast to adherens and desmosomes, gap junctions do not seal membranes together, but actually link the interior of cardiomyocytes, allowing the movement of ions between them and provide a low resistance electrical connection. Proteins called connexins form the gaps between two neighboring sarcolemmal membranes, and can be in an open or closed state, thereby coupling or uncoupling adjacent cardiomyocytes. This property allows cardiomyocytes to be in electrical contact, thereby propagating the cardiac signal and making sure cardiomyocytes contract and relax in synchrony.

In fish, all three junction types are known to be distributed all around and at the polar tips of the spindle-shaped cardiomyocytes (**Figure 7**(**a**)). The actin-binding

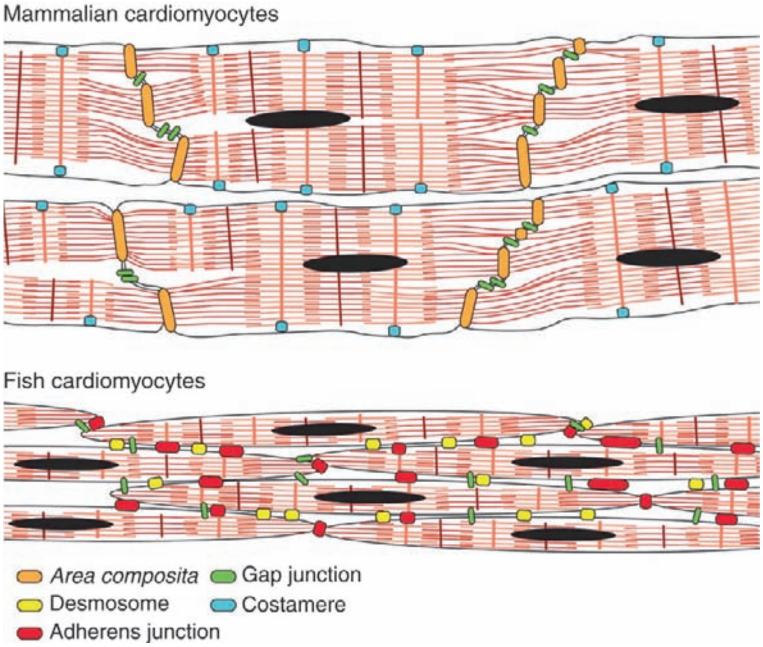

Figure 7 Schematic representation indicating adhering junction localizations and cardiomyocyte arrangements in the mammalian and fish ventricle. Note that mammalian cardiomyocytes are more rectangular shaped and often connected at the two poles by specialized adhering junctions (area composita; plural areae compositae). The Z-bands are attached to the lateral costameres. By contrast, fish cardiomyocytes are elongated and spindle shaped and, for the most part, laterally connected by desmosomes and adherens junctions. The Z-bands of two neighboring cardiomyocytes are often directly connected by adherens junctions. Illustration drawn by Sebastian Piepenhoff.

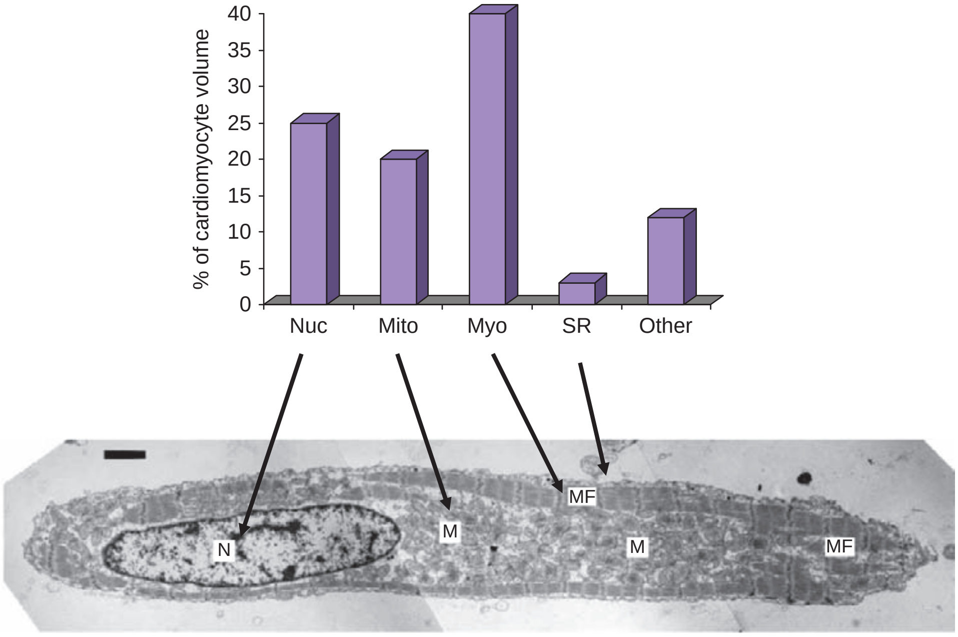

Figure 8 Percentage volume that each cardiomyocyte component occupies compared with total cell volume. Nuc = nucleus, Mito, mitochondria; Myo, myofibrils; SR, sarcoplasmic reticulum. Reproduced from Vornanen M (1998) L-type Ca^{2+} current in fish cardiac myocytes: Effects of thermal acclimation and beta-adrenergic stimulation. *Journal of Experimental Biology* 201: 533–547, with permission from Company of Biologists.

adherens junction can often be found at the lateral sides, directly attached to the Z-band material. By contrast, adult mammalian cardiomyocytes are usually connected at two poles via structures called intercalated disks (**Figure 7**(**b**)). The majority of the junctional area (≥90%) between mammalian cardiomyocytes is occupied by structures called area composita located together with gap junctions within the intercalated disks. Area composita structures represent mammalian-specific mixed-type adhering junctions. These junctions consist of typical desmosomal and adherens junctional components. The Z-bands are for the most part connected laterally at structures called costameres.

Summary

We can now piece together the entire fish cardiomyocyte and the percentage volume (on average) that each component occupies (**Figure 8**). Fish cardiomyocytes are long, thin, and spindle shaped, with a large S/A ratio and no t-tubular system. The external and internal environments of the cardiomyocyte are separated by the sarcolemmal membrane. The nucleus (or nuclei) has a central location, occupying approximately 25% of total cell volume. The myofibrils lie directly under the sarcolemmal membrane and occupy between 30% and 65% of cardiomyocyte volume. The percentage of space that mitochondria take up is generally inversely related to myofibrillar volume, being approximately 15–45%. The mitochondria are found centrally within the cell, with a variable amount of glycogen and fat droplets surrounding it. The SR is located at the periphery of the cell, either in close association with (jSR) or free from (fSR) the sarcolemmal membrane. SR volume is 2–6% of total cardiomyocyte volume. We must remember, however, that fish cardiomyocyte ultrastructure is neither uniform nor permanent; it is malleable and several factors (including species, activity level, and temperature) can impact the percentage volume occupied by each component within the cardiomyocyte. Thus, the fish cardiomyocyte is an excellent example of how cellular structure can fit perfectly to its function.

Glossary

Bulbus arteriosus The term given to the outflow tract found in most teleost fishes.

Collagen An extracellular protein, typically found in large blood vessels, that has less elastic properties than elastin.

Conus arteriosus The term given to the outflow tract found in all elasmobranch fishes and some other primitive fishes.

Elastin An extracellular protein, typically found in large blood vessels that is characterized by its elastic properties.

Glycosaminoglycans Long unbranched sugar molecules surrounding a protein core which are an important component of connective tissues due to their effectiveness in resisting pressure changes.

Truncus arteriosius The term given to the section of vessel invested with cardiac epithelium but devoid of cardiac muscle that follows the conus in the outflow tract of lungfishes and coelacanths.

Introduction

The outflow tract of the heart is the name given to that part of the vasculature, within the pericardium, which connects the ventricle to the ventral aorta in most fishes (**Figures 1** and **2**; **see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes). This terminology is factual and implies no homology except that the tract is derived from the subintestinal blood vessel in embryological development. The actual junction between the connecting vessel and the ventral aorta defines the arterial pole of the heart, implying that all structures behind the arterial pole are derived from cardiac mesoderm although this has been the subject of considerable debate over the last century – a debate that continues today.

Terminology, Phylogeny, and Development

All jawed fishes (Gnathostomes) have an outflow tract (**Figure 1**). In sharks and rays (elasmobranchs), the predominant connecting vessel (*conus arteriosus*) is tubular and largely composed of cardiac muscle, whereas in bony fishes (teleosts), the outflow tract (bulbus arteriosus) resembles a greatly swollen blood vessel and is largely made up of elastin, collagen, and smooth muscle (**Figures 1** and **2**). The conus is also well developed in the more phylogenetically ancient teleosts and is often regarded as the ancestral condition, whereas the bulbus represents the apogee of teleost evolution. Developmental and histochemical studies suggest that all structures within the pericardium are of cardiac origin and should be recognized as such in the nomenclature of the regions of the wall. Nevertheless, in the present discussion, generic nomenclature for bulbus and conus will be used: middle, inner (facing the blood vessel lumen), and outer (facing the pericardium).

The predominant view for a century and a half has been that, during the evolution of fishes, the conus was replaced by the ventral aorta growing backward into the pericardium. Perhaps due to stresses imposed by the ejection of blood from the ventricle, this region of the ventral aorta was then remodeled to form a distinct bulbus (**Figure 3**). Recently, however, this view has been challenged as a bulbar vessel has been identified between the conus and the ventral aorta in sharks (**Figure 4**) and a conal remnant has been identified at the junction between the ventricle and bulbus in numerous species of advanced teleosts (**Figure 5**).

The jawless fishes (Agnathans), as a potential stem group for the craniates, could provide answers regarding the ancestral circulatory design. However, the strangeness

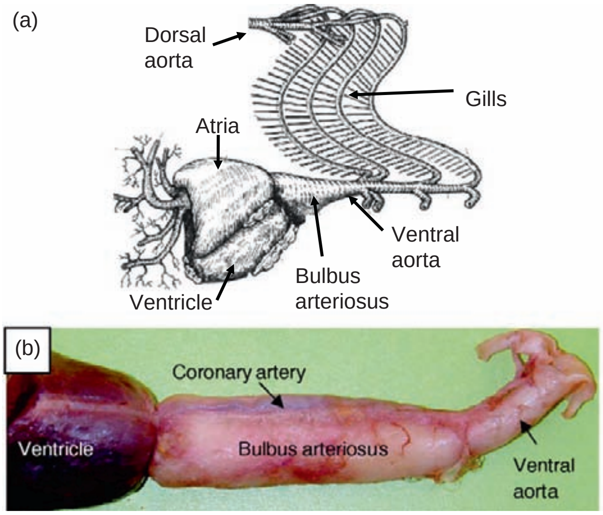

Figure 2 The cardiac outflow tract separates the ventricle from the ventral aorta. (a) An illustration of an adult zebrafish heart and the major vasculature in the cardiac region. The heart pumps the blood from the atrium and ventricle into the bulbus arteriosus before entering the ventral aorta. (b) The ventricle, bulbus arteriosus and ventral aorta of a blue marlin. Scale = 10 cm. (a) Modified from Hu N, Yost HJ, and Clark EB (2001) Cardiac morphology and blood pressure in adult zebrafish. *Anatomical Record* 264: 1–12. (b) From Braun MH, Brill RW, Gosline JM, and Jones DR (2003) Form and function of the bulbus arteriosus in yellowfin tuna (*Thunnus albacores*), bigeye tuna (*Thunnus obesus*) and blue marlin (*Makaira nigricans*): Static properties. *Journal of Experimental Biology* 206: 3311–3326.

and variety of their circulatory systems preclude them from contributing much to this debate. As opposed to higher vertebrates, Agnathans have a partially open circulation lacking capillary beds. Hagfishes have large sinuses on the venous side and up to five accessory pumps to assist the heart in boosting the low-pressure circulation. Centrally, they lack an intrapericardial outflow tract as the ventral aorta, lying outside the pericardium, connects directly to the ventricle (**see also Hagfishes and Lamprey:** Hagfishes and **Design and Physiology of the Heart**: Cardiac Anatomy in Fishes). However, although there is no evidence of a bulbus or conus within the pericardium, a slight thickening of the ventral aorta outside the pericardium has been referred to as a bulbus. On the other hand, lampreys, which are better candidates for the stem group of the fishes and have a more robust circulatory system, do have a bulbus downstream of the ventricle that bears resemblances to the teleost bulbus in structure but lacks elastin. However, the lamprey bulbus may be a necessary rather than ancestral condition as blood is incompressible and the heart output has to be accommodated somewhere.

The situations in lungfishes and lobed-fin fishes are also unique. In coelacanths (*Latimeria chalumnae*, the surviving member of the lobe-finned fishes), a conus, containing cardiac muscle, is followed by a section of vessel invested with cardiac epithelium but devoid of cardiac muscle, which is called the truncus arteriosus (**Figure 6**). It is surprising that the recently described

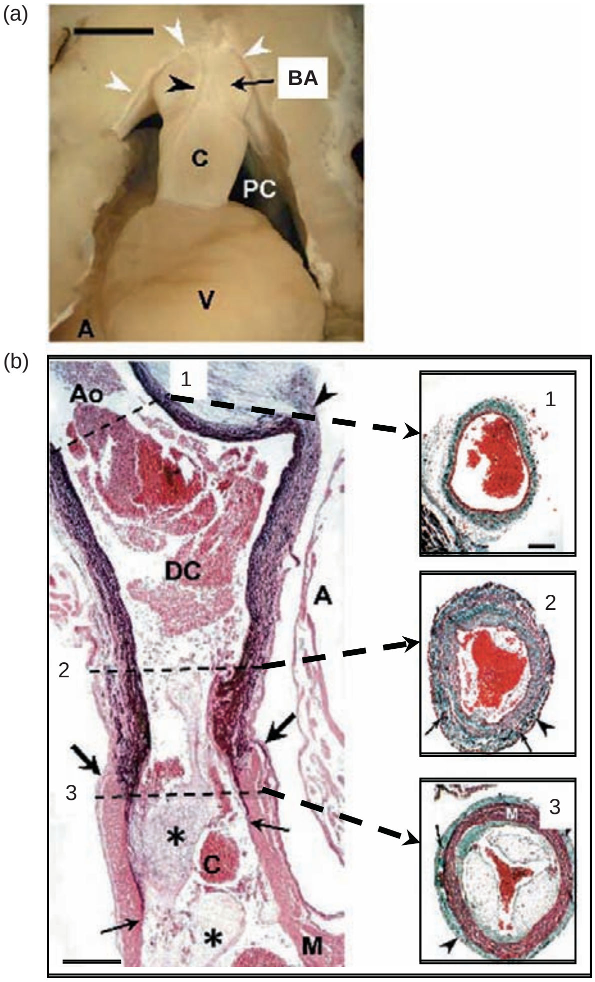

Figure 4 Bulbus arteriosus in an elasmobranch. (a) Ventral view of the heart of an adult *Galeus atlanticus* (catshark). A, atrium; C, conus arteriosus; BA, bulbus arteriosus. The white arrowheads point to the pericardium, black arrowhead indicates a coronary artery. Scale = 0.2 cm. (b) Sagittal section of the ventral aorta (VAo) and cardiac outflow tract of an adult catshark. The separation between the two sections of the cardiac outflow tract (conus arteriosus (C)) and bulbus arterious (BA)) is marked with large arrows. The conus contains myocardium (M) in its walls and has two rows of valves (asterisks). The bulbus has no myocardium and is rich in elastin (purple staining). Small arrows indicate the beginning of elastin staining. Arrowhead = distal boundary of pericardial cavity. Scale = 500 μm. Sections 1–3. Transverse sections of the (1) ventral aorta, (2) bulbus arteriosus, and (3) conus arteriosus. At sections 2 and 3, the outflow tract is lined with epicardium (arrows) and crossed by coronary arteries (arrowheads). Scale = 300 μm. Modified from Duran AC, Fernandez B, Grimes AC, *et al.* (2008) Condrichthyans have a bulbus arteriosus at the arterial pole of the heart: Morphological and evolutionary implications. *Journal of Anatomy* 21: 597–606.

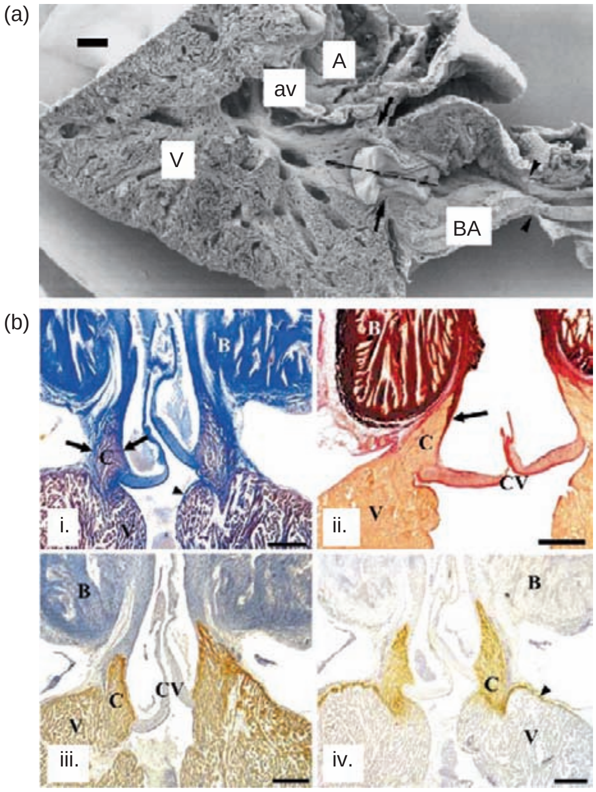

Figure 5 Conus arteriosus in a teleost (a) Mid-sagittal section of the left side of an adult gilthead seabream heart. V, ventricle; A, atrium; av, atrioventricular valve; BA, bulbus arteriosus. Arrows indicate the conus region and the left conus valve. Arrowheads mark the bulbus–ventral aorta junction and the insertion of the pericardium. Scale = 50 μm. The broken line through the conus valve indicates the approximate planes of section in (b) Longitudinal sections of the heart through the ventricle–bulbus junction. A ring of compact myocardium is interposed between the ventricle and the bulbus arteriosus. This myocardial segment has a conus shape which tapers at its distal end. Its base blends with the ventricular myocardium. (i) Mallory's trichrome stain for fibrous connective tissue. The conus myocardium is surrounded on its inner and outer sides by collagenous fibrous layers (arrows) which merge at the tapered end. The outer fibrous layer separates the conus from the bulbus distally. The inner fibrous layer continues proximally with the ventricular subendocardium (arrowhead). (ii) Weigert–van Gieson stain. Muscle = yellow, Collagen and elastin = pink and red. The inner fibrous layer (arrow) is very rich in elastin. Note the differences in staining with the outer fibrous layer. The bulbus also stains intensely. (iii) MF20 immunostaining for myosin heavy chains (muscle). Both the conus and the ventricular myocardium stains intensely. (iv) L9393 immunostaining for laminin. Intense staining for laminin is specific to the conus. Laminin is barely detectable in the ventricular myocardium, except at the outer ventricular surface (arrowhead). Scale = i–iii, 250 μm; iv, 200 μm. Modified from Schib JL, Icardo JM, Duran AC, *et al.* (2002) The conus arteriosus of the adult gilthead seabream (*Sparus auratus*). *Journal of Anatomy* 201: 395–404.

bulbus at the termination of the outflow tract in elasmobranches was not referred to as a truncus. In lungfishes, there is a complex spiral valve within the conus (**Figure 7**) and a somewhat simpler division within the truncus, strongly suggesting that a premium is placed on separation of the oxygenated and deoxygenated blood as it flows from the ventricle where the two streams are effectively divided during ventricular contraction.

Form and Function of the Bulbus Arteriosus

Form

The bulbus arteriosus comes in a myriad of shapes, from bulbous to tubular (**Figure 8**). However, the functional significance of these shapes is unknown. In the bulbous types, the major swelling is proximal and the bulbus tapers distally to meet the ventral aorta. There are no valves within or at either end of the bulbus in the vast majority of fishes and the few contrary reports may be erroneous. When the bulbus is collapsed, the volume of the chamber is reduced by ridges or even discrete longitudinal and radial elements in less phylogenetically advanced teleosts such as rainbow trout, tuna, and marlin (**Figure 9**). The ridges and elements, with very little mechanical strength, do not make any contribution to the structure of the wall. Another interesting modification in deep-sea fishes (**see also Deep-Sea Fishes**) is an inner tube that extends from the ventricle for about one-third of the bulb. The inner tube is made up of gelatinous and collagenous tissue.

The middle layer makes up the majority of the wall and smooth muscle is the predominant cell type, often being arranged helically or circumferentially along the length of the bulbus (**Figure 10**). The smooth muscle of the middle layer is embedded in an extracellular filamentous matrix of thin and thick filaments. The thick filaments are microfibrillar elastin, which also occurs in the external and internal layers of the bulbus. Microfibrillar elastin is much more compliant than the amorphous type of elastin found in many fish blood vessels. Support for the histology has come from an examination of the zebrafish (*Danio rerio*) genome, which has revealed the existence of two elastin genes, presumably one for the fibrillar and one for the amorphous type. The two structural proteins, collagen (stiff) and elastin (compliant), as well as polysaccharide chains and glycoproteins, make up the extracellular matrix and are secreted by smooth muscle cells. These muscle cells undergo a process of maturation from a secretory to a muscle phenotype as they migrate from the inner toward the middle layer. Collagen occurs throughout the layers of the bulbus, although it is more compact and ordered in the outer layer.

Blood vessels, derived from the coronary circulation (**see also Design and Physiology of the Heart:** The Coronary Circulation) which runs along the bulbus (**Figures 1** and **2**),

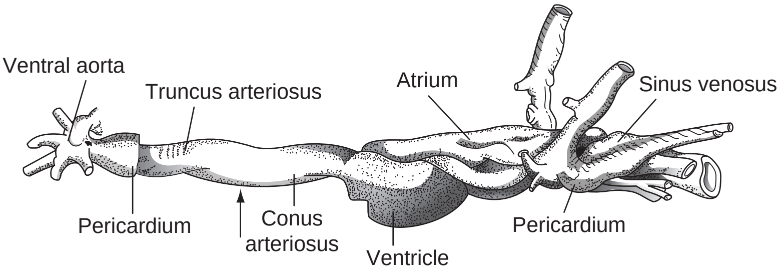

Figure 6 Sketch of the excised heart from *Latimeria chalunnae* (Coelocanth). Lateral view, dorsal to the top, cranial to the left. The black arrow marks the junction of the truncus arteriosus with the conus arteriosus. Modified from Grimes AC and Kirby ML (2009) The outflow tract of the heart of fishes: Anatomy, genes and evolution. *Journal of Fish Biology* 74: 983–1036.

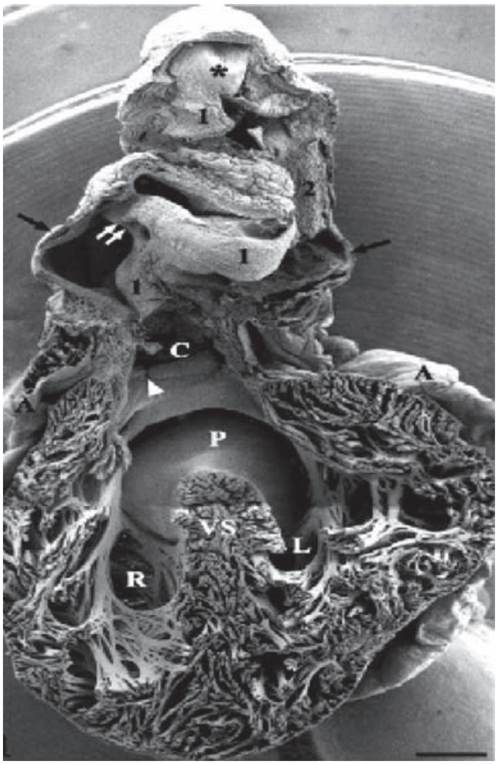

Figure 7 *Protopterus dolloi* (African lungfish). (a) Panoramic view of the heart. The heart has been sectioned frontally (dorsal segment, anterior view). The outflow tract has been dissected further to show the location of the intraluminal folds (1 (spiral) and 2 (bulbar) folds). The ventricle and the ventricular septum (VS) (L, R, left and right ventricle, respectively). The atrioventricular plug (P) sits on top of the ventricular septum, nearly occluding the atrioventricular communication. The outflow tract arises from above the ventricular septum. It contains three portions separated by proximal and distal flexures (large arrows). The proximal portion, the conus arteriosus (C), is almost vertical and contains the outflow valves (arrowheads indicate vertical indentation). The spiral fold (1) follows a spiraling course and runs the entire length of the outflow tract. This fold is connected to an additional mass of mesenchymal tissue (double arrow) located near the proximal flexure. Note the presence of a hole in the connecting area. The bulbar fold (2) occupies the middle and distal outflow tract, upward from the distal flexure. The two folds fuse at the distal outflow tract (asterisk). A, atrium. Scale = 500 μm. Modified from Icardo JM, Brunelli E, Perrotta I, *et al*. (2005) Ventricle and outflow tract of the African lungfish *Protopterus dolloi*. *Journal of Morphology* 265: 43–51.

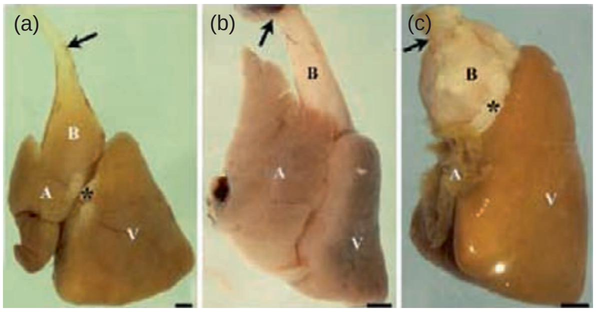

Figure 8 Examples of the variety of bulbus shapes.
(a) *Trachurus trachurus* (Atlantic horse mackerel): Pear-shaped
(b) *Trigla lucerna* (tub gurnard): Cylindrical and elongated.
(C.) *Sparus pagrus* (Seabream): short and thick. V = ventricle, A= atrium, B = bulbus arteriosus. The arrows mark the upper insertion of the pericardium and the boundary between the bulbus and the ventral aorta. Fat tissue (asterisks in a and c) accumulates in the subepicardium. Scale = 0.1 cm. Modified from Icardo JM (2006) Conus arteriosus of the teleost heart: Dismissed, but not missed. *Anatomical Record Part A* 288A: 900–908.

are usually accompanied by autonomic nerve fibers (lacking a myelin sheath). Both blood vessels and nerves are restricted to the outer layer of the bulbus and, as a result, these nerves innervate smooth muscle fibers at their ends, not along their length. However, as blood vessel penetration was long thought to be essential for nerve growth, fishes lacking a well-developed coronary circulation have little or no direct nerve connections with smooth muscle. Regardless, these nerves can release transmitters that diffuse through the wall to cause smooth muscle contraction or relaxation. A coordinated contraction can be developed between smooth muscle cells if both chemical and electrical connectivity can be established between them. This may be ensured by specialized regions of their walls that are very closely apposed (**Figure 10**(**c**)), but such regions have not been confirmed in many species. Of note is the fact that the bulbi of most Antarctic teleosts, despite lacking blood vessels, are innervated, implying that blood vessels are not necessary for innervation.

The internal epithelium of endocardial cells, thought to align with the direction of blood flow, contains large

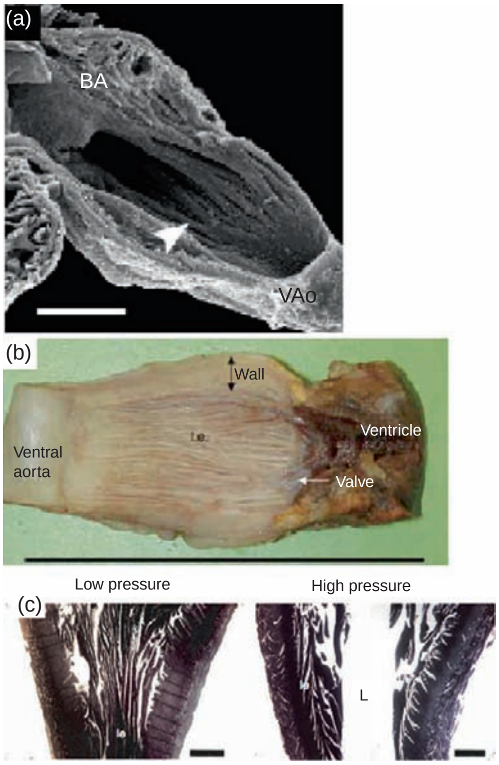

Figure 9 Internal elements of the bulbus arteriosus. (a) Scanning electron microscopy of the sagittal section of the bulbus arteriosus of a 3 months postfertilization zebrafish heart. BA, bulbus arteriosus; VAo, ventral aorta. The asterisk indicates the bulboventricular valve. The arrowhead identifies one of the elevated ridges along the inner surface of the bulbar wall. Scale = 100 μm. (b) The bulbus of a blue marlin dissected open to reveal the internal longitudinal elements (l.e.). Scale = 10 cm. (c) Longitudinal sections through a yellowfin tuna bulbus demonstrating what occurs with the longitudinal and radial elements at low and high pressures. Scale = 1 mm. Figure 10 Transmission electron micrographs demonstrating the structure of the layers of the bulbus. From yellowfin tuna. All sections are transverse. (a) The collagenous outer layer. The collagen fibers are not arranged in a single direction. The majority of the fibers is arranged longitudinally (lf) but there are also bundles of circumferential fibers (cf). Scale = 300·nm. (b) The middle layer. The long axes of the elastin fibrils are aligned with the long axes of the smooth muscle cells, indicating a circumferential arrangement. The smooth muscle cells possess a number of plasmalemmal vesicles along the edge of the membrane (arrow). Scale = 1.45 μm. (c) Smooth muscle within the middle layer of the bulbus. This section reveals that smooth muscle cells are not always sparsely distributed within the elastin and can occur in close proximity. The smooth muscle cells have plasmalemmal vesicles under the edge of the membrane (arrows). Scale = 1.55 = μm. (d) Electron micrograph of a longitudinal element (le). The endothelial cells contain plasmalemmal vesicles underneath the membrane (arrow) as well as larger, electron-dense vesicles scattered throughout the cell (arrowheads). Scale = 1.55 μm. Stained with uranyl acetate and lead. From Braun MH, Brill RW, Gosline JM, and Jones DR (2003) Form and function of the bulbus arteriosus in yellowfin tuna (*Thunnus albacores)*, bigeye tuna (*Thunnus obesus*) and blue marlin (*Makaira nigricans*): Static properties. *Journal of Experimental Biology* 206: 3311–3326.

numbers of moderately dense bodies (MDBs; **Figures 10(d)** and **11**) that are released from the inner layer into the blood stream. In various species, MDBs have been suggested as storage sites for catecholamines, histamines, and mucopolysaccharides (long sugar chains), but it may be that both the population of cells containing the MDB and the MDB themselves are not uniform and contain a variety of substances, each with different functions. Endocardial cells invest the ridges as well as the free cord-like structures that lie along the inner bulbus wall. The outer, pericardial, epithelium is formed by flattened cells which are tightly linked to each other and contain large number of vesicles, which suggests exchange of materials with the pericardial cavity. There can be no doubt that one of the major roles of the bulbus is secretory, affecting both proximal and distal targets.

The Antarctic ice fishes, both those with and without red blood cells, are unique among teleosts because there is no elastin in the wall of the bulbus. Smooth muscle of the middle layers is embedded in a filamentous meshwork, which may confer elastic properties to the bulbar wall. The filamentous meshwork structurally resembles

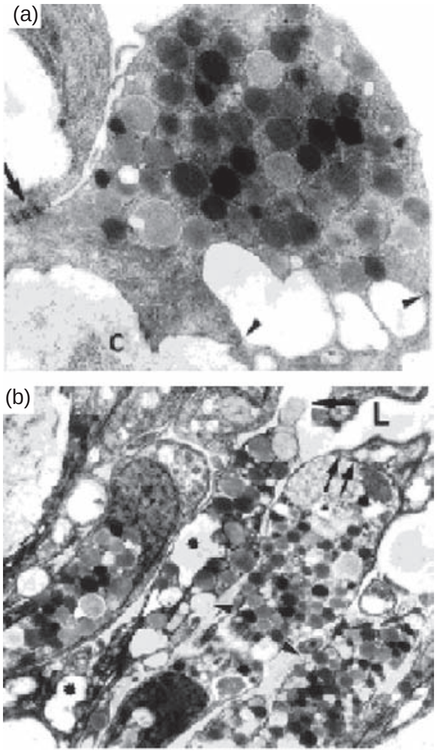

Figure 11 (a) Transmission electron micrographs of bulbar endocardial cells. They contain rounded, membrane-bound vacuoles filled with a homogeneous material of low-to-high electron density. Cells are joined by desmosome-like plaques (arrows) and gap junctions (arrows). Some collagen fibrils (C) appear under the endocardium. Magnification ×7075. (b) Detail of one endocardial element in contact with the bulbar lumen (L). Cells appear filled with rounded secretory vacuoles, many of which appear to be discharging their content directly into the blood (arrow) and into the extracellular area of the element (arrowheads). Some cells show a peripheral band of microfilaments (double arrow) which is accompanied by the formation of irregular cell surface extensions. Asterisks = fused vesicles. Magnification ×4550. Modified from Icardo JM, Colvee E, Cerra MC, and Tota B (1999) Bulbus arteriosus of the Antarctic teleosts. I. The white-blooded *Chrionodraco hamatus. Anatomical Record* 254: 396–407.

glycosaminoglycans (GAGS, long sugar chains) and indicates that a change in synthetic activity, from myofibrillar to structural polysaccharide chains, occurs at extremely low temperatures. Collagen is restricted in the outer layer but never associated with the smooth muscle of the middle layer.

Function

For efficient gas exchange, water flow over and blood flow through the gills should be continuous (**see also Ventilation and Animal Respiration:** Efficiency of Gas Exchange Organs). However, unlike in air-breathing vertebrates, which use the summed compliance of a long arterial tree to smooth pulsatile output from the heart, the juxtaposition of the heart and gills in fish requires the same job to be subserved by a relatively short ventral aorta and bulbus arteriosus. To this end, the extreme compliance of the bulbus allows it to expand during contraction, absorbing some of the energy of ventricular contraction. Then, during relaxation, and contrary to the situation in normal blood vessels, the bulbus maintains an elevated blood pressure even as internal diameter and volume decrease. An insight into this phenomenon can be gained by inflating the bulbus using a syringe and measuring the pressure generated. Plotting pressure against volume yields an r-shaped curve, showing that initially the bulbus is quite stiff but that it grows more compliant as more volume is injected (**Figure 12**(**a**)). Conversely, as the bulbus empties, it effectively becomes stiffer as it shrinks, resulting in a higher-than-expected pressure at small volumes.

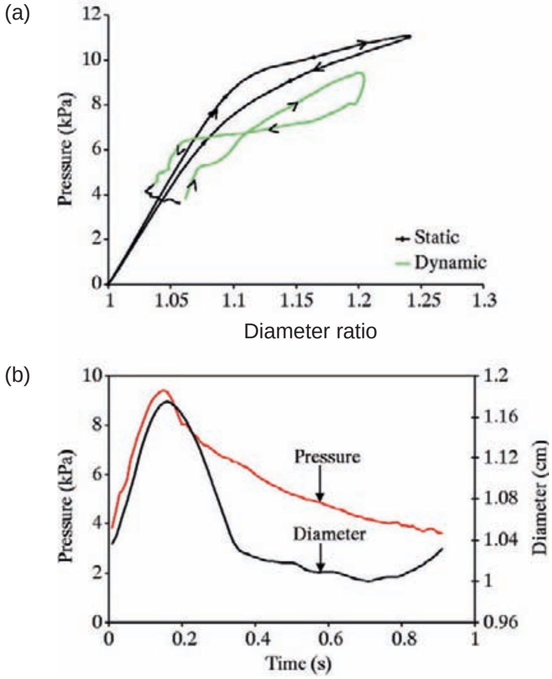

Figure 12 Recordings from a yellowfin tuna. (a) Comparison of static and dynamic pressure–diameter (P–D) loops. The dynamic trace (green) was created by plotting pressure against diameter for a single cardiac cycle. The static P–D curve (black) was created by a bulbar inflation from a syringe, post mortem. Arrows indicate the clockwise or anticlockwise cycling of the loop. (Diameter ratio is the diameter divided by the initial diameter.) (b) Recordings of bulbar blood pressure and diameter changes through a single cardiac cycle show that pressure remains significantly elevated despite large decreases in bulbar diameter. Elevated pressure = continued flow. Modified from Braun MH, Brill RW, Gosline JM, and Jones DR (2003) Form and function of the bulbus arteriosus in yellowfin tuna (*Thunnus albacores)*: Dynamic properties. *Journal of Experimental Biology* 206: 3327–3335.

Along with this specialized inflation behavior, the bulbus is compliant enough to hold several times the output of each heartbeat. A large compliance plus maintenance of positive pressure results in continuous blood flow throughout the cardiac cycle (**Figure 12**(**b**)). *In vivo* recordings of bulbar dimensions and pressures in a living tuna show that the bulbus in living fish does indeed act as predicted by mechanical inflation of the isolated bulbus: it helps convert the discontinuous blood flow from the ventricle into continuous blood flow in the ventral aorta (**Figures 12**(**a**) and **13**).

These properties of the bulbus are mostly passive, due primarily to both the shape and the material properties of the bulbar wall. Therefore, it is expected that the costs for maintenance of blood flow will be relatively low. Indeed, the difference between the inflation and deflation curves, or the amount of energy lost in a single inflation cycle, is relatively small (**Figure 13**) and, as a result, the bulbus is very efficient at returning energy to the circulation.

The plateau of the r-shaped curve represents the range over which the bulbus is most effective at storing large volumes of blood. The extreme compliance of the plateau is due to a number of factors, but most important is the high content of elastin in the walls of the bulbus. For example, 70% of the bulbus in salmonids is elastin, while carp bulbus is made up of nearly 90% elastin. The amount of stiff collagen in most bulbi is relatively low, for example, in rainbow trout (*Oncorhynchus mykiss*) the elastin:collagen ratio is 14. Despite this, the high stiffness and strength of collagen mean that this amount should be sufficient to significantly limit the expansion of the bulbus. However, unlike in normal blood vessels, the collagen fibers are usually arranged in such a manner that they are not significantly recruited until the bulbus undergoes a very large, possibly nonphysiological inflation. Over the operational range of the bulbus, it is unlikely that the collagen fibers play much of a role in limiting bulbar expansion. Some of the collagen may also be involved in setting the plateau of the r-shaped pressure–volume curve, as removing the contribution of either collagen or smooth muscle to the inflation results in a decrease in the height of the plateau (**Figure 14**). However, it is the shape and internal anatomy of the bulbus that play the largest role in setting the height of the plateau.

Despite the amount of elastin and limited effect of collagen, the bulbus is quite stiff at low filling pressures, resulting in the steep initial rise of the r-shaped curve. It is an interaction between radius, pressure, and tension, as described by the law of Laplace that explains this. The force in the wall (tension, T) that must be overcome for expansion to occur is equal to the pressure (P) in the vessel multiplied by the radius ($T = P \times R$). Therefore, a small lumen requires high pressure to open. The lumen of the relaxed bulbus is extremely small and, thus, a high pressure is required to open the lumen for flow (**Figure 9**(**c**)).

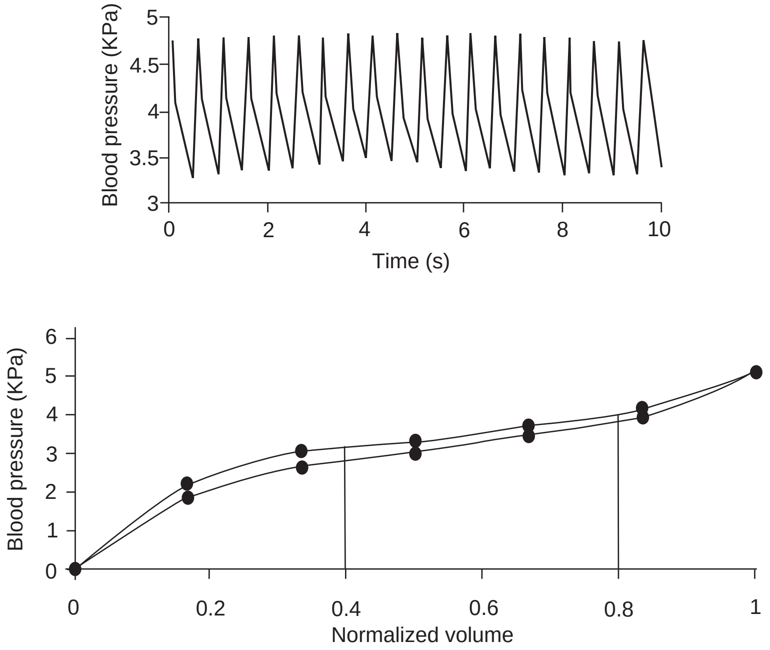

Figure 13 Pressure–volume loop for a 2.17-g stickleback showing that the blood pressure recorded from an anesthetized 5.5-g stickleback by bulbar puncture (inset) corresponds to the plateau of the curve created via static inflation of the bulbus with a syringe. Note that the blood pressure in the fish is always maintained above zero throughout the cardiac cycle. Modified from Jones DR, Perbhoo K, Braun MH (2005) Necrophysiological determination of blood pressure in fishes. *Naturwissenschaften* 92: 582–585.

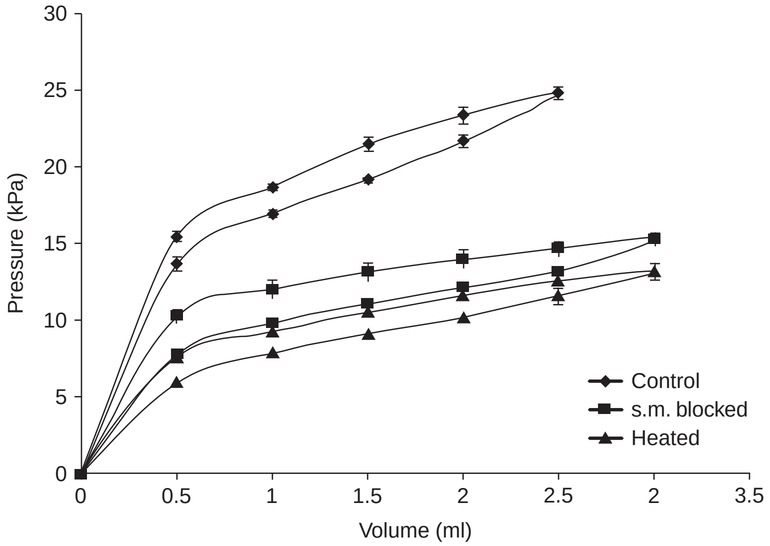

Figure 14 Yellowfin tuna (*N* = 4). Mean *P–V* loops from fresh bulbi before and after undergoing two treatments: a 10^{-5}·mol l^{-1} solution of nicardipine to inactivate the smooth muscle (s.m. blocked) and a high-temperature tissue bath to denature the collagen (heated). As the mechanical contributions of smooth muscle and collagen are effectively removed, the level of the plateau decreases. Values are means ± SEM. From Braun MH, Brill RW, Gosline JM, and Jones DR (2003) Form and function of the bulbus arteriosus in yellowfin tuna (*Thunnus albacores)*, bigeye tuna (*Thunnus obesus*) and blue marlin (*Makaira nigricans*): Static properties. *Journal of Experimental Biology* 206: 3311–3326.

Variations in the internal anatomy (ridges, longitudinal and radial elements, and tubes) result not only in variation in the effective internal radius but also in differences in the pressures required to open the bulbus, and, consequently, differences in the levels of the plateau.

The plateau portion of the pressure–volume loop has a strong correlation with the blood pressure in the living animal (**Figure** 15(**a**)). Moreover, central arterial blood pressure varies considerably among fishes (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping). Thus, the material properties and shape must be matched to the physiological needs and arterial blood pressure of fishes. Therefore, in teleosts, the bulbus is tuned to the arterial blood pressure through variations in the shape and major constituents of the wall in the long term and smooth muscle contraction or relaxation in the short term. The short-term tuning changes allow blood pressure to increase during exercise and fall at rest. The tuning is so precise that it is possible to obtain a value for blood pressure in the living animal from inflating the isolated bulbus because the plateau of the r-shaped pressure–volume curve corresponds to the operational blood pressure range of the fish (**Figure** 15(**b**)).

In any cardiac system, a large elastic chamber just outside the heart smoothes the pressure fluctuations generated by the ventricle, reducing the peak and raising the trough. In fishes, the claim is frequently made that the reduction in peak pressure will protect the delicate gill capillaries from high blood pressure. However, there is some doubt whether the capillaries are ever in danger. In fish, gill capillaries are able to withstand considerable pressure due to their small size. For instance, the wall tension in a 10-μm diameter gill capillary at an extreme pressure (for a fish) of 80 mmHg is 0.1 g cm^{-1}, a very small force. For comparison, the tearing strength of 1 cm of the finest tissue paper requires a force 500-times larger. The very small size of capillaries gives the wall tension a considerable mechanical advantage over the pressure. Obviously, systolic pressure reduction to protect the gill capillaries is not a necessary function of the bulbus.

Form and Function of the Conus Arteriosus

Form

The conus is a tubular, muscular structure of variable length with many pocket valves either in rows running along its length or in discrete tiers running around the inner circumference. The conus of most sharks has between two and six transverse rows with three to six valves in each row, although even in a single species (dogfish) there may be two or three rows of valves depending on the length of the conus (**Figure 16**). When the rows are well defined, they divide the conus into separate compartments. Primitive actinopterygians can have nine transverse rows with four to eight valves in each row (**Figure** 17). Embryologically, the conus has

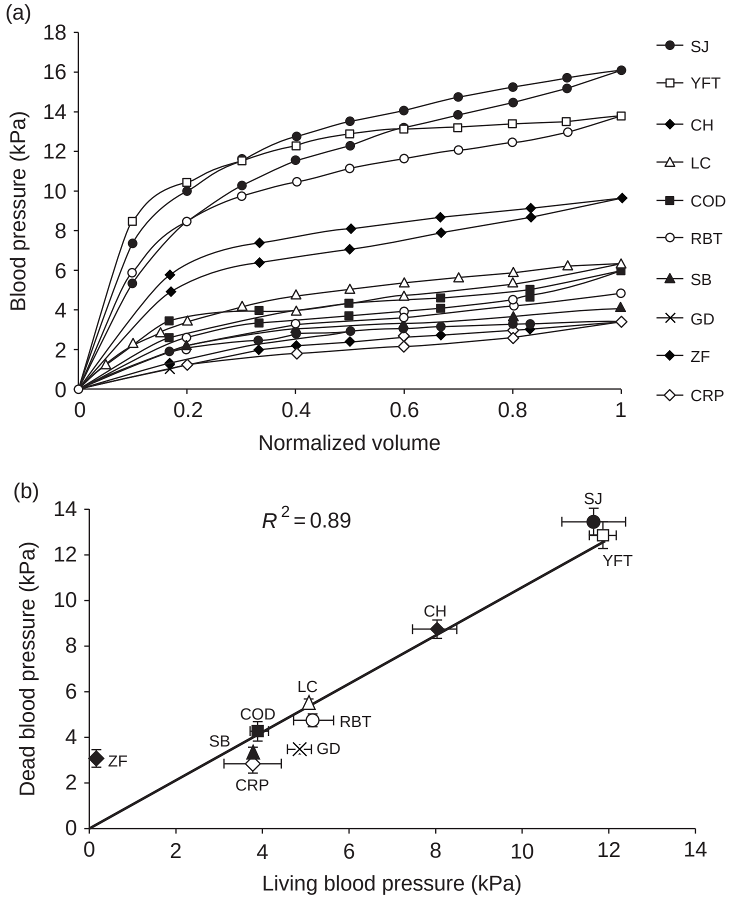

Figure 15 (a) Pressure–volume loops for the bulbus arteriosus of ten species of teleost fish showing how the level of the plateau varies between species. Species are as follows: SJ, skipjack tuna, *Katsuwonus pelamis* (<5 kg); YF, yellowfin tuna, *Thunnus albacares* (1.9 ± 0.1 kg); CH, coho salmon, *Oncorhynchus kisutch* (3.1 ± 0.4 kg); LC, lingcod, *Ophiodon elongates* (<2 kg); COD, cod, *Gadus morhua* (>0.5 kg); RBT, rainbow trout, *Oncorhynchus mykiss* (0.6 kg); SB, stickleback, *Gasterosteus aculeatus* (0.003 ± 0.001 kg); GD, giant danio, *D. aequipinnatus* (0.0037 ± 0.0003 kg); ZF, zebrafish, *Danio rerio* (0.0006 ± 0.0001 kg); CRP, carp, *Cyprinus carpio carpio* (0.5 ± 0.1 kg). (b) The relationship between the *in vivo* blood pressures recorded from fish in (a) and the blood pressures calculated by integration of the area between 40% and 80% of the r-shaped inflation curves. Standard error of the mean for *in vivo* determinations and bulbar inflations are shown for each species. R^2 = coefficient of determination. The relationship is highly significant and indicates that not only can *in vivo* blood pressure be calculated from static *in vitro* inflations, but that each bulbus is tuned to work at an optimal pressure range. Modified from Jones DR, Perbhoo K, Braun MH (2005) Necrophysiological determination of blood pressure in fishes. *Naturwissenchaften* 92: 582–585.

four endocardial ridges which, even in the absence of valve formation, are capable of coming together and occluding the conus during contraction. Pocket valves, with the cavity oriented toward the ventral aorta, develop from the dorsal and lateral ridges, the ventral ridge usually being vestigial. Up to six tiers can be present in selachians, but in more advanced representatives the number is usually reduced. In contrast, in the ancient teleosts (e.g., *Polypterus* (Bichirs and ropefish) and *Lepidosteous* (gar pike)), many rows of valves occur in the conus and their claimed orientation into tiers seems to be dependent on the 'eye of the beholder'. The valvular system is extremely complex; valves vary in shape from square to triangular to circular and in size from really elongated to just a small prominence (**Figure 16**). Nevertheless, the mechanism of valve formation has been modeled on a computer using the interaction of only two substances, I (inhibitor) and A (activator). I inhibits the synthesis of the A, which in turn activates the production of both I and A. All types of valve formations observed in nature can be generated as long as the conus is allowed to lengthen, which mirrors the natural situation because the longer the conus the more valves there are in it.

The outer layer of the conus consists of cardiac epithelial cells, which are continuous with those covering the ventricle. The region between the epithelium and the middle layer contains connective tissue abundant in collagen fibers and many blood vessels that arise from the coronary vasculature. The middle layer consists of

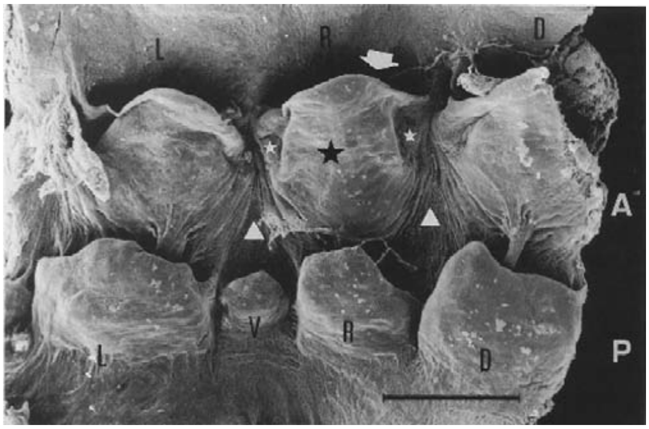

Figure 16 Scanning electron micrograph of the conus arteriosus from the dogfish (*Scyliorhynus canicula*) displayed in the open cut view to show the anterior (A) and posterior (P) transverse rows of valves. In the anterior row, there are three rows of valves: left (L), right (R), and dorsal (D). In the posterior row, there are four rows: left (L), ventral (V), right (R), and dorsal (D). As indicated in the right anterior valve, each valve has two components, namely, the leaflet (black asterisk) and the sinus (arrow). Note the difference in thickness between the central body and the lateral parts (white asterisks) of the leaflet. The triangle indicates the triangular spaces between adjacent leaflets in the anterior rows of valves. Scale = 1 mm. Modified from Sans-Coma V, Gallego A, Munoz-Chapuli R, et al. (1995) Anatomy and histology of the cardiac conal valves of the adult dogfish (*Scyliorhinus canicula*). *Anatomical Record* 241: 496–504.

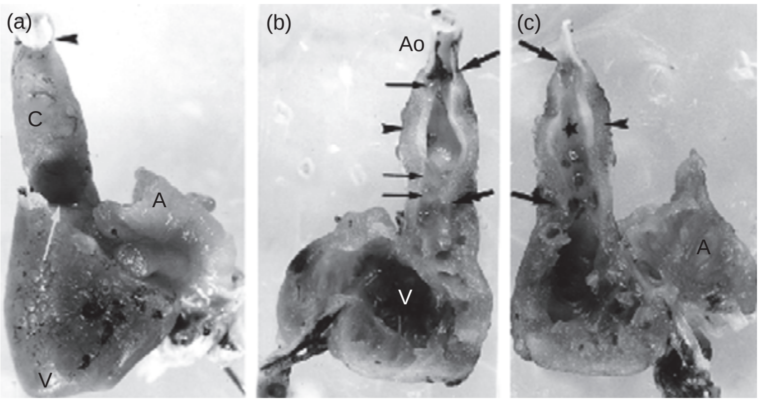

Figure 17 (a) Panoramic view of the sturgeon heart. Left-sided view. The conus (C) is displaced toward the right side of the ventricle (V). White arrow indicates the constriction at the conus origin. A, atrium. Magnification ×4. (b)This sturgeon heart was opened longitudinally following the conus axis. The (b) left and (c) right halves are presented. Note that the left side of the ventricular chamber is larger than the right side due to the location of the ventricle–conus junction. (b, c) Thick arrows indicate the conus limits. The lower thick arrow also indicates the ventricle-conus constriction. Thin arrows in (b) indicate the location of the conus valves. Note that a long segment of the conus is devoid of valves (star in (c). The subendocardial layer in this segment is very thick and resembles the aortic wall. Arrowheads point to the myocardial coat. A, atrium; Ao, intrapericardial portion of the ventral aorta; V, ventricle. Magnification ×4. Modified from Icardo JM, Colvee E, Cerra MC, and Tota B (2002) Structure of the conus arteriosus of the sturgeon (*Acipenser naccrii*) heart. I. The conus valves and the subendocardium. *Anatomical Record* 267: 17–27.

myocytes, which are generally smaller in diameter than those of the atrium and ventricle. The myocytes are separated by capillaries as well as by collagen and some elastin fibers, resembling the compact myocardium of the ventricle (**Figure 18**). Even if the ventricle is predominantly spongy with many trabeculae, the conus is always made up of compact myocardium. Complex connections, which greatly increase the surface area for electrical and chemical contact, join the ends of adjacent myocytes, while junctional complexes along their length hold the myocytes in register for synchronous contraction. In elasmobranchs, the myocytes are arranged circularly, while in the sturgeon (*Acipenser naccarii*), the arrangement is considerably more complex which may allow better emptying of the conus. Collagen fibers occur in the subendocardial space along with nerve fibers and terminals (**Figure 19**). In close contact with these terminals, granulated cells containing dense core vesicles occur. These granulated cells occur near axonal endings in the subendocardium, which have been interpreted as endings involved in the liberation of catecholamines. The granulated cells are made of chromaffin tissue that secretes

(c) Myocyte of the dorsal surface, perinuclear region. N, nucleus, M, mitochondria. In the perinuclear region is the Golgi complex (Go) from which originate central core granules (arrow). Scale = 0.38 μm. Modified from Zummo G and Farina F (1989) Ultrastructure of the conus arteriosus of *Scyliorhinus stellaris. Journal of Experimental Zoology Supplement* 2: 158–164.

amines into the bloodstream of the conus. It has been suggested that the chromaffin tissue could hemodynamically couple ventricular and conal activity (**Figure 19**).

Conal valves vary in complexity not only between species but also depending on their position within the conus. Typically, each valve has two parts. An outer leaflet which is free of attachment to the wall along its anterior border, containing and surrounding a sinus, which is probably sculpted from the endocardial ridges by the force of the blood **Figures 15** and **20**). The leaflets are thicker in the center than at their attachment to the walls and are stratified into two or three main layers: an outer and inner fibrosa, mainly composed of collagenous fibers oriented circumferentially sandwiching a layer of loose connective tissue rich in GAGs mixed up with collagenous and elastic fibers (**Figure 21**). Valves in the lower tier may also be attached to the ventricle by way of tendinous cords. In dogfish (*Scyliorhinus canicula*) with 2 sets of valves, those at the junction of the conus and ventral aorta receive contributions to their structure from the ventral aorta and are very large and can close against one another, and resist considerable back pressure from the blood without opening, even when the conus is relaxed. In contrast, the leaflets at the junction of the ventricle and conus are smaller and anchored to the conus wall by tendinous cords and cannot close in the absence of conal contraction. The ineffectiveness of the lower valve group in stopping flow in the absence of conus contraction is compounded by the fact that the ventral valve is much reduced. In the dogfish, each conal-aortic valve is tied to its corresponding ventricular-conal valve by a stout tendinous cord, made up of collagenous and elastic fibers covered by endocardium, suggesting that closing of the anterior valves begins as the posterior valves close. Embellishments in other sharks include increases in the complexity and branching of the cords, which act as guide ropes and prevent the individual valves being

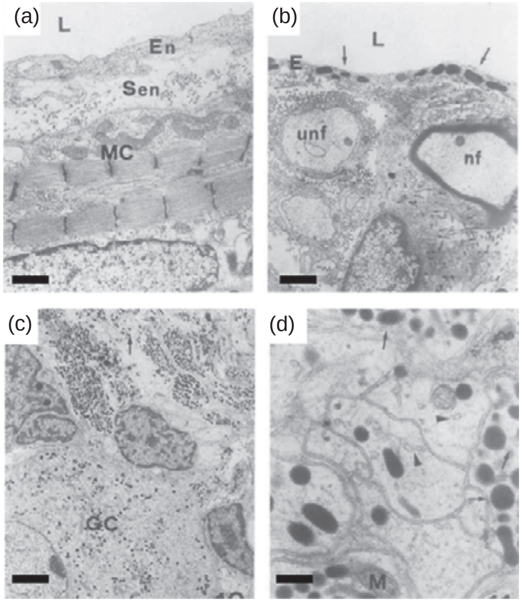

Figure 19 Transmission electron micrograph of the conus arteriosus from the dogfish (*Scyliorhynus sellaris*). (a) The endocardium covering the luminal surface. L, conal cavity. Figure 21 Light micrograph from the conus arteriosus of the dogfish (*Scyliorhynus canicula*). Transverse section of the leaflet of an anterior valve. The connective tissue of the central body is stratified in three layers: outer fibrosa (arrow), spongiosa (asterisk), and inner fibrosa (arrowhead). Scale = 100 μm. From Sans-Coma V, Gallego A, Munoz-Chapuli R, et al. (1995) Anatomy and histology of the cardiac conal valves of the adult dogfish (*Scyliorhinus canicula*). *Anatomical Record* 241: 496–504.

turned inside out as well as in the number of cords linking corresponding valves in different rows together (**Figure 22**). Included in the variability mix are a couple of sharks (*Pristiophorus japonicus* and *Discobatis sinensis*) which have the smallest valves bordering the aorta and the largest closest to the ventricle!

The variability in valve formations among elasmobranchs seems rather minor when other species are investigated. For example, in the ancient living fossil, the sturgeon, the conus has three rows of valves. The distal row has four leaflets, whereas the two proximal rows exhibit great variation in leaflet number, size, and shape. The three rows of valves are joined by tendinous cords. The conus has two restrictions at the conus-aorta and ventricular-conus junctions which, due to the ineffective nature of the valves and their arrangement, may form sphincters which arrest blood flow during conus contraction.

In sturgeon, the conus does not run right to the edge of the pericardium to connect to the ventral aorta. A distinct transitional region exists between the conus and ventral aorta, which differs from the conus behind and ventral aorta ahead. This could be an equivalent to the truncus of higher vertebrates, although recent investigations have questioned this. During early development, the entire conus is myocardial, but around the fourth day the distal portion takes on smooth muscle characteristics. Elastin appears somewhat later and the distal segment comes to look more and more like a blood vessel. This vessel is undoubtedly of cardiac origin. The distal segment has been named the bulbus arteriosus, which implies that the outflow tract came to be formed by a bulbus arteriosus

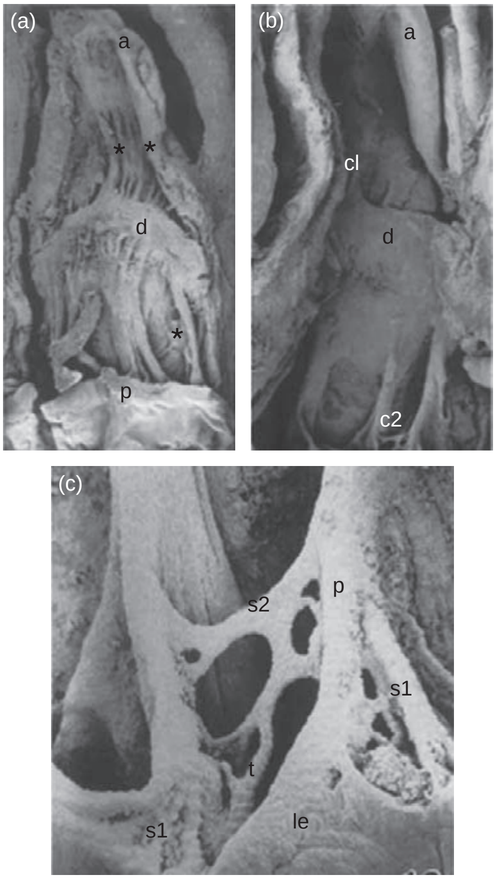

Figure 22 Images from the conus arteriosus of Rhizoprionodon terraenovae (Atlantic sharpnose shark). (a) Conal valves from 50 cm R. terraenovae. Valves of the anterior tier (a) lack chordae tendinae, while the proximal (p) and distal (d) tiers are supported by chordae (asterisks). X33. (b) Conal valves from adult R. terraenova. Chordae (c1) that support the distal (d) tier of valves branch less than the chordae (c2) that support the proximal (p) tier. a = anterior valve. X40. (c) Conal valve from adult R. terraenovae. Primary (p) chordae may attach directly to the valve leaflet (le) or branch to form secondary chordae that may attach to the leaflet (s1) or to adjacent chordae (s2). Secondary chordae may then branch to form tertiary (t) chordae, which then attach to the leaflet. X 200. Modified from Hamlett WC, Schwartz FJ, and Schmeinda CE (1996) Anatomy, histology and development of the cardiac valvular system in elasmobranchs. *Journal of Experimental Biology* 275: 83–94.

and conus arteriosus in early evolutionary history. If the bulbus truly is a bulbus and not a truncus, then this seems to place the final nail in the coffin of the theory that the ventral aorta grows backward into the pericardium to obliterate the conus and form the bulbus.

In fact, if the ventral aorta actually gobbles up the conus arteriosus in the course of its evolutionary advance, how is it that a conus has been identified in a wide range of advanced teleosts? Initial studies on the gilthead seabream (*Sparus auratus*) showed a distinct muscular segment between the ventricle and bulbus, organized very differently from the completely trabeculated (spongy) ventricle (**Figure 5**). Criteria used to identify this muscular segment as a conus were its shape, its inner wall of well-vascularized compact myocardium, the presence of elastin and collagen in the inner and outer layers of the wall, and support of the ventricular-bulbar valves. The presence of a conus or conal segment has been confirmed in a large number of other species recently. The conus is most obvious in the 80% or so of species with trabeculated hearts because the conus is made up of compact myocardium and readily distinguished from the heart muscle. In species with compact hearts, if the conus is not a discrete chamber then it generally has the form of a fibrous ring at the base of the ventricle. The valve leaflets are inserted into the lower end of the conus forming a fibrous hinge, facilitating valve movement. The conus is furnished with two pocket-like valves, although there is considerable variation between species. The fact that the valves are attached to the conus wall means that they should properly be called conal valves.

Function

What function(s) does the conus perform? One role it certainly shares with the bulbus is secretory. Amines are released from glomus cells in the inner portion of the wall in elasmobranchs. Other substances are released from the outer layer of the conal wall. The presence of many vesicles in the superficial epithelium suggests very active exchange with the pericardial fluid. In addition, the outer layer may contribute to the formation and maintenance of the immune system in sturgeons as it has the appearance of a complex lympho-hemopoietic tissue. It would be interesting to investigate this tissue in other fishes.

From a hemodynamic perspective, the view of many authors is that the conus is just a muscular bulbus and performs similar roles as the elastic bulbus. Can the conus store and release some of the ventricular pulse and prolong outflow from the heart? This seems unlikely because cardiac muscle is much stiffer than the smooth muscle that predominates in the wall of the bulbus. Furthermore, the conus is contracting during cardiac outflow, which will further stiffen the wall and reduce its volume. Perhaps by its contraction the conus adds to the ejection fraction from the heart, although virtually all studies show this contribution to be minor with blood flow slowing or even stopping before or by the end of the each cardiac cycle.

Conal contraction is delayed with respect to that of the ventricle by the presence of nodal tissue between the ventricle and conus by 250–500 ms. The wave of electrical activation spreads across the conus causing it to contract from the bottom to the top. The first thing that occurs is that the ventricular-conal valves, which are too small to bridge the opening in the relaxed conus, will be brought together and stop flow from the heart. The same will take place in other tiers of valves as the contraction wave passes. The conal-aortic valves are large and can close passively due to backflow of blood from the ventral aorta. When the heart refills, it is probable that the conus is filled along with the ventricle. Hence, there will be a volume of blood contained within the conus for the ventricle to push against. As noted previously, blood is incompressible and this contained blood places an extra burden on the ventricle and accommodating this extra load may be an added bonus of the presence of a bulbar structure between the conus and ventral aorta. Nevertheless, the whole stroke volume has to be accommodated and this function falls on the ventral aorta and other elastic structures such as cavernous bodies, which are present in the gill vasculature.

The conus provides us with snapshots in development of form and function that stretches from the most ancient to most advanced jawed fishes. The early conal design of a contractile conus with four endocardial ridges is capable of arresting blood flow in the low-pressure embryonic circulation and embellishments such as valves and sphincters improve the capacity to hold against higher pressures, both above and below atmospheric in sharks and rays. Reductions in both the size of the conus and number of valves finally give us a superb design that is able to hold against pressures that in some teleosts can be among the highest in the animal kingdom and also closes actively. This is evolution by natural selection painted with a broad brush and, as Stephen J. Gould pointed out, the character of imperfections and improvisations sheds light on evolutionary origins, relationships, and mechanisms.

Glossary

Action potential A small and transient change of voltage across the cell membrane when the negative resting potential momentarily becomes nearly zero volts and quickly returns to the original level in a few milliseconds. The action potential is possible because of the activity of ion channels, proteins of the cell membrane selectively allowing certain inorganic ions to pass through their pore.

Atrium A thin-walled chamber of the heart that is primarily comprised of cardiac muscle tissue.

Cardiac cycle The changes in blood pressure, blood flow, and electrical activity that accompany cardiac filling and emptying associated with a single heartbeat.

Cardiac output (V_b) Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.

Cardiac stroke volume (V_s) Volume of blood pumped out of the ventricle in a single heartbeat; the difference between ventricular end-diastolic volume and end-systolic volume.

Chronotropy Pertaining to heart rate.

Diastole A period of the cardiac cycle when cardiac muscle is relaxed or relaxing. It is associated with filling the heart with blood.

Diastolic Pertaining to diastole, it is the lowest pressure in a pressure pulse.

Electrocardiogram A recording of the waves of electrical activity associated with each heartbeat.

End-diastolic volume Volume of blood in a cardiac chamber at the end of filling (diastole).

End-systolic volume Volume of blood in a cardiac chamber at the end of emptying (systole).

Heart A valved, muscular pump that propels fluid, usually blood or lymph, around the circulatory system.

Inotropy Pertaining to force or vigor of cardiac contraction.

Isometric A contraction with the same length.

Isotonic A contraction with the same force or tension.

Myocardial power output The external work performed by the heart per unit time.

Systole A period of the cardiac cycle when cardiac muscle is contracted or contracting. It is associated with the ejection of blood from the heart.

Systolic Pertaining to systole, it is the highest pressure in a pressure pulse.

Ventricle A thick-walled chamber of the heart that is primarily comprised of cardiac muscle tissue.

Vis-a-fronte A term for a supplementary cardiac filling mechanism that uses energy directly from ventricular contraction; literally, the force from in front.

Vis-a-tergo A term for a cardiac filling mechanism that uses energy contained in venous blood; literally, the force from behind.

Introduction

The fish's heart, like that of other vertebrates, is a muscular pump that contracts rhythmically (the heartbeat). Each cardiac contraction generally produces sufficient energy to eject blood into an artery, propelling it in a continuous motion through blood vessels and back to the heart, usually without further pumping. Therefore, the heart is the powerhouse of the circulatory system.

The cardiac chambers within the pericardial cavity of fish are the sinus venosus, atrium, ventricle, and an outflow tract. Each chamber plays an important role in the integrated function of the heart. The main role of the sinus venosus is to generate and propagate the action potential, which initiates the heartbeat (**see also Design and Physiology of the Heart:** Action Potential of the Fish Heart). The main role of the outflow tract is to help depulse arterial pressure and flow before blood reaches the delicate gill capillaries (**see also Design and Physiology of Arteries and Veins:** Branchial Anatomy). This article delineates the primary role of the atrium and ventricle, which is to rhythmically pump blood and eject a specific volume of blood at a specific blood pressure with each heartbeat.

The rhythmic activity associated with each heartbeat is called a cardiac cycle. The cardiac cycle can be described from three perspectives: the emptying and filling of cardiac chambers; the patterns of pressure generation; and the electrical events associated with this activity (the electrocardiogram (ECG)). Cardiac anatomy and cellular structure, as well as the mechanistic basis for the action potential and cardiac contraction, are discussed elsewhere in this encyclopedia (**see also Design and Physiology of the Heart:** Cardiac Anatomy in Fishes, Action Potential of the Fish Heart, Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux, and Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element).

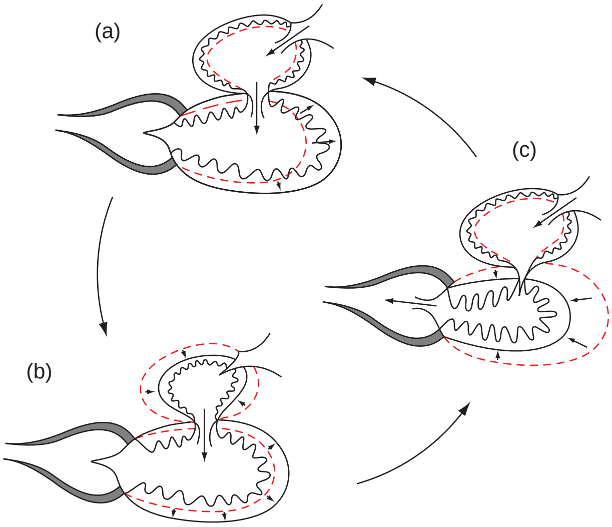

Figure 1 A schematic diagram of the three main phases of filling and emptying of four cardiac chambers of the fish heart. (a) Both the atrium and ventricle are filling due the venous blood pressure. (b) The atrium contracts (as shown by the small arrows), further expanding and completing the filling of the ventricle. (c) The ventricle contracts, ejecting fluid into the bulbus arteriosus. At the same time, the atrium begins to fill.

The Cardiac Cycle

The cardiac cycle can be divided into periods of systole and diastole, which correspond to cardiac muscle contraction and relaxation, respectively. During systole, cardiac muscle generates blood pressure and ejects blood by decreasing the volume of the ventricle or atrium. When the cardiac muscle relaxes during diastole, the atrium and ventricle can fill with blood and increase their volume. For example, in a spontaneously beating isolated heart from a rainbow trout, the atrial contraction can be seen to precede ventricular contraction and how both chambers alternate between diastolic and systolic states (see **Video Clip 1**). The net result of these synchronized contractions is a unidirectional flow of fluid through the cardiac chambers.

The Flow Events: Cardiac Chamber Filling and Emptying

Figure 1 illustrates the sequential filling and emptying of the cardiac chambers during a cardiac cycle.

The cardiac cycle begins with the atrium and ventricle in a relaxed state. During diastole, blood flowing from central veins fills the atrium and partially fills the ventricle, passing through the sinus venosus, the sino-atrial (SA) canal and the atrio-ventricular (AV) canal. Atrial contraction (atrial systole) then ejects blood from the atrium and into the ventricle, which is still in diastole, and this completes ventricular filling. The contributions of these two phases of ventricular filling vary among species, with sometimes only ~50% occurring via atrial contraction. In addition, the contribution of passive ventricular filling may decrease at high heart rates when the diastole is shorter.

Atrial relaxation (atrial diastole) occurs while the ventricle is contracting (ventricular systole). However, before ventricular contraction starts, the propagation of the action potential from the atrium is briefly delayed in the AV canal. This AV delay ensures that blood has sufficient time to move from the atrium and complete ventricular filling. Ventricular contraction ejects blood into the outflow tract past an opened bulbo-ventricular (BV) valve. The cardiac cycle is completed when the ventricle relaxes (ventricular diastole).

The Pressure Events

Blood flow follows an energy gradient, which is usually a difference in blood pressure (potential energy) between two points in the circulatory system. In general, the pressures developed by the fish heart are similar in form but lower in magnitude to those of the mammalian left ventricle. There remain, however, important differences among fishes in both the magnitude and the form of the pressure waves during the cardiac cycle, as shown by the three examples in **Figure 2**.

The heart imparts energy to the blood when it starts its circuit of the body. Most of this energy is lost to vascular resistance. Cardiac filling uses any remaining energy in venous blood. Venous blood in the central veins normally has sufficient kinetic and potential energy to completely fill the atrium and start filling the ventricle during atrial

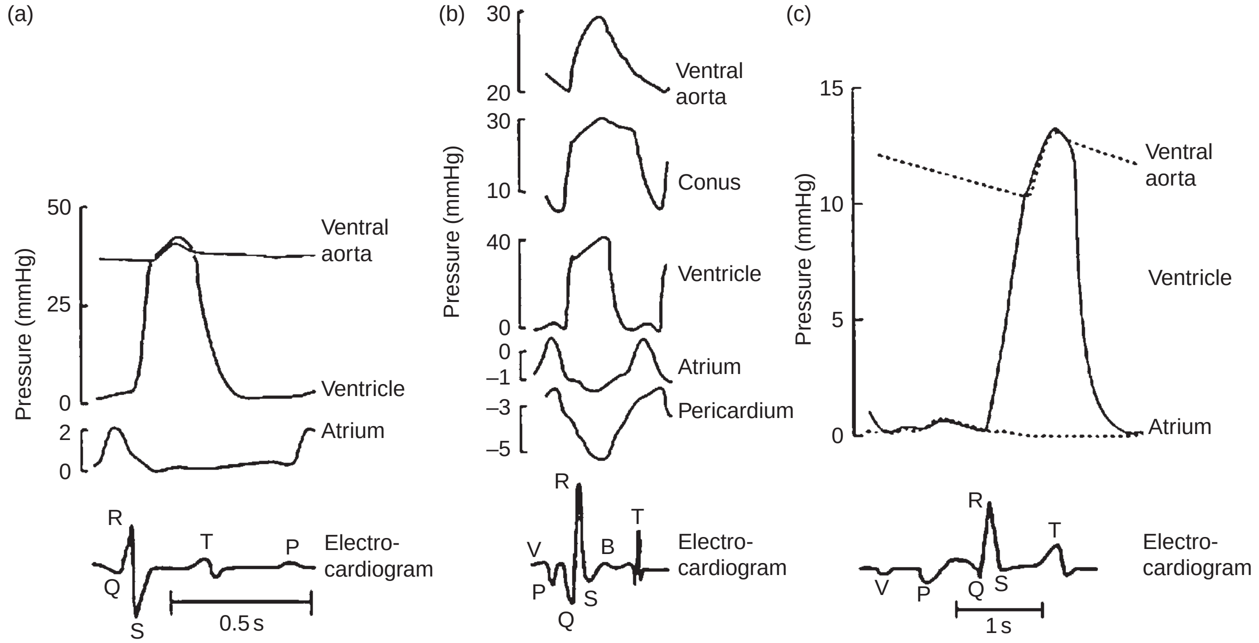

Figure 2 Features of the cardiac cycle in three different fishes. Representative examples of the changes in blood pressure and electrical activity (the electrocardiogram, ECG) associated with the cardiac cycle are illustrated for (a) the trout heart, (b) the shark heart, and (c) the hagfish heart. The ECG is shown in the lower panel, with each of the major electrical waves labeled (see text for details). The coincidence of these electrical waves with the contractions and relaxations of the cardiac chambers can be seen by a comparison with the blood pressure events for the atrium, ventricle, and main outflow vessels shown above. From Farrell AP and Jones DR (1992) The heart. In: Hoar WS, Randall DJ, and Farrell AP (eds.) *Fish Physiology, Volume XII, Part A: The Cardiovascular System*, ch. 1, pp. 1–88. San Diego, CA: Academic Press.

diastole (**Figure 2**). This type of cardiac filling is termed *vis-a-tergo* (literally, the force from behind) because the energy comes from venous blood.

Atrial and ventricular blood pressures rise slightly during diastolic filling of these chambers. Atrial contraction (systole) then increases atrial blood pressure and completes ventricular filling. Atrial systole consists of an isometric (same length) muscle contraction, which builds up blood pressure and closes the SA valve. Once the SA valve is closed the muscle contraction becomes isometric, resulting in a rise in atrial pressure to its systolic value, which forces blood into the ventricle through the AV canal. When the atrium relaxes, atrial blood pressure returns to its diastolic level.

The AV canal and its valves offer minimal resistance to blood flow between the atrium and ventricle; consequently, there is never a very large difference between atrial and ventricular blood pressures during ventricular diastole.

Although the thin-walled atrium generates a much smaller systolic pressure compared with the thick-walled ventricle, there is sufficient pressure to stretch the wall of the ventricle and achieve a faster rate of ventricular filling. Conversely, the more compliant atrium allows atrial filling to be accomplished using just the low venous blood pressure.

Before blood can leave the ventricle, ventricular contraction must generate a blood pressure that can overcome the arterial diastolic blood pressure, which is considerably higher than the ventricular end-diastolic blood pressure. Therefore, ventricular systole involves a vigorous isometric contraction that rapidly and substantially increases ventricular pressure (**Figure 2**). This pressure rise first closes the AV valve and then opens the BV valve when ventricular pressure slightly exceeds arterial diastolic blood pressure. Ventricular contraction then becomes progressively isotonic, emptying the ventricle and forcefully ejecting blood into the outflow tract. This isotonic contraction results in a parallel rise of arterial blood pressure until systolic arterial blood pressure is reached. Ventricular relaxation follows, causing ventricular pressure to fall below arterial blood pressure, which closes the BV valve. Arterial pressure falls slowly toward its diastolic pressure until the next heartbeat, as blood moves through the circulatory system. As a result of the cardiac cycle, arterial blood pressure has a pulse (peak = systolic; trough = diastolic).

Cardiac Filling

Atrial filling (end-diastolic volume) is determined by various factors, including: end-systolic volume (which sets how much blood was present before filling started), the pressure gradient (which sets the rate of filling and the degree of cardiac stretch), wall compliance (which sets the amount of pressure needed to stretch the wall), and heart rate (which sets the time available for filling). The same factors, as well as atrial contraction, set end-diastolic volume of the ventricle. Atrial and ventricular end-systolic volumes are set by the strength of their respective contractions, which are determined in large part by cardiac stretch (see Frank–Starling effect below). All of the above factors can vary, altering the volume and pressure outputs of the heart.

The Special Case of *vis-a-fronte* Cardiac Filling in Fishes

A special form of supplementary atrial filling has been recognized in sharks, lungfishes, salmonids, and tunas, suggesting an early appearance in the evolution of the chambered vertebrate heart. These fishes have a pericardial cavity that acts like a rigid structure, largely as a result of stiff surrounding tissues adhering to the pericardium. Consequently, whenever the contracting ventricle decreases its volume, another chamber must correspondingly expand to conserve volume within the rigid pericardial cavity (**Figure 3**). Thus, the more compliant atrium expands, assisting atrial filling, courtesy of the energy imparted by the powerful ventricular contraction. Mechanistically, ventricular contraction actually creates a subambient intrapericardial pressure pulse, which is transmitted across the atrial wall, lowering its diastolic blood pressure and creating a more favorable blood pressure gradient for atrial filling from central veins. This supplementary atrial filling mechanism is termed *vis-a-fronte* (literally, a force from in front) because some of the energy of a ventricular contraction is used directly to fill the heart rather than have the energy travel all the way through the circulatory system.

Vis-a-fronte filling may be particularly important in fish with subambient venous blood pressures (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping). However, *vis-a-fronte* filling gives way to *vis-a-tergo* filling when fish become more active, likely because venous blood pressure increases with activity.

Another type of *vis-a-fronte* cardiac filling probably plays a minor role in the filling of the atrium and ventricle of all chambered hearts. It involves the recoil of the elastic elements of the heart. Some of the energy of contraction is stored in the wall of the heart until diastole. Elastic recoil during relaxation then sucks blood into the chamber.

The Electrical Events

Waves of electrical activity accompany each heartbeat. This electrical activity has a magnitude that can be recorded on or near the surface of the skin as the ECG. Because the ECG is the sum of the electrical changes (depolarizations and repolarizations) during the cardiac cycle, its pattern closely corresponds to and precedes contractions and relaxations (**Figure 2**). The ECG pattern seen in fishes is very similar to that of mammals, but with additional events.

The principal electrical components are the P-wave, the QRS-wave, and the T-wave. In some fish, the ECG starts with a small V-wave, which represents the contraction of bundles of cardiac muscle in the sinus venosus; a V-wave is absent in the mammalian ECG. Shortly afterward, a larger P-wave represents the syncytial contraction of atrial muscle (**Figure 2**). The interval between the V- and P-waves is indicative of the time taken for the action potential to travel

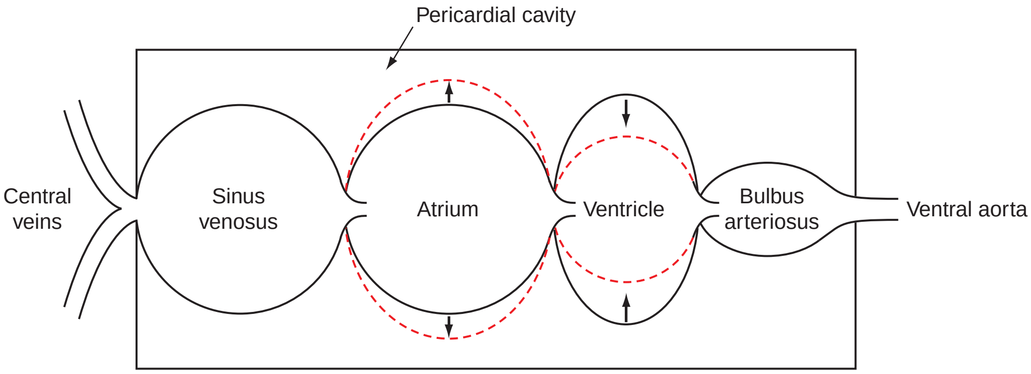

Figure 3 A schematic diagram of the synchrony between ventricular contraction and atrial expansion as produced with *vis-a-fronte* atrial filling when a rigid pericardium creates a pericardial cavity with a near constant volume. As the volume of the ventricle decreases (direction of arrows to the broken line), the volume of the atrium expands (direction of arrows to the broken line).

from the sinus to the atrium. A considerably larger QRS-wave represents the syncytial contraction of the thicker ventricular muscle. The interval between the P- and R-waves is indicative of the AV delay, the time taken for the action potential to travel through the AV canal, the connection channel between the atrium and ventricle.

The electrical activity associated with the ventricular relaxation is represented by the T-wave (**Figure 2**). However, atrial repolarization is usually overwhelmed by the simultaneous ventricular contraction because the ECG only integrates and does not differentiate between simultaneous electrical events. In hagfishes, however, a protracted AV delay of the action potential along its long AV (**see also Design and Physiology of the Heart:** Action Potential of the Fish Heart) canal means that atrial repolarization can be visualized as a T-wave preceding the QRS-wave.

Pumping Assistance

In some fishes, the ventricle does not generate sufficient energy for blood to complete the circuit of the entire circulatory system. There are several assistance mechanisms.

Contractions by Other Cardiac Chambers

The multivalved conus arteriosus of elasmobranchs assists arterial blood flow with rhythmic contractions of its cardiac muscle (**see also Design and Physiology of the Heart:** The Outflow Tract from the Heart). These contractions result in a small B-wave in the ECG, in between the S- and T-waves. A Br-wave, following the T-wave, can sometimes signal conal repolarization.

While the V-wave in the ECG corresponds to a coordinated contraction of cardiac muscle, the contribution of sinus contraction to cardiac filling is uncertain. Without ostial valves between the sinus venosus and central veins, a sinus contraction is just as likely to propel blood backward rather than forward into the atrium. Thus, rhythmic contractions of the sinus venosus may be more important in preventing the *vis-a-fronte* effect of ventricular contraction from distending the very thin-walled sinus venosus, which would slow down atrial filling.

Other Mechanisms

In mammals, venous blood flow is assisted by the massaging effect of skeletal muscle contractions, which is all too apparent when humans collapse after standing still for too long because venous return from the lower limbs becomes insufficient. The importance of this mechanism is unknown for fish because they lack parietal venous valves, which prevent backflow of blood during vein compression in mammals.

Some fishes also have accessory hearts that assist venous blood flow (**see also Design and Physiology of the Heart:** Accessory Hearts in Fishes). The volumes of the sinus venosus and ductus Cuvier may be regulated by tonic activity of the muscle in their walls.

Cardiac Output

Cardiac output ($\dot{V}_b$) is the volume of blood pumped per unit time out of the ventricle. $\dot{V}_b$ varies by an order of magnitude among fishes ($10\text{–}100\ \mathrm{ml\ min^{-1}\ kg^{-1}}$) (**Table 1**). Because the main purpose of blood flow is to deliver oxygen to tissues, $\dot{V}_b$ is tightly coupled with a fish's metabolic rate. $\dot{V}_b$ is determined by how fast the heart beats (heart rate, f_H) and the volume of blood ejected from the ventricle with each heartbeat (cardiac stroke volume, V_s).

Cardiac Stroke Volume

V_s is typically in the range of $0.3\text{–}0.6\ \mathrm{ml\ kg^{-1}}$, but varies by an order of magnitude among fishes. It is exceptionally large in Antarctic ice fishes ($10\ \mathrm{ml\ kg^{-1}}$) (**Table 1**). V_s is the difference between ventricular end-diastolic volume and end-systolic volume. However, end-systolic volume cannot decrease very much because the heart normally ejects 80–95% of its volume. Consequently, altering end-diastolic volume is the main mechanism for changing V_s with environmental change.

Over the long term, the heart ejects all the blood it receives. This occurs automatically because cardiac muscle cells have a special intrinsic property, the Frank–Starling mechanism: they can automatically increase their mechanical work when muscle fibers are stretched. (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and Cardiac Cellular Length-Tension Relationship). Consequently, whenever end-diastolic volume increases with additional filling, cardiac stretch enhances the force of the subsequent contraction and end-systolic volume remains unchanged. In essence, hearts automatically pump harder when stretched so that additional filling is automatically matched by appropriate cardiac emptying. A consequence of the Frank–Starling mechanism is that V_s is directly related to venous filling pressure (**Figure 4**).

Fishes increase V_s up to threefold (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping and **Integrated Control and Response of the Circulatory System:** Integrated Responses of the Circulatory System to Hypoxia). Much of this range is

possible through the intrinsic response to cardiac filling (**Figure 4**) and so automatic regulation of V_s is particularly important for fishes, even hagfish. (In contrast, mammals rarely increase V_s by 50%.) As a result, venous blood pressure is directly related to V_s. Even so, with end-systolic volume near zero, any substantial increase in V_s requires more blood to be returned to the heart. Whenever a portion of the Frank–Starling curve occurs at subambient filling pressures (**Figure 4**), this is usually taken as an indication of *vis-a-fronte* atrial filling. In fact, opening the pericardium shifts the Frank–Starling curve toward higher filling pressures (**Figure 4**).

Extrinsic factors alter the sensitivity of the heart to a given filling pressure (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping). For example, increasing cardiac contractility (positive inotropy) with adrenergic stimulation (of neural or humoral origin) shifts the Frank–Starling curve to the left, increasing cardiac sensitivity to venous blood pressure (**Figure 4**). Conversely, weakening cardiac contraction (negative inotropy) with cholinergic stimulation (of vagal origin) lowers its sensitivity to venous blood pressure. Cardiac contractions are also weakened by hypoxia and reducing blood pH (acidosis). These adverse conditions are tolerated better by some fish (e.g., hagfish, carp, and eels) than others (e.g., salmon). Temperature also directly affects the force of cardiac contraction. To compensate for the negative inotropic effect of cold temperature, rainbow trout can increase in ventricular mass over several weeks; a larger mass compensates for the lower force per unit mass.

Heart Rate

The intrinsic activity of pacemaker cells sets the basal rate at which a fish heart beats (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping and Action Potential of the Fish Heart). Heart rate varies by an order of magnitude among fishes (**Table 1**). Active fishes at warmer temperatures tend to have a high f_H in association with their high metabolic rate. In addition, many extrinsic factors modulate this basal rate, making f_H either faster (positive chronotropy) or slower (negative chronotropy) than the pacemaker rate.

Autonomic nerves can slow and accelerate f_H. Parasympathetic vagal stimulation slows down f_H in most fishes. Vagal nerve endings (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes) release acetylcholine, which binds to muscarinic receptors, causing cardiac cells to hyperpolarize and take longer to reach the threshold for an action potential (**see also Design and Physiology of the Heart:** Action Potential of the Fish Heart). In addition, acetylcholine slows the rate of rise of the pacemaker potential and increases the AV delay. Tonic vagal activity normally exists in resting fish, which depresses f_H below the intrinsic

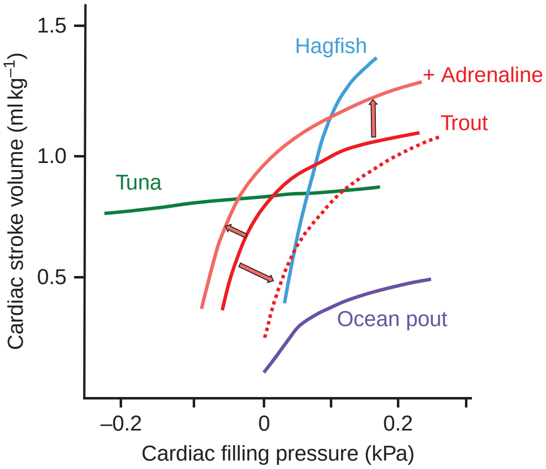

Figure 4 Starling curves for fish hearts *in vitro*. The Starling curve is the relationship between the cardiac filling pressure and the resulting volume of fluid ejected with each heartbeat. When the heart is distended with a higher filling pressure, there is greater filling and it responds by increasing the force of contraction to ensure that the additional volume of fluid entering the heart is ejected. Consequently, the heart automatically ejects the volume of fluid it receives over the range of the Starling curve. Starling curves vary among species, however, as shown by the lines for the different species. Stroke volume is lower in the sluggish ocean pout (purple solid line), whereas tuna (green solid line) operate at subambient filling pressure and are relatively insensitive to filling pressure. In addition, both the strength of contraction, as influenced by hormones and nerves, and the pericardium can influence the position of the curve. In trout (red lines), opening the pericardium (red broken line) shifts the curve to the right of the closed pericardium preparation (red solid line) by reducing *vis-a-fronte* filling. Adrenaline increases contractility and shifts the trout curve to the left and upward (pink solid line). Adapted from Olson KR and Farrell AP (2006) The cardiovascular system. In: Evans DH and Claiborne JB (eds.) *Fish Physiology*, 3rd edn., pp. 119–152. Boca Raton, FL: CRC Press.

pacemaker rate. In contrast, sympathetic neural stimulation typically increases f_H. Sympathetic nerve endings release noradrenaline (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes), which typically binds to cardiac β-adrenoceptors, increasing the pacemaker frequency, improving conduction velocity, and increasing the rate of relaxation of cardiac muscle. Likewise, hormones, such as adrenaline and noradrenaline, which are released from chromaffin cells in fishes (**see also Hormonal Responses to Stress:** Catecholamines), also stimulate β-adrenoceptors. Tonic adrenergic tonus can also exist in resting fish, which increases f_H above the intrinsic pacemaker rate. Thus, simultaneous adrenergic tonus and cholinergic tonus can have opposing effects on f_H in a resting fish, and their relative importance can vary considerably among species and with changes in activity and environments.

Important exceptions to the above scheme are hagfishes and lampreys. Hagfishes have no cardiac innervation, but have chromaffin cells within the heart (**see also Hagfishes and Lamprey:** Hagfishes). Lamprey hearts have nicotinic–cholinergic receptors, which increase f_H when acetylcholine is released from the vagus nerve. Many fishes, including lampreys, elasmobranchs, and some teleosts, lack sympathetic cardiac innervation (**see also Brain and Nervous System:** Autonomic Nervous System of Fishes).

Temperature is the most potent environmental factor affecting f_H, which typically doubles with an acute increase of 10 °C. Temperature directly affects the pacemaker potential and the duration of the action potential (**see also Integrated Control and Response of the Circulatory System:** Integrated Responses of the Circulatory System to Temperature and **Design and Physiology of the Heart**: Action Potential of the Fish Heart). To compensate for the direct effect of temperature, fishes can reset their pacemaker rate over time at a new temperature, for example, warm acclimation lowers the pacemaker rate. Temperature compensation can also involve changes in cholinergic and adrenergic tonus.

Very few fish have a maximum f_H much greater than $\sim$120 beats per minute. Recognized exceptions are tunas, zebrafish, and fish larvae. This upper limit to f_H may reflect cellular limitations related to excitation–contraction coupling events (**see also Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux).

Central Arterial Blood Pressure

The heart generates blood pressure to overcome the vascular resistance to blood flow. Similar to a mechanical pump, the heart operates over a certain range of arterial blood pressures without compromising cardiac stroke volume, that is, end-systolic volume is unchanged by increased work. This intrinsic property of the heart is termed 'homeometric regulation'. Species differences in the homeoregulatory ability of fish hearts are reflected in the almost order of magnitude difference in central arterial blood pressure among fishes (**Table 1**). These species differences in central arterial blood pressure reflect differences in ventricular wall thickness, shape and composition, as well as vascular resistance. The number of myofibrils per cardiac cell and the percentage compact myocardium also vary among fishes (**see also Design and Physiology of the Heart:** Cellular Ultrastructure of Cardiac Cells in Fishes).

Cardiac Work

The heart's overall performance, like any pump, is assessed by its ability to generate flow and pressure. The external work performed by the heart per unit time (myocardial power output, mJ s^{-1} or mW) is estimated from the product of V_b and arterial blood pressure (an estimate that neglects the small contribution of venous blood pressure). The range for power output per kilogram of fish varies by 100-fold among fishes. Hagfishes have the weakest heart and only tuna hearts are able to routinely generate central arterial blood pressures that approach those found in mammals (**Table 1**).

The cardiac muscle normally works aerobically and myocardial oxygen consumption is linearly related to myocardial power output. Therefore, the estimates of power output weighted to body mass (**Table 1**) provide an indirect index of the cost to the fish of cardiac pumping. This cost is typically less than 1% of the fish's overall oxygen uptake. Even so, only a small portion of the oxygen consumed by the heart is converted to mechanical work such that mechanical efficiency is generally of 10–20%. This estimate power output, however, does not accurately reflect the mass-specific capability of the heart since ventricular mass varies eightfold among fishes. Species comparisons are also made using power output weighted to ventricular mass to take into account the eight-fold variation in ventricular mass among fish species. The result is a much lower range for power output values among species because the power capability of a gram of fish heart does not vary by 100-fold. Thus, variation in ventricular mass is important in determining the power output developed by the heart of a fish.

Summary

The job of the heart is to generate blood flow and blood pressure. This task falls primarily to the ventricle and secondarily, the atrium. V_b and central arterial blood pressure vary considerably not only among fishes but also in response to metabolic needs and environmental change.

Glossary

Action potential A small and transient change of voltage across the cell membrane. The action potential is possible because of the activity of ion channels, proteins of the cell membrane selectively allowing certain inorganic ions to pass through their pore.

Delayed rectifier A potassium ion channel that activates relatively late (delayed opening) after the onset of cardiac action potential, that is, its opening is time dependent. A rapid and a slow component are separated according to their relative rates of opening. It allows efflux of potassium ions from the cell and thereby makes the membrane potential more negative.

Depolarization The reduction in electrical potential difference (voltage) measured across a cell membrane. This means the inside of the cell becomes less negative with respect to the outside of the cell. Depolarization occurs during the upsweep of the action potential (opposite of repolarization).

Diastolic depolarization Slow depolarization of membrane potential between two successive action potentials in the pacemaker cells of the heart. It forms the basis for automaticity of the heart and determines heart rate. It is also called pacemaker potential.

Electrocardiogram A voltage waveform generated by the electrical activity of the whole heart. Action potentials of cardiac muscle cells sum and cause voltage changes which are conducted by body fluids and can be recorded from a distance of the heart.

Equilibrium potential The membrane potential (voltage) at which there is no net flow of current for a particular ion. This value can be calculated for any ion using the Nernst equation and is based on the intracellular and extracellular concentrations of that ion.

Inward current A flow of positively charged ions across the membrane into the cell.

Inward rectifier A channel that passes potassium ions much better into the cell than out of the cell. Passive flow of ions through ion channels can principally occur in either direction (in or out) depending on the electrochemical gradient (driving force) of the ion across the membrane. However, the small outward current is physiologically more important.

Ion channel A protein or a group of proteins that form water-filled pores that span the cell membrane. These pores, when open, allow a rapid flow of ions through the cell membrane. Each channel type is specific for one inorganic ion (sodium, calcium, potassium, or chloride).

Outward current A flow of positively charged ions across the membrane out of the cell.

Repolarization A change of membrane voltage back to the polarized state that prevailed before the action potential was generated, that is, increase in the negativity of membrane potential.

Resting membrane potential The stable negative membrane potential (from –70 to –90 mV) of the resting myocyte.

Threshold potential The value of membrane voltage needed to excite a full-blown action potential, that is, the potential (about –60 mV) at which sodium influx exceeds potassium efflux across the cell membrane and results in depolarization of the cell membrane.

Voltage-gated channel An ion channel whose opening and closing is governed by changes in membrane voltage. Opening and closing of the channel takes some time, that is, its operation is voltage and time dependent.

What Is the Cardiac Action Potential?

Contraction of each cardiac myocyte is initiated by an electric excitation of the cell membrane (sarcolemma) in the form of a small voltage change ($\sim$0.1 V) called the cardiac action potential (AP). The rate and rhythm of the heart beat, and an orderly spread of contraction through atrial and ventricular myocardium of the fish heart are determined by the conduction of AP over the heart.

The AP excites all cardiac myocytes in each heartbeat because cardiac cells are electrically connected. The rapid and orderly spread of the AP ensures that the cardiac muscle contracts in an effective manner to reduce the volume of the lumen of the cardiac chamber and ejects blood into either another cardiac chamber or the arterial system. Without an AP, there would be no cardiac pumping. If all cardiac cells were not synchronized in their activity, the pumping would become inefficient. With all cardiac cells contracting, the small voltages in different parts of the heart are summed and can be observed from the surface of the heart or from the surface of the fish as an electrocardiogram (ECG) (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping).

The cardiac AP is necessary to maintain a constant and undisturbed pumping function of the heart in exercise and under various environmental stresses (hypoxia, anoxia, acidosis, and temperature changes) that fish may experience in their habitat. However, the shape, amplitude, and duration of the cardiac AP vary depending on environmental conditions and exercise level of the fish. In fact, the functionally different myocyte types of the fish heart (the pacemaker cells, atrial myocytes, ventricular myocytes, and conducting cells) generate an AP with different shapes that are appropriate for their special functions.

The cardiac AP is produced by orderly opening and closing of sarcolemmal ion channels, ion-specific pores of the cell membrane, which allow carriage of electric charges mainly by sodium, potassium, and calcium ions.

Different Phases of the AP

In the vertebrate heart, the shape of AP is complex and heterogeneous in different cardiac compartments. Five functionally different phases (0–4) can be separated from the vertebrate cardiac AP, as exemplified by the AP of a rainbow trout (*Oncorhynchus mykiss*) ventricular myocyte (**Figure 1**).

A noncontracting cardiomyocyte has a stable resting membrane potential (RMP) of −70 to −90 mV (phase 4) relative to the extracellular compartment. It is characteristic for atrial and ventricular myocytes of the heart, and maintains the relaxed and unexcited state (diastole) of atrial and ventricular muscle.

When depolarizing current hits the myocyte, membrane voltage abruptly swings from the RMP toward positive voltages generating an upstroke (depolarization) of the AP (phase 0). As a consequence, membrane potential attains a value close to the zero membrane potential or slightly above it. This is the initiation signal for the contraction phase (systole) of the heart, since it activates calcium influx from extracellular space into the cytoplasm of the cardiac myocyte. The rate and extent of AP upstroke also determine the velocity at which the excitation spreads over the different parts of the heart.

The upstroke of the cardiac AP is followed by a small negative deflection (phase 1) that is often inconspicuous or even absent in fish cardiac myocytes. Phase 2 is the longest stage of the AP and is called the plateau phase because the membrane potential remains relatively constant near the zero membrane potential or slowly creeps toward more negative voltages. This phase is crucial for shortening and force production of cardiac myocytes since it determines the time which is available for diffusion of calcium from extracellular space into the cytosol of myocytes to activate contraction of the myofilaments (**see also Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux and Cardiac

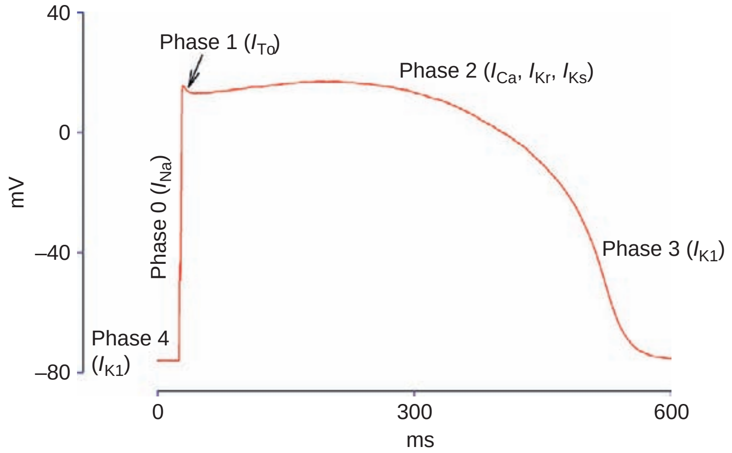

Figure 1 Different phases of cardiac action potential in a ventricular myocyte of the rainbow trout. Five phases (phase 0–phase 4) and ion currents responsible for those voltage changes are indicated. Transient outward current (I_{To}) responsible for phase 1 has not been examined in fish.

Excitation-Contraction Coupling: Calcium and the Contractile Element).

The last phase of cardiac AP (phase 3) is the fast restoration of the negative RMP or final repolarization, which initiates a decrease of cytosolic calcium concentration by turning a net sarcolemmal calcium influx into a net calcium efflux and thereby results in cessation of the systole. Restoration of the RMP is essential for two reasons: it moves the heart into diastole and allows refilling of the atrium and ventricle with blood. Further, it restores the excitability of the cell membrane. Recovery of voltage-gated ion channels from the inactivated state requires a certain time at negative membrane potentials to restore the three-dimensional conformation which is necessary for their opening.

The Ionic Basis of AP

The changes in membrane voltage associated with the AP require electrical charge to be moved across the cell membrane. These electrical charges are mainly carried by sodium, calcium, and potassium ions that pass through ion-specific channels of the sarcolemma (**Figure 1**). Ion channels are integral membrane proteins that form waterfilled pores in the lipid membrane. There are several families of ion channels, each including several channels with distinct ion specificities, voltage dependences, and opening and closing rates.

The stable RMP of atrial and ventricular myocytes is maintained by a diffusion of potassium through potassium-selective pores called the inward rectifier (Kir2) channels. In resting myocytes, the Kir2 channels are constantly open and allow a small efflux of potassium out of the cell (I_{K1}, an outward current) that balances any inward leakage of positively charged ions into to the cell. Potassium efflux through the Kir2 channels locks the membrane potential to the equilibrium potential of potassium ions, until depolarization from the neighboring myocytes will distort the membrane potential from its resting value.

The phase 0 upstroke of AP is produced by sodium influx into the myocyte via sodium-selective ion channels. Sodium channels open and close rapidly generating very fast and transient sodium current (I_{Na}, an inward current) that quickly depolarizes the membrane potential. The larger the I_{Na}, the faster the rate of AP upstroke, that is, the voltage change at the site of AP generation that then excites the next site. The size of I_{Na} is dependent on the density of sodium channels in the cell membrane, and therefore conduction velocity of the AP is determined by the number of sodium channels per unit of membrane area.

Depolarization of the sarcolemma causes closing of the Kir2 channels as the changing membrane voltage drives intracellular magnesium ions and free polyamines (spermine and spermidine) into the pore of these channels thereby clogging them. On the other hand, sodium-dependent depolarization of cell membrane triggers opening of the voltage-dependent calcium channels, which mediate calcium influx (I_{Ca}, an inward current) into the cell and contribute to the long phase 2 plateau of the cardiac AP. During the plateau, changes in membrane potential are small, since a small efflux of potassium through various potassium channels and calcium influx through L-type calcium channels almost cancel each other and practically prevent changes of membrane potential.

Toward the end of the plateau, depolarization of cell membrane causes opening of various voltage- and time-dependent potassium channels, thereby increasing potassium efflux across the membrane. Enhanced potassium efflux together with decreasing calcium influx initiates repolarization of cell membrane at the end of phase 2. There are two main voltage-dependent potassium currents, the rapid and slow component of the delayed rectifier (I_{Kr} and I_{Ks}, respectively), which contribute to the initiation of repolarization. When these channels start to repolarize the cell membrane, the increasing polarization of membrane potential unplugs the Kir2 channels (by forcing magnesium and polyamines out of the channel pore), which then terminates AP by the fast repolarization of phase 3 and restores the RMP (phase 4).

The Shape of AP Varies in Different Sites of the Heart

The basic shape of the cardiac AP, as exemplified by the ventricular AP, is modified according to the varying requirements of different cardiac compartments (**see also Design and Physiology of the Heart:** Cardiac Anatomy in Fishes), producing an ordered propagation of electrical excitation (**Figure 2**) and contraction. The electrical excitation of the fish hearts originates from a small aggregation of specialized myocytes located in the junction between the sinus venosus and the atrium as a ring-formed structure. The cells of the sinoatrial tissue generate APs, which first spread to and among atrial myocytes, triggering atrial contraction, and then to and among the ventricular muscle. Between the atrium and the ventricle, the spread of the electrical impulse is slowed in the myocytes of the atrio-ventricular canal, creating a sufficient delay that allows enough time to fill the ventricle with blood before the contraction of ventricular wall begins. From the myocytes of the atrio-ventricular canal AP is rapidly conducted to the apex of the ventricle and, from there, toward the base of the ventricle triggering a squeezing contraction of ventricular muscle and forcing blood toward and into the bulbus arteriosus.

Pacemaker APs

Pacemaker cells of the sino-atrial tissue usually lack the I_{K1} described above and therefore do not have a stable

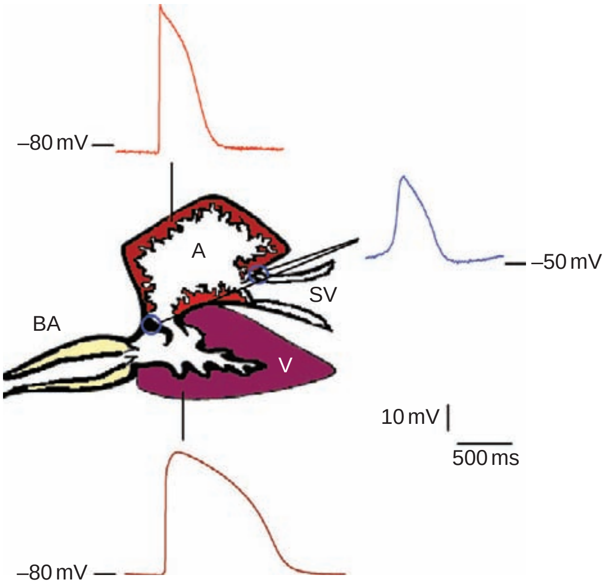

Figure 2 Schematic presentation of action potential shapes in different parts of the fish heart. Spontaneously firing nodal tissues of the sino-atrial junction and the atrio-ventricular canal are indicated with blue rings. SV, sinus venosus; A, atrium; V, ventricle; BA, bulbus arteriosus.

RMP. Instead, phase 4 is characterized by a slowly rising diastolic depolarization, also called pacemaker potential that results in spontaneous firing of pacemaker APs. Several ion channels/transporters of the cell membrane and calcium released from the sarcoplasmic reticulum are involved in the generation of the pacemaker AP, but the mechanism of cardiac pacemaking is still heavily disputed.

Steepness of diastolic depolarization dictates the firing rate of the pacemaker cell: the steeper the rate of rise, the sooner the threshold voltage for the firing of the upstroke is achieved. In pacemaker cells, the AP upstroke is generated by calcium currents, and not by sodium channels as in the nonpacemaker tissues. Since each pacemaker firing triggers a heartbeat, the steeper the pacemaker potential, the higher the heart rate.

In rainbow trout of 200–300 g in body mass, the circular nodal tissue is about 0.2 mm in width (diameter) and 3 mm in height and contains approximately 30 000 myocytes. However, there are probably only a few number of small primary pacemaker cells that have fast diastolic depolarization and which determine the heart rate. The nodal tissue also contains secondary pacemaker cells with slightly shallower diastolic depolarization and therefore lower firing rate. In these cells, the rate of final upstroke is faster and they conduct impulse faster than the primary pacemaker cells. The cells of the atrio-ventricular canal also produce slowly rising pacemaker APs.

Atrial AP

Atrial and ventricular myocytes have a stable negative RMP of about –70 to –90 mV, maintained by the I_{K1} current, and therefore need an inward current flow (depolarization) from a neighboring myocyte to elicit their own AP. It is the current flow from the pacemaker cells (pacemaker AP) that elicits AP in atrial myocytes. Primary and secondary pacemaker cells are electrically coupled to atrial cells, and when electric current from pacemaker cells depolarizes the RMP of atrial myocytes to the threshold value of about –60 mV, that is, to voltage where inward I_{Na} exceeds outward currents through potassium channels, a fast depolarization is blown out. Electrical coupling among atrial cells enables a fast spread of AP throughout the atrial myocardium.

The fast upstroke and short duration of the atrial AP compared with that of ventricular AP are functionally important as they enable fast atrial emptying into the ventricle. The faster upstroke of atrial AP results in a faster impulse conduction through atrial muscle. The shorter duration of the atrial AP results in a shorter duration of atrial contraction.

These distinctive features of the atrial AP are due to specific ion channel composition of atrial myocytes. The density of the I_{K1} is usually much smaller in atrial than ventricular myocytes, which makes them more easily excitable by current flow from the pacemaker tissue. On the other hand, the density of the I_{Kr} is much larger than in ventricular myocytes, which helps to limit the duration of atrial AP. At least in some fish species (e.g., crucian carp, *Carassius carassius*), the slow component of the delayed rectifier potassium current (I_{Ks}) is also present.

AP of the atrio-ventricular canal

The atrial muscle AP is conducted to the ventricle via the atrio-ventricular canal along the myocytes in the inner layer of the canal. Here, the AP has a similar shape as in the primary pacemaker tissue of the sinoatrial ring. This has several important implications: (1) the rate of AP upstroke is slower, delaying the conduction of the impulse and allowing adequate filling of the ventricle with blood; (2) the AP does not have stable RMP and therefore myocytes of the atrio-ventricular canal can function as an ancillary pacemaker – this would only become important if the sino-atrial pacemaker fails or if atrial conduction is blocked for some reason because the pacemaker potential is not as steep as that for the primary pacemaker cells; and (3) atrial tissue is prone to arrhythmias, which could easily propagate to the ventricle and generate detrimental ventricular arrhythmias without the slow conduction of the atrio-ventricular canal.

Ventricular AP

Ventricular APs are characterized by fast upstroke and long plateau duration. They are elicited by impulses from the atrial tissue by the myocytes of atrio-ventricular canal. Long AP duration is correlated with longer duration of contraction in comparison to atrial muscle. The long plateau phase makes the ventricular myocardium less vulnerable to arrhythmias than the atrial muscle. The ventricular contraction proceeds from the apex of ventricle to the base of the ventricle, thereby giving forward direction to the blood flow toward the bulbus arteriosus. In order to do this, the AP must be quickly conducted from the atrio-ventricular canal to the apex of the ventricle. It is not known how this happens, since corresponding histological structure to the mammalian His–Purkinje conduction pathway has not been found in the fish ventricle.

Species-Specific Differences in AP

There are large species-specific differences in shape and duration of cardiac AP among teleost fishes (**Figure 3**). In general, the more active or athletic species, which tend to have higher heart rates, also have shorter atrial and ventricular APs than more sluggish species. Relatively short cardiac APs are found, for example, in rainbow trout and perch (*Perca fluviatilis*), while long APs are typical, for example, in the less athletic swimmers such as the crucian carp. At 18 °C, the duration of atrial AP ranges from about 150 ms (roach, *Rutilus rutilus*) to 350 ms (crucian carp), while the duration of ventricular AP varies from approximately 315 ms (rainbow trout) to 740 ms (crucian carp and burbot, *Lota lota*). At 4 °C, the duration of fish cardiac AP is 2–4 times longer than at 18 °C. Species-specific differences in AP duration are due to variation in ion channel densities and differences in ion channel isoforms among the fish.

Effects of Autonomic Nervous Transmitters

The rate and force of cardiac contraction are modulated by the autonomous nervous system through the parasympathetic cholinergic and the sympathetic adrenergic nervous systems via release of acetylcholine and adrenaline, respectively. These changes must, in the first instance, involve alterations to the AP shape.

Pacemaker cells, atrio-ventricular canal myocytes, and atrial myocytes are particularly densely innervated by the autonomic nerves (**see also Design and Physiology of the Heart:** Cardiac Anatomy in Fishes). Acetylcholine, the neurotransmitter released from the parasympathetic nervous system, has a strong effect on APs of pacemaker cells and atrial myocytes. Acetylcholine release slows heart rate by strongly decreasing the rate of diastolic depolarization of the primary pacemaker cells. Low concentrations of acetylcholine markedly shorten the AP duration of atrial myocytes, greatly weakening atrial contraction. In some fish species (tilapia *Oreochromis nilotica* and *O. aureus*, crucian carp) shortening of AP occurs at lower concentrations than its pacemaker effect, causing a depression of atrial contraction before any changes appear in the heart rate. The effects of acetylcholine are mediated by a specific kind of inward rectifier potassium channels, which are activated by binding of acetylcholine to the muscarinic cholinergic receptors of the myocyte plasma membrane and by the inhibition of I_{Ca}.

The effects of the sympathetic nervous system are much weaker in comparison to those of the parasympathetic nervous system in fish. The effects of adrenergic neurotransmitters on cardiac AP are relatively poorly elucidated in fish. In the goldfish (*Carassius auratus*) adrenaline increases the duration of atrial and ventricular AP, while in the winter-acclimatized eel (*Anguilla anguilla*) adrenaline prolongs ventricular AP without effect on atrial AP. Lengthening of AP duration is produced by the increased density of I_{Ca} and results in stronger heartbeats.

Effects of Oxygen Shortage

In mammalian hearts, hypoxia directly and greatly shortens the cardiac AP, which helps to reduce the energetic adenosine triphosphate (ATP) demand of the myocyte and aids survival of the hypoxic cell. AP duration is shortened due to the opening of sarcolemmal ATP-sensitive potassium channels. In the fish heart, the effects of hypoxia on the duration of cardiac AP are

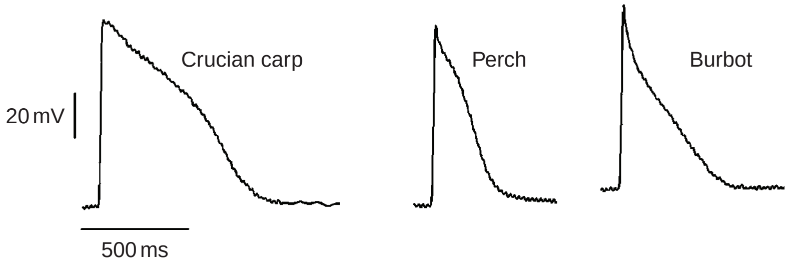

Figure 3 Comparison of atrial action potentials (APs) from crucian carp, perch, and burbot hearts. Note the triangular shape of burbot AP and large differences in AP duration between crucian carp and perch atria.

apparently much milder or even opposite to that of the mammalian heart, despite ATP-sensitive potassium channels also being present in fish heart. A small shortening of ventricular AP has been noted in the hypoxic goldfish heart, while a modest prolongation of cardiac AP is present in the cyanide poisoned (anoxic) ventricle of the crucian carp, a sibling species to the goldfish. Similar effects can be deduced from the QT segment of the ECG in other fish species during hypoxia. These findings suggest that hypoxic shortening of cardiac AP duration may be superseded by vagally mediated bradycardia, which is a reflex unique to fishes (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia).

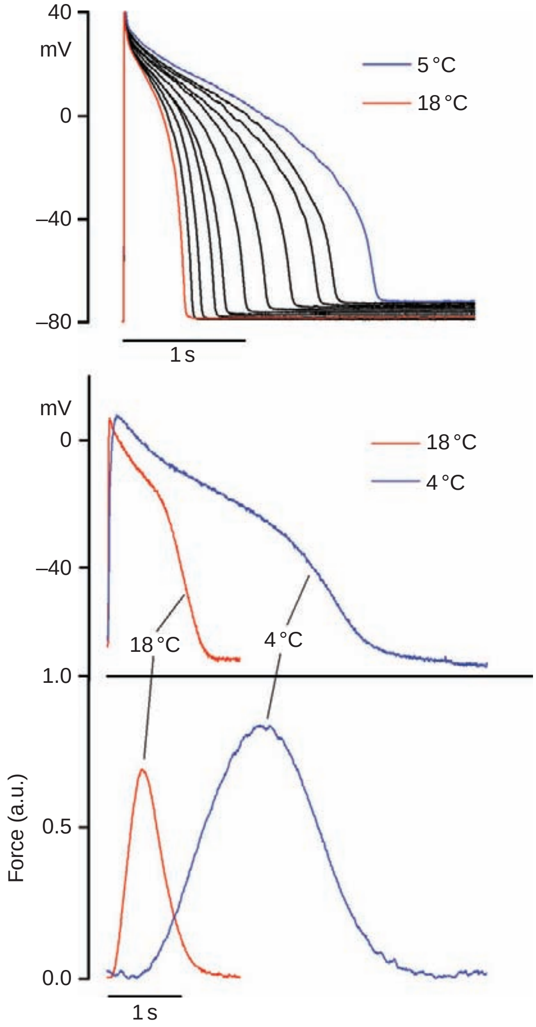

Figure 4 Temperature has strong effect on the duration of fish cardiac AP and contraction. (Top) Continuous recording of AP from a ventricular myocyte of crucian carp when temperature was gradually elevated from 5 to 18 °C. Note the shortening of AP duration and increase in RMP. (Middle and bottom) Effects of temperature change on ventricular AP and associated contractions in crucian carp heart at 4 and 18 °C. Modified from Paajanen V and Vornanen M (2004) Regulation of action potential duration under acute heat stress by $I_{K,ATP}$ and I_{K1} in fish cardiac myocytes. *American Journal of Physiology* 286: R405–R415.

Effects of Temperature Changes

The cardiac AP is strongly changed by temperature (**Figure 4**). Lowering of temperature increases the duration and reduces the rate of upstroke of cardiac AP (**see also Temperature:** Temperature and Excitable Membranes). As a consequence, heart rate and velocity of impulse conduction over the heart are depressed, and the duration of contraction of each cardiac myocyte lasts longer. The longer duration of AP allows more time for calcium influx through the sarcolemma and at least partly compensates for the temperature-dependent decrease in calcium influx via I_{Ca}. Prolonged depolarization also allows more time for the myofilaments to generate force. On the other hand, due to the prolonged AP contraction–relaxation cycle gets longer and may limit maximum heart rates at low temperatures. Due to these changes in electrical activity of cardiac myocytes, the fish heart becomes sluggish in the cold but may contract more forcefully. However, in several fish species chronic exposure to low temperatures results in compensatory changes in cardiac AP. Cold-induced increase in the density of I_{Na} partly alleviates the temperature-dependent depression in the rate of AP upstroke and velocity of impulse conduction, while upregulation of sarcolemmal potassium currents counteracts temperature-dependent prolongation of AP. These cold-induced changes in ion channel function make room for positive compensation in heart rate and hence cardiac output, which may be adaptive at seasonally changing temperature conditions at north-temperature latitudes.

Glossary

ATPase A protein whose activity is fueled by the hydrolysis of adenosine triphosphate (ATP). Key ATPases involved in excitation–contraction coupling are Ca-pumps and myosin ATPases.

Buffers Proteins that bind and hold other molecules. They can bind a given molecule strongly (high affinity) or bind a large number of a given molecule (high capacity). The affinity and capacity are determined by the type of buffer and by physical variables such as temperature and pH.

Ca transient The term used to describe the transient rise and fall of cytosolic Ca with each contraction–relaxation cycle.

Ca-pump Proteins (such as sarco(endo)plasmic reticulum Ca-ATPase or plasma membrane Ca-ATPase) that utilize the energy of adenosine triphosphate to pump Ca across a membrane, usually against a concentration gradient. These are often called Ca-ATPases.

Calcium-induced calcium release (CICR) The term that describes how extracellular Ca influx across the cell membrane induces the release of Ca from the intracellular stores of the sarcoplasmic reticulum.

Cell-surface-area-to-volume ratio A mathematical expression of the amount of cell membrane (area) divided by the amount of intracellular space (cytosolic volume).

Contractility A measure of the power and/or the capacity of myofilament contraction.

Cytosol The fluid part of the intracellular space, which exists between the cell-surface membrane and the membrane-bound organelles.

Depolarization The reduction in electrical potential difference (voltage) measured across a cell membrane. This means the inside of the cell becomes less negative with respect to the outside of the cell. Depolarization occurs during the upsweep of the action potential (opposite of repolarization).

Excitability The capability of a living cell to respond to stimuli and is often related to membrane voltage.

Excitation–contraction coupling The term used to describe the progression from membrane excitation with an AP to the rise of the Ca transient to cell contraction.

Force–frequency relationship The term which describes how the strength of cardiac contraction varies with the frequency of cardiac contraction. If force increases as contraction frequency increases, it is called a positive force–frequency relationship. If force decreases with increased contraction frequency, it is called a negative force–frequency relationship. Most fish show a negative force–frequency relationship across their normal range of heart rates.

Hormones Substances produced by one tissue that are transported to another tissue to induce a physiological response.

Myofilaments The contractile apparatus of the myocyte (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element).

Plasma membrane Ca-ATPase (PMCA) The Ca pump on the sarcolemmal membrane that transports Ca out of the cell.

Repolarization A change of membrane voltage back to the polarized state that prevailed before the action potential was generated, i.e., increase in the negativity of membrane potential.

Rest (resting) state When the membrane of an excitable cell is not excited. The membrane is held in a polarized state called 'the resting membrane potential' awaiting a depolarizing action potential (**see also Design and Physiology of the Heart**: Action Potential of the Fish Heart).

Sarco(endo)plasmic reticulum Ca-ATPase (SERCA) The Ca pump on the sarco plasmic reticulum (SR) membrane that is responsible for pumping Ca out of the cytosol and into the SR.

Steady state This is achieved when Ca flux routes are balanced so that the amplitude and rate of the Ca transient is the same from beat to beat.

Working myocardium The regions of the heart that contract and propel the blood when excited via excitation–contraction coupling. These muscular regions are made up of the contractile myocytes of the atrium and ventricle.

Introduction

The cardiac action potential (AP) and the ion channels that open and close to excite the cardiac myocyte are discussed in **Design and Physiology of the Heart**: Action Potential of the Fish Heart; this article focuses on the cellular Ca fluxes that result from the cardiac AP and lead to myocyte contraction. Specifically, this article explores the sources and routes of Ca movement during each contraction–relaxation cycle. The contraction–relaxation cycle is the cellular equivalent of the heartbeat. Routes of cellular Ca flux associated with the contraction–relaxation cycle are very important for understanding heart contractility because the rate (how fast) and magnitude (how much) Ca movement directly determines the rate and strength heart contraction. How Ca actually causes contraction the myofilaments in fish cardiac cells is explained in **Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element.

The Ca Transient

The most important term in this article is the 'Ca transient'. It is often abbreviated as $\Delta[\mathrm{Ca}^{2+}]_i$, where Δ is a change in intracellular ('$_i$') Ca concentration ($[\mathrm{Ca}^{2+}]$) during a single contraction–relaxation cycle. A typical Ca transient from a mammalian cardiac myocyte is shown in **Figure 1**. One can see that Ca (blue line) rises quickly (~100 ms) and then decays more slowly (~400 ms), thus causing the characteristic shape of the transient change in intracellular Ca concentration.

The Ca transient actually refers to the change in 'free' Ca inside the cytosol. A large amount of Ca is not free inside the cell but rather is bound to buffers. Buffers are proteins that bind other molecules. For example, a Ca buffer binds Ca. The amount of Ca that a buffer can bind and the strength of the binding greatly vary. Very little is known about the buffering power of the fish cardiac myocyte; hence, for the purpose of this article we will assume it does not differ sizably from mammals. The important point to remember is that because the Ca transient is a measure of free Ca, much larger amounts of total Ca are required to activate a free Ca transient of a given magnitude.

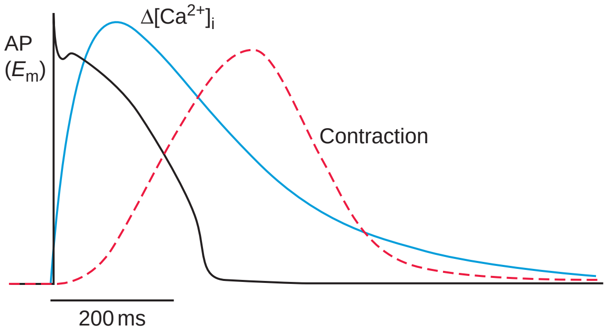

Figure 1 The three key events in the process of excitation–contraction coupling. The figure shows the time course of an action potential (black line), Ca transient (blue line), and myocyte contraction (red dashed line). Data are from a rabbit ventricular myocyte at 37 °C. Adapted from figure 1 inset in Bers DM (2002) Cardiac excitation–contraction coupling. *Nature* 415: 198–205.

Excitation–Contraction Coupling

Excitation–contraction (e–c) coupling is the term used to describe the progression from membrane excitation with an AP to the rise of the Ca transient to myocyte contraction. The time course of e–c coupling can be observed for a mammalian myocyte in **Figure 1**. Notice the central role of the Ca transient (blue line). It is the link between cardiac excitation (black line showing the AP) and cardiac contraction (dotted red line).

As discussed in **Design and Physiology of the Heart**: Action Potential of the Fish Heart, there are a number of different types of myocytes that make up the fish heart and each are specialized for different functions. For example, some cells do not contract very much but are important in electrical conduction (i.e., pacemaker cells). The process of e–c coupling usually refers to the cardiac myocytes that are powering cardiac contraction. These are the myocytes of the atrium and the ventricle. Thus, in this article, the term cardiac myocyte refers to an atrial or ventricular myocyte that is part of the working myocardium.

When thinking about routes of cellular Ca flux during e–c coupling, it is perhaps best to visualize a schematic model through which one can track Ca movement. A schematic model of a fish cardiac myocyte is provided in **Figure 2**. The key components involved in cellular Ca flux are labeled and briefly described in the legend, but each is discussed in detail later.

The most important aspect of myocyte morphology for e–c coupling is the large surface area-to-volume ratio found in fish myocytes, which is on average fourfold greater than in mammals. Thus, for any given volume of cytosol, there is four times as much area of membrane through which Ca can enter in the fish myocyte than in the mammalian myocyte. Consequently, this increase in surface area-to-volume ratio increases the effectiveness of extracellular ion flux pathways in changing the ionic makeup of the cytosol.

Figure 2 shows how the sarcolemma (SL) is the outer cell membrane and the interface between the extracellular and intracellular space (cytosol). Embedded in that membrane are a number of ion channels (**see also Design and Physiology of the Heart**: Action Potential

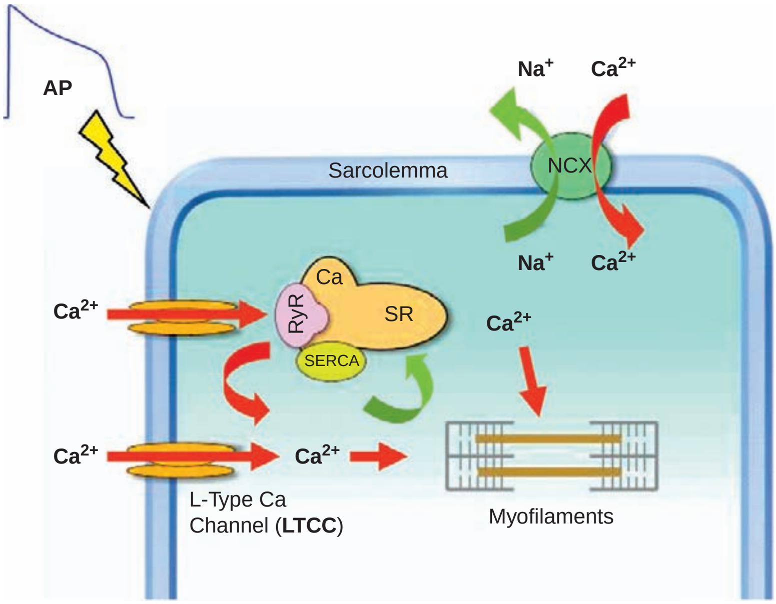

Figure 2 Schema for excitation–contraction coupling in the fish cardiac myocyte. The figure shows a portion of a fish cardiac myocyte. The sarcolemma (SL) is the cell membrane separating the intra- and extracellular space. The figure shows the SL being excited by an action potential (AP) which opens L-type Ca channels (LTCC) in the cell membrane allowing Ca influx (red arrows) down its concentration gradient into the cell. Ca can also enter the cell via reverse-mode Na–Ca exchange (NCX). Ca influx can trigger Ca release from the sarcoplasmic reticulum (SR) through ryanodine receptors (RyR). Together, these Ca influxes cause a transient rise in Ca that initiates contraction at the myofilaments. Relaxation occurs when Ca is removed from the cytosol (green arrows) either back across the SL via forward-mode NCX or back into the SR via the SR Ca-pump (SERCA).

of the Fish Heart that allow ions to pass from outside to inside or inside to outside. The key SL membrane proteins involved in the Ca transient are the L-type Ca channels (LTCC) and the Na–Ca exchanger (NCX). These proteins are responsible for the movement of Ca and Na across the SL membrane.

The key intracellular structure involved in generating the Ca transient is the sarcoplasmic reticulum (SR). This organelle can store large amounts of Ca (~1 mM) and can release a portion of it into the cytosol during e–c coupling. Ca release from the SR occurs primarily through proteins called ryanodine receptors. Ca can be removed from the cytosol by reuptake into the SR via a Ca pump called sarco(endo)plasmic reticulum Ca-ATPase (SERCA). Ca is buffered inside of the SR with a protein called calsequestrin. There are a number of other intracellular organelles, such as the mitochondria and the nucleus, that can accumulate Ca, but this Ca is not directly involved in e–c coupling; therefore, it is not dealt with in this article.

The myofilaments are also illustrated in **Figure 2**. Ca must bind to the myofilaments for contraction to occur and be removed from the myofilaments for relaxation to proceed. The rise and fall of cytosolic Ca determines the interaction between Ca and the myofilaments, and hence myofilament contraction, as discussed in **Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element.

Finally, there are a number of other buffers in the cytosol that bind Ca with different affinities and rates. Although these will impact on the shape and rate of the Ca transient, no information exists for these buffers in the fish heart and therefore, they are not further discussed.

The Rising Phase of the Ca Transient

The rising phase of the Ca transient in **Figure 1** is due to Ca influx into the cytosol. This Ca can be of extracellular origin (coming in across the SL) or of intracellular origin (released from the SR). The relative contribution of each Ca source can vary between fish species. Similarly, the source of Ca contributing to the mammalian Ca transient varies. The relative contribution of SR versus SL Ca flux is dependent upon species, tissue type (atrium or ventricle), and development stage. In fish, in general, the extracellular Ca route is by far the most important for contributing Ca to the Ca transient. The SR plays a minor role (<15%). However, in certain species, such as rainbow trout and tuna, and under certain conditions, Ca release from the SR can play a greater (up to 60%) role. Important modulators of the relative importance of SR Ca release are temperature and heart rate. These are discussed later on.

Extracellular Ca Influx – the LTCC

The main Ca influx pathway across the SL is the LTCC. This is a voltage-gated ion channel that is closed when the membrane is at rest but opens during depolarization (e.g., during an AP) allowing Ca to flow into the cell. There is a large driving force for Ca influx when these channels open because the concentration of extracellular Ca (millimolar range) is more than 100-fold greater than the concentration of intracellular Ca (nanomolar range). This large driving force, the high number of LTCCs in the cell membrane, and the large surface area-to-volume ratio are responsible for the rapid rising phase of the Ca transient. This rapid rising phase is evident in the Ca transients from a bluefin tuna (*Thunnus orientalis*) cardiac myocyte (**Figure 3**). One can measure the amount of Ca entering the cell via LTCC during an AP in fish myocytes using electrophysiological techniques. Studies show that between 20 and 80 μmol l^{-1} of Ca can enter the fish myocyte through LTCCs (with the exact amount depending on fish species and method of investigation). This Ca influx generates a Ca transient that is alone of sufficient concentration to initiate myofilament interactions and myocyte contraction.

It is important to notice that the rising phase of the Ca transient, though rapid, is short. This is because LTCCs stop conducting Ca soon after opening, which is termed 'ion-channel inactivation'. This inactivation depends on two features: the repolarization of the membrane during the AP (voltage-dependent inactivation), and the fact that Ca itself can stop the channel from conducting more Ca (Ca-dependent inactivation). The cessation of Ca conductance is very important for the heart. Without it, cytosolic Ca would stay elevated and the heart would not be able to relax and thus not be able to fill with blood between beats.

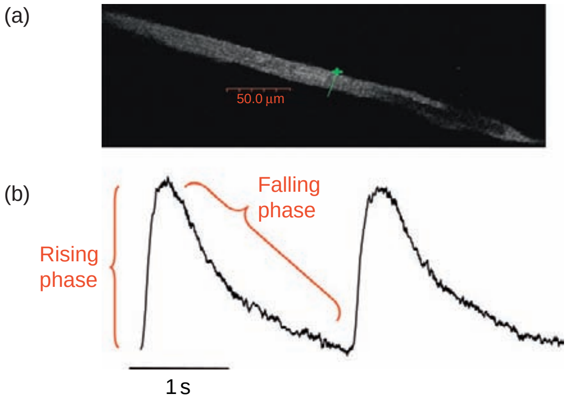

Figure 3 Cellular Ca transient in a ventricular myocyte of the bluefin tuna (*Thunnus orientalis*). (a) A tuna myocyte filled with a fluorescent dye that images Ca. The green line shows where in the myocyte the Ca transient (b) is measured from. (b) The time course of two consecutive Ca transients from the above myocyte. The fast rising phase and the slow decaying phase of the transient are clearly visible. Adapted from figure 2 in Shiels HA, Di Maio A, Thompson S, and Block BA (2011) Warm fish with cold hearts: Thermal plasticity of excitation–contraction coupling in bluefin tuna. *Proceeding of the Royal Society B* 278: 18–27

Extracellular Ca Influx – the NCX

The primary role of the NCX is to remove Ca from the cytosol. The NCX transfers three Na^{+} and one Ca^{2+} in opposite directions across the SL membrane. Because of the unequal charge transfer (Na movement carries a net charge of 3 and Ca carries a net charge of 2), there is a net movement of positive charge in the direction of Na transport. When the myocyte is at rest, the exchanger moves Ca out of the cell and brings Na in. This is called 'forward-mode exchange' and is important for the decaying phase of the Ca transient as dicussed later on.

The NCX can also bring Ca in across the SL membrane and can thus contribute to the rising phase of the Ca transient. This is called 'reverse-mode exchange'. This Ca influx mechanism is dependent on the membrane potential. During the upsweep (i.e., phase 0; **see also Design and Physiology of the Heart**: Action Potential of the Fish Heart) of the AP when the membrane is depolarized, the exchanger reverses direction and brings Ca into the cell and moves Na out. The direction of the exchanger is secondarily dependent on the concentrations of Ca and Na on either side of the membrane. Thus, the direction of ion transport on the exchanger is dependent on both the membrane potential and ion concentrations.

There are only a small range of membrane voltages (~0–10 mV during a normal AP) that favor reverse-mode Ca influx via the NCX. In most mammalian myocytes, this Ca-influx pathway is not very important to the rising phase of the Ca transient. However, the high surface area-to-volume ratio enhances the effectiveness of this pathway in fish myocytes. Further, fish tend to have a higher intracellular Na concentration, which again enhances the efficacy of reverse-mode NCX. As a result, Ca influx via this pathway can be a significant contributor to the rise of the Ca transient in fish compared with mammals. Indeed, the Ca transient resulting from Ca influx on the NCX is alone sufficient to cause partial myofilament contraction in most fish species studied to date. In rainbow trout, inhibiting Ca influx on the NCX reduces the contractility of the myocytes by 30–50%. In crucian carp (*Carassius carassius*), ~70 μmoll $^{-1}$ can be brought into the cell during the upsweep of an AP via reverse-mode NCX. Together, the NCX and the LTCC therefore can bring in ~150 μmoll $^{-1}$ Ca from the extracellular space, which generates a Ca transient of sufficient magnitude to activate a full-scale contraction in crucian carp. Of this amount, almost 50% of the total SL Ca influx occurs via reverse-mode NCX.

Similar to the LTCC, there are processes that stop Ca influx on the NCX, thereby limiting the size and duration of the rising phase of the Ca transient. The first is repolarization of the membrane potential during phase 3 of the AP (**see also Design and Physiology of the Heart**: Action Potential of the Fish Heart), which removes the permissive membrane voltage window for Ca influx. Second, as the Ca transient rises, the concentration of Ca in the cytosol rises reducing the favorable concentration gradient for Ca influx on the NCX. In fact, together, the repolarization of the membrane and the rising phase of the Ca transient itself cause the NCX to change direction and start moving Ca out of the cell. As discussed more in the following sections, this switch to forward-mode NCX activity (Ca pumped out) is important for the decay of the Ca transient and myocyte relaxation.

Thus, the inactivation of the LTCCs and the change in direction of the NCX brings the contribution of extracellular Ca influx to the rising phase of the Ca transient to an end.

Intracellular Ca Flux – SR

The SR is a large intracellular membranous network-like organelle that forms intimate contacts with the SL and the myofilaments. The primary role of the SR in cardiac myocytes is to act as a site for regulated storage and release of Ca. The amount of SR in the fish myocyte varies between species and although there are exceptions to this rule, it appears that active fish, such as salmonids (e.g., salmon and trout) and scombrids (e.g., tuna and mackerel), have a greater amount of SR than less active species (e.g., carp).

In general, the fish SR plays a minor role in e–c coupling compared with adult mammals. For example, in rainbow trout, release of Ca from the SR contributes ~15–20% of the Ca in the Ca transient; the remainder comes across the SL via LTCCs or reverse-mode NCX. In contrast, in the adult rat, ~15–20% comes in across the SL and the rest is released from the SR. Thus, e–c coupling in fish differs from mammals primarily with respect to the role of the SR in Ca transient formation. In mammals, extracellular Ca influx is small and contributes only a small amount of Ca to the rising Ca transient. Even so, this small influx is vital as it acts as an ionic trigger to cause the ryanodine receptors to open and the SR to release its Ca into the cytosol. This process is called Ca-induced Ca release (CICR) and is discussed subsequently. This SR Ca release is far larger than the Ca influx across the SL and thus, the rate and magnitude of SR Ca release is the key determinant of the rising phase of the Ca transient in mammals.

Ca-Induced Ca Release

The process by which Ca influx across the SL causes Ca release from the SR is called CICR. A role for CICR is hotly debated for fish cardiac myocytes. It is completely absent in some fish species, usually (but not always) in slow and sluggish fish such as carp. Athletic fish with fast heart rates and high blood pressures (such as salmon and tuna) often show more CICR. Ca release from the SR therefore plays a larger role in the rise of the Ca transient in these species. This is illustrated for bluefin tuna myocytes in **Figure 4**. Clearly, inhibiting the SR (and thus CICR) reduces the overall Ca transient amplitude and slows the rising phase of the Ca transient in this species. Also apparent is how inhibiting the SR slows the falling phase of the Ca transient. This is discussed subsequently.

Under supra-physiological conditions (10 μM isoprenaline – a pharmacological opener of LTCCs), SL Ca influx can result in significant CICR in the rainbow trout myocyte, but its physiological role is still unclear. Current research suggests that physiological stimuli, such as rapid changes in temperature and *in vivo* levels of adrenergic stimulation, can increase the importance of CICR in rainbow trout cardiac myocytes. Nevertheless, only a small percentage (<10%) of total SR stores appears to be released via CICR in fish myocytes.

Theoretically, the Ca influx across the SL that causes CICR can be through either or both the LTCC and the NCX. In mammals, it is almost exclusively via the LTCC. However, due to the larger role for Ca influx on the NCX

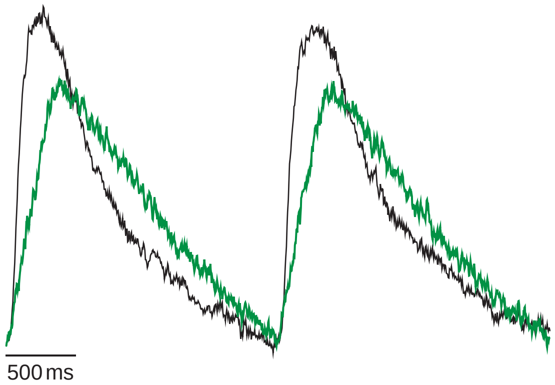

Figure 4 Role of the SR in the Ca transient in the bluefin tuna (*Thunnus orientalis*) ventricular myocyte. The black line shows the Ca transient under normal conditions. The green line shows the effect of inhibiting SR Ca release and SR Ca uptake on the shape of the Ca transient. In this species, inhibiting SR Ca release decreases Ca transient amplitude and slows the rising phase of the Ca transient. Inhibiting SR Ca uptake slows the decay of the Ca transient. These experiments were conducted at 14 °C. Adapted from figure 3 in Shiels HA, Di Maio A, Thompson S, and Block BA (2011) Warm fish with cold hearts: Thermal plasticity of excitation–contraction coupling in bluefin tuna. *Proceeding of the Royal Society B* 278: 18–27.

in fishes, studies show that NCX can induce CICR in the fish myocyte.

In general, the contribution of the intracellular Ca stores of the SR to the rise in the Ca transient is small for most fish studied to date. However, due to the large surface area-to-volume ratio of the fish myocyte, the peripheral location of myofilaments and the high efficacy of SL Ca flux pathways, the SR's Ca store may not be necessary for e–c coupling under normal conditions. The fact that large levels of adrenergic stimulation can induce greater CICR may suggest that under periods of stress or intense activity, the SR stores are released to augment SL Ca fluxes and generate a larger and faster Ca transient. This could create a stronger faster heart beat, enabling the fish to escape/survive adversity.

The Effect of Temperature on the Rising Phase of the Ca Transient

Fish body temperature is dependent on the temperature of their environment. Thus, when water temperature changes, cardiac temperature changes. The rate and amplitude of the rising phase of the Ca transient is directly affected by temperature. This is illustrated for a rainbow trout atrial myocyte in **Figure 5**. **Figure 5(a)** shows the effect of rapid (seconds) temperature change on the Ca transients, and **Figure 5(b)** shows the effect on Ca influx through LTCCs. Warm temperatures tend to speed up the rate of rise of the Ca transient. This is partially because of the effect of temperature on Ca influx via LTCCs, which is faster and greater in amplitude at warm temperatures (larger downward deflection in **Figure 5(b)**). Cool temperatures tend to slow down the rate of rise and also increase the amplitude of the Ca transient. This is because slower kinetics allow more time for Ca influx across the membrane through LTCC.

Fish cannot avoid temperature effects on their heart cells when they swim through water of different temperatures. However, certain hormones can compensate for the effects of temperature on cellular Ca flux. For example, adrenaline is released when a fish moves rapidly into water of a new temperature and it stimulates Ca flux through the LTCC.

Interestingly, unlike the LTCC, Ca flux via NCX is not dramatically affected by either rapid temperature change or adrenergic stimulation in fish. This means that this pathway operates independent of rapid changes in environmental temperature, certainly a beneficial feature for maintaining heart function of fish living in fluctuating environments.

Rapid temperature changes can also affect the Ca transient by changing the rate at which the heart beats. Warm temperatures increase heart rate through direct action on the pacemaker rate (**see also Design and Physiology of the Heart**: Action Potential of the Fish Heart). Increased frequency of contraction causes a decrease in the amplitude of the intracellular Ca transient. This reduces the force of contraction and is termed the negative force–frequency relationship. The negative force–frequency relationship impacts the ability of the heart to beat forcefully at fast contraction rates. Most fish do not have fast heart rates; they are typically below 120 beat per minute (2 Hz) even at warm temperatures. Fish compensate for this limitation in maximum heart rate by having stretchy hearts that can pump large volumes of blood (albeit slowly). This works because cardiac output is the product of heart rate and the volume of blood pumped by the heart. If heart rate is limiting, then cardiac output can be modulated by changing the volume of blood pumped at a given rate. These ideas are discussed in more detail in **Design and Physiology of the Heart**: Cardiac Cellular Length-Tension Relationship.

Seasonal temperature changes also impact cellular Ca flux in fish hearts. When fish are chronically exposed to the cold (e.g., during winter) they compensate by building more SR in their myocytes and the SR

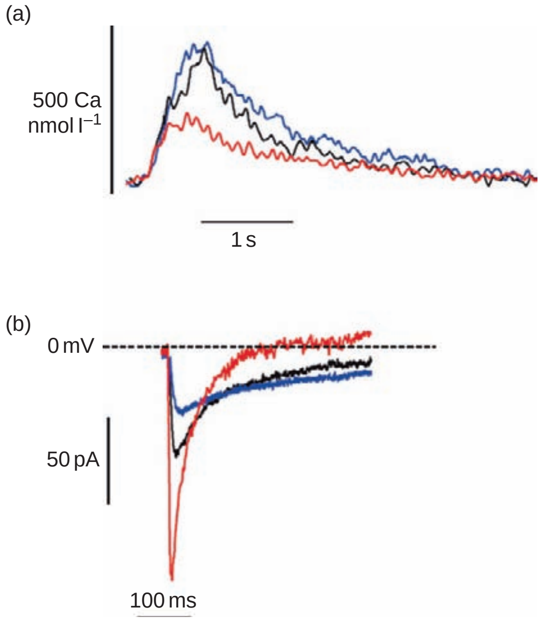

Figure 5 The effect of acute temperature change on the cellular Ca transient (a) and LTCC currents (b) from an atrial myocyte from the rainbow trout (*Oncorhynchus mykiss*) at 7 (blue), 14 (black), and 21 (red)°C. (a) The effect of temperature on the Ca transient in this species. Warm temperatures result in smaller Ca transients than cold temperatures. (b) Ca influx as an ionic current (measured in pico-amps, pA) across the SL membrane through the LTCCs. Warm temperature gives a faster current with a larger peak amplitude than colder temperatures. However, at colder temperatures, the ion channels stay open longer so that more Ca crosses the SL and the Ca transient is bigger. Data adapted from Shiels HA, Vornanen M, and Farrell AP (2002) Effects of temperature on intracellular [Ca^{2+}] in trout atrial myocytes. *Journal of Experimental Biology* 205: 3641–3650.

plays a greater role in delivering and removing Ca during the Ca transient. Interestingly, species that live at cold temperatures all year round (such as the cold-active burbot (*Lota lota*) and salmon shark (*Lamna ditropis*)) have a steady-state large complement of SR in their myocytes, which appears to be greatly involved in the cellular Ca transient during e–c coupling. Furthermore, cold-tolerant mammals, such as hibernators, also increase their SR content during the cold. Thus, intracellular Ca flux through the SR may be an evolutionarily conserved adaptation for cold tolerance.

The Falling Phase of the Ca Transient

Relaxation of the cardiac myocyte is dependent on Ca removal from the cytosol. This Ca efflux leads to the falling (decay) phase of the Ca transient, which can be seen for both the mammalian myocyte in **Figure 1** and the fish myocyte in **Figure 3**. This Ca removal can occur via either of the two main efflux pathways illustrated in **Figure 2**. Ca can either be moved back across the SL membrane via the NCX, or pumped into the SR via the SERCA pump. As the majority of Ca enters the fish cardiac myocyte across the SL membrane, in a steady state, the majority of Ca must also leave the cell via this route. Similar to Ca influx, the large surface area-to-volume ratio of the fish myocyte will aid in the efficacy of SL Ca efflux. However, the SR of active fish species is able to store large quantities of Ca and thus, in these animals, the SR may also play a role in the decay of the Ca transient. This is illustrated in **Figure 4** by the significant slowing of the Ca transient decay when SR uptake is inhibited in the bluefin tuna ventricular myocyte.

Extracellular Ca Efflux

The NCX operating in forward mode transports Ca out of the cell. This is the primary pathway to remove Ca from the cytosol and is the main cause of the decay in the Ca transient in fish cardiac myocytes. Forward-mode NCX is favorable during the onset of relaxation because of the initially high intracellular Ca concentration and the progressive repolarization of the membrane potential. An alternative route for Ca efflux across the SL is the plasma membrane Ca-ATPase (PMCA) Ca pump. However, based on mammalian studies, this pathway is expected to make a very minor contribution (if any) to the decay of the Ca transient, although its activity has not been directly measured in fish myocytes.

The prominent role of the NCX in relaxation is evidenced by the fact that NCX activity alone (SR function inhibited) can clear the cytosol of Ca and allow relaxation in rainbow trout myocytes. In contrast, inhibiting the rainbow trout NCX severely retards relaxation. Inhibiting both the NCX and the SR completely abolishes relaxation. This is because Ca levels remain elevated inside the cytosol and the myofilaments stay in a contracted state.

Ca Storage in the SR

The SR contributes to the falling phase of the Ca transient by pumping Ca out of the cytosol and into the SR. This pumping action is achieved through the efforts of the SR Ca-pump or SERCA. Pumping Ca into the SR takes energy, which is generated by breaking down ATP.

A surprising finding is that despite its limited role in e–c coupling, the fish SR has a massive ability to store Ca. The steady-state SR Ca content of the rainbow trout atrial myocyte is $>1000\,\mu\text{mol}\,\text{l}^{-1}$ (measured via application of caffeine, which opens ryanodine receptors and lets Ca out of the SR and into the cytoplasm). Mammalian SR Ca content is in the range of $\sim 50–250\,\mu\text{mol}\,\text{l}^{-1}$. Furthermore, the mammalian SR spontaneously releases Ca when the content reaches much above $150\,\mu\text{mol}\,\text{l}^{-1}$. Thus, fish SR can hold much greater amounts of Ca without spontaneously releasing it. How the fish SR is able to store this level of Ca is unclear. Differences in intra-SR buffering via calsequestrin may be involved. Other Ca buffers inside the SR or accessory proteins (triadin and junctin) that regulate ryanodine receptor function may be involved but this awaits future study. Certainly, for the rainbow trout at least, the SR contains more than enough Ca to support contraction. In fact, if the SR released all of its Ca into the cytosol in one go, levels could approach those associated with Ca toxicity.

A separate and fascinating question is: Why is the fish SR capable of accumulating large amounts of Ca? Again, the reasons are unclear. Because SR Ca content is only high in active fish species (or cold fish species), it has been speculated that the SR may act as a Ca reservoir that can be tapped into if physiology demands it. For example, if a faster or greater Ca transient is required (because the fish is chasing or being chased), the SR may provide a Ca reserve that can be added to SL Ca influx to bolster the size and rate of the Ca transient. However, so far this hypothesis has been difficult to prove.

The Effect of Temperature on the Decay of the Ca Transient

The low temperature sensitivity of the NCX was described above. The NCX is the primary way Ca is removed from the cytosol during relaxation and thus Ca removal via this pathway is not overly temperature dependent. However, the activity of SERCA is temperature dependent in fish. Thus, the role of SR Ca uptake in the decay of the Ca

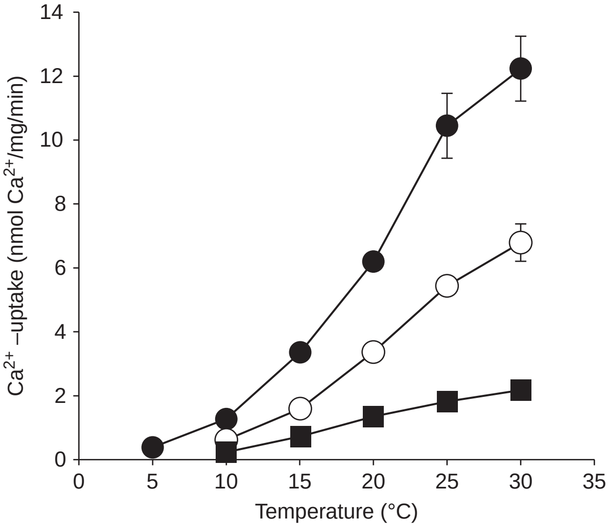

Figure 6 The temperature dependence of SR Ca uptake in isolated SR membrane preparations from different tuna species. ●, Pacific bluefin (*Thunnus orientalis)*; ○, albacore (*Thunnus alalunga)*; ■, yellowfin (*Thunnus albacares)*. The figure clearly shows how SERCA function depends on species and also how cold temperature reduces SERCA activity. Values are means ± SE of three to four experiments. Adapted from figure 2a in Landeira-Fernandez AM, Morrissette JM, Blank JM, and Block BA (2004) Temperature dependence of the Ca^{2+}-ATPase (SERCA2) in the ventricles of tuna and mackerel. *American Journal of Physiology* 286: R398–R404.

transient varies with temperature in fish hearts. Ca pumping by SERCA slows down as temperatures dip. This can be seen for a number of tuna species in **Figure 6**. It is important to note that tuna are athletic fish which actively utilize the SR during e–c coupling. Furthermore, all of the tuna species in **Figure 6** are subject to temperatures between 10 and 25 °C during normal foraging behavior in the oceans. Thus, temperature can severely affect the ability of the SR to contribute to the decay of the Ca transient in this group of fish.

Adrenergic stimulation can help to combat this depressive effect of the cold. There is an accessory protein attached to SERCA called 'phospholamban', which is sensitive to the signaling cascades activated by adrenaline. When the fish gets cold and releases adrenaline, this adrenaline activates phospholamban, which increases SERCA activity and results in more Ca being pumped into the SR. Interestingly, long-term cold exposure (overwintering; cold acclimation) increases the amount of SERCA protein in the fish SR too. Whether this is just because there is more SR in chronic cold species as discussed earlier, or if there is also specifically more SERCA in these animals' SR, remains unclear.

Ultimately, the proteins involved in removing Ca from the cytosol between heartbeats must keep up as heartbeat frequency increases, otherwise the decay of the Ca transient is severely compromised. As warm temperatures increase heart rate, relaxation must occur more quickly to return Ca to resting levels (i.e., pre-AP levels) before the next contraction begins. Failure to do so increases resting-state (diastolic) Ca, a response that occurs at fast contraction frequencies in fish and compounds the negative force–frequency response. The inability of the myocyte to relax between beats disrupts cardiac filling, which negatively impacts cardiac pumping.

Summary

The contraction–relaxation cycle of the cardiac myocyte is fueled by the cycling of Ca to and from the myofilaments. This Ca can be of intra- or extracellular origin with the relative proportion changing with species, temperature, and heart rate. The transient rise and fall of cytosolic Ca is called the Ca transient and its rate and amplitude determine the rate and strength of myocyte contraction. The collective rate and strength of myocyte contraction throughout the working myocardium force blood from the heart and around the body of the fish.

Glossary

Ca^{2+} activation When a muscle contraction is stimulated by the binding of Ca^{2+} to the cardiac troponin (cTn) complex.

Ca^{2+} affinity The measure of the ability of a protein to bind Ca^{2+}.

Ca^{2+} sensitivity The measure of the ability of a myocyte to contract in response to Ca^{2+}.

Cardiac troponin complex A group of three proteins, cardiac troponin I (cTnI), cardiac troponin C (cTnC), and cardiac troponin T (cTnT), that is attached to the actin thin filament that triggers the formation of cross-bridges during contraction.

Contractile element The components of the sarcomere responsible for the contractile reaction.

Contractile reaction The series of biochemical and biophysical reactions that result in the formation of cross-bridges and the generation of force by the cardiomyocyte.

Cross-bridge A physical connection that forms between the myosin thick filament and the actin thin filament. The formation of cross-bridges causes the sarcomere to shorten during a contraction.

Ectotherm (adj ectothermic) An organism whose body temperature is largely determined by heat exchange with its surroundings. It does not produce and retain enough metabolic heat to elevate its body temperature above ambient temperature, but may use behavioural mechanisms to regulate body temperature.

Endotherm An animal that maintains a set body temperature, regardless of a change in external temperature.

Muscle contraction When a muscle cell shortens and generates force.

Protein conformation The three-dimensional shape of a protein in space.

Protein sequence The specific sequence of amino acids that compose a protein.

Sarcomeres The functional elements of a muscle cell responsible for shortening during a contraction.

Thick filament The structural element of a sarcomere that is composed of the protein myosin.

Thin filament The structural element of a sarcomere that is composed of the protein actin.

α-stat The change in blood and cellular pH that occurs in ectotherms when their body temperature changes.

Cardiomyocyte Contraction: An Overview

The contraction of all vertebrate hearts is powered by the generation of cross-bridges between two very abundant proteins termed thick and thin filaments, which are found in all muscle cells. The thick filaments are composed of the protein myosin and the thin filaments are primarily composed of the protein actin. Globular actin monomers are aligned in a chain, like beads on a string, to create the thin filament (**Figure 1**). The myosin molecule has a head and a tail. The tails are aligned side by side but staggered so that the myosin heads protrude out from the assemblage called the thick filament. Within the cardiomyocytes, the many such myosin thick filaments and actin thin filaments are arranged in a parallel overlapping pattern within structures called 'sarcomeres' (**Figure 1**). During a contraction, the myosin heads rotate out from the thick filament and form temporary connections with the actin thin filament. These physical connections are called cross-bridges. Once attached, the myosin head flexes causing the thin filament (actin) to slide past the thick filament (**Video Clip 1**). This causes

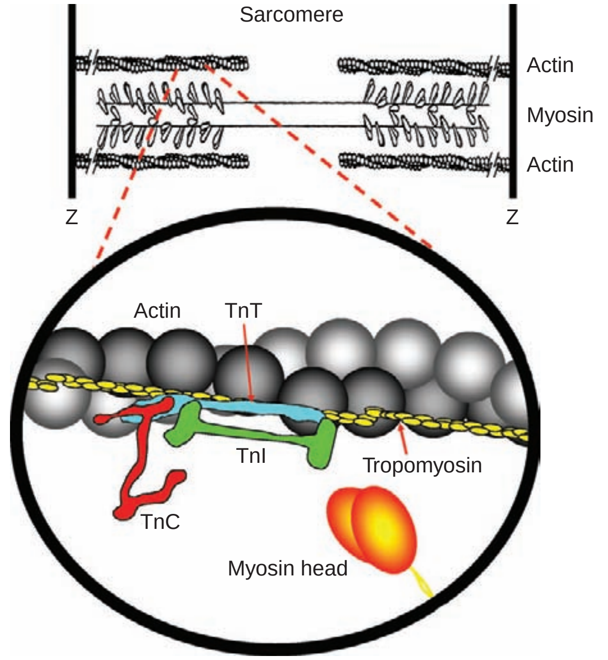

Figure 1 Schematic diagram of the cardiac sarcomere (a) and of the regulatory complex (b) associated with the actin filament responsible for making the contractile reaction activated by Ca^{2+}. Adapted part of figure 1 from Gordon AM, Regnier M, and Homsher E (2001) Skeletal and cardiac muscle contractile activation: Tropomyosin "rocks and rolls". *News in Physiological Science* 16, 49–55, used with permission from the American Physiological Society.

the length of the sarcomere to shorten by about 10%, which is termed a 'contraction'. During relaxation, the cross-bridges release and the myosin and actin filaments return to their original positions. This mechanism of muscle contraction is described as the 'sliding-filament model'. Thus, each time the heart contracts, every cardiomyocyte undergoes this contractile reaction almost in unison for each cardiac chamber. Therefore, for a heart that is beating 20 times per minute, it repeats every 3 s. The number of cross bridges that are formed is proportional to the amount of force that is developed and the rate of cross-bridge cycling is related to the rate at which force is developed. The number of cross-bridges that can be formed is directly related to the amount of calcium released into the cytoplasm after the cell is excited by the action potential. In this manner, calcium is not only critical in determining the force of contraction, but it also initiates the contraction–relaxation cycle of the cardiomyocyte.

The Activation of a Cardiomyocyte Contraction by Ca^{2+}

When a muscle is relaxed, actin and myosin are not interacting and force cannot be generated. This is because the sites where myosin binds to actin are blocked by a rod-shaped protein called 'tropomyosin' (TM). This protein lies along the actin filament (**Figure 1**) and is locked in place by a group of proteins called 'the cardiac troponin (cTn) complex'. The cTn complex is made up of three different proteins: cardiac troponin I (cTnI) (I for inhibitory), which binds directly to actin; cardiac troponin T (cTnT) (T for tropomyosin), which binds the cTn complex to TM; and cardiac troponin C (cTnC) (C for Ca^{2+}), which binds Ca^{2+} to trigger cardiomyocyte contraction. Thus, the cTn complex is bound directly to the thin filament but acts as a latch mechanism to initiate the binding of actin and myosin.

Muscle contraction is initiated when intracellular Ca^{2+} rises as a result of the action potential and binds to cTnC. The cTnC protein then changes its shape (a conformational change), which exposes a number of hydrophobic, charged amino acids within the core of cTnC. These amino acids then attract and pull cTnI away from the actin filament (the latch mechanism), allowing TM to move freely across the surface of actin, which uncovers the myosin-binding sites on the actin molecules. Myosin heads can now attach to actin, which is termed a cross-bridge (**Video Clip 1**).

The cross-bridges release when the intracellular Ca^{2+} decreases (pumped back into the sarcoplasmic reticulum (SR) or out of the cell), causing Ca^{2+} to be released from cTnC. As a result, cTnC returns to its original conformational shape and releases cTnI, which reattaches to the actin filament. Thus, the latch mechanism that locks TM in a blocking position over the myosin binding sites is reestablished. As no new cross-bridges can form, the myocyte relaxes.

The Influence of Temperature on Ca^{2+} Binding by the Contractile Element

As is the case with most physiological systems, a change in temperature alters the ability of the heart to contract. Reducing temperature a few degrees causes the human heart to beat slower and with weaker contractions. This compromises the heart's ability to circulate blood. One reason for the weaker contraction is that the heart has become less sensitive to Ca^{2+} as temperature decreases. As a result, more Ca^{2+} is required to generate the same strength of contraction. However, the maximum amount of Ca^{2+} that can be released to trigger a myocyte contraction is limited. Even so, animals that routinely function at a lower temperature than humans cannot survive such a loss of Ca^{2+} sensitivity and cardiac function. Something must be different in the fish heart because the human heart would literally stop beating at 5 °C, whereas rainbow trout (*Oncorhynchus mykiss*) heart functions fine at 5 °C. Hearts in polar fishes operate at even colder temperatures. So, the fish heart must compensate for the effect of low temperature on Ca^{2+} sensitivity.

One way the rainbow trout heart does this is by being more sensitive to Ca^{2+} than the mammalian heart. When compared at the same temperature, the trout heart is approximately 10 times more sensitive to Ca^{2+} than the mammalian heart. This means that it takes 1/10th the amount of Ca^{2+} to generate a contraction in the rainbow trout heart when compared with a mammalian heart at the same temperature. The ability for cardiac tissue from rainbow trout, frog (*Rana pipiens*), and rat (*Rattus norvegicus*) to generate force in response to Ca^{2+} over a range of temperatures is shown in **Figure 2**. The Ca^{2+} concentration (μM) required to generate half-maximal force ($K_{F½}Ca$) is plotted on a logarithmic scale. This figure clearly shows, for all three species, the inverse relationship between temperature and the Ca^{2+} concentration required to generate half-maximum force. The difference among species is evident when a comparison is made at the same temperature. For example, at 7 °C, it takes less Ca^{2+} to generate half-maximal force in the rainbow trout heart (2.8 μM) compared with either the frog (5.6 μM) or the rat (28.2 μM) – a 10-times difference between rainbow trout and rat.

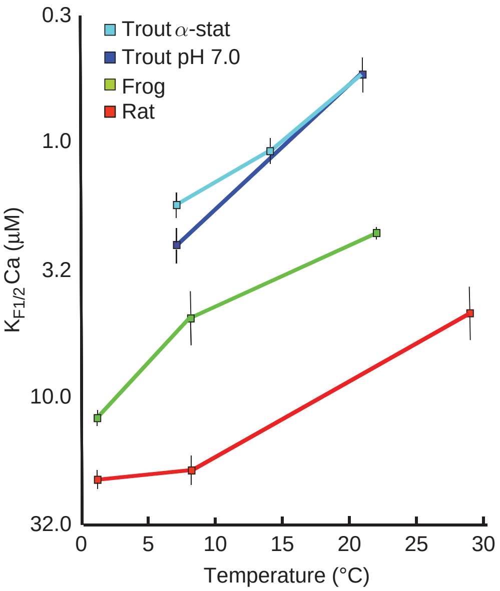

Figure 2 Comparison of the Ca^{2+} sensitivity of force generation by ventricular fibers isolated from hearts of rainbow trout, frog, and over a range of temperatures. Ca^{2+} sensitivity was measured as $K_{F1/2}Ca$, which is the Ca^{2+} concentration required to generate half-maximum force. When compared at the same temperature, the trout preparations required 10-fold less Ca^{2+} to generate the same measure of force than those from the mammalian species. Adapted from Churcott CS, Moyes CD, Bressler BH, Baldwin KM, and Tibbits GF (1994) Temperature and pH effects on Ca^{2+} sensitivity of cardiac myofibrils: A comparison of trout with mammals. *American Journal of Physiology* 267: R62–R70, used with permission from the American Physiological Society.

An equally important observation is possible, if the line for the rat is extrapolated to 37 °C. The $K_{F1/2}Ca$ for rat is similar to that of the rainbow trout at 7 °C. Thus, when compared at their respective physiological temperatures, the Ca^{2+} sensitivities of the rat and rainbow trout hearts are approximately the same. This suggests that the comparatively high Ca^{2+} sensitivity of the rainbow trout heart acts to compensate for the desensitizing effect of low temperature on Ca^{2+} sensitivity.

Adaptation of the Trout Contractile Element to Low Temperature

What is responsible for the comparatively high Ca^{2+} sensitivity of the rainbow trout heart? To begin answering this question, a series of studies were undertaken to compare the structure and function of rainbow trout and human cTnC. The logical place to start with is cTnC because it is a Ca^{2+}-binding protein. The comparison of rainbow trout and human cTnC structure and function is revealing in this regard.

Of the 161 amino acids that comprise cTnC, rainbow trout cTnC has 13 unique residues compared with the amino acid sequence of human cTnC (**Figure 3**). Since the amino acid sequence determines protein function, such differences in amino acid sequence could be important to Ca^{2+}-binding ability. Thus, the ability of these two proteins to bind Ca^{2+} was compared by monitoring the protein as it bound Ca^{2+} at 37 °C, 21 °C, and 7 °C. At all temperatures, Ca^{2+} affinity of rainbow trout cTnC is ~2.3 times that of human cTnC (**Figure 4**). In addition, the Ca^{2+} affinity of both proteins decreased as temperature decreased. Therefore, rainbow trout cTnC activates the contractile reaction at a lower Ca^{2+} concentration and the Ca^{2+} affinity of cTnC is directly related to temperature. Thus, the effect of low temperature on the Ca^{2+} affinity of cTnC is at least partially responsible for desensitizing the heart to Ca^{2+}.

Mutant human cTnC proteins have been used to identify the specific amino acids responsible for the comparatively high Ca^{2+} affinity of trout cTnC. These proteins contained different combinations of the amino acids found in rainbow trout cTnC. Four amino acid residues in rainbow trout cTnC were responsible for its comparatively high Ca^{2+} affinity: asparagine (N), isoleucine (I), glutamine (Q), and aspartate (D) at positions 2, 28, 29, and 30, respectively, in cTnC (NIQD HcTnC). Furthermore, when NIQD HcTnC was incorporated into rabbit cardiomyocytes, the Ca^{2+} sensitivity of force generation by these cardiomyocytes was increased by around twofold (**Figure 5**). This confirms that a cTnC molecule with a higher Ca^{2+} affinity does increase the Ca^{2+} sensitivity of cardiac

tissue. Together, these results demonstrated that trout cTnC is partially responsible for the high Ca^{2+} sensitivity of the rainbow trout heart. However, further work is needed to explain why the rainbow trout heart is ~10-fold more sensitive to Ca^{2+} than the mammalian heart and this may involve other proteins such as cTnI and cTnT.

Phylogenetic Analysis of cTnC from a Variety of Vertebrate Species

Clearly, the sequence and function of cTnC have changed during the evolution of the vertebrate heart. By compiling all known amino acid sequences of cTnC, a phylogenetic tree can be created, based on how similar the proteins are to each other. This type of analysis aligns the protein sequences to identify amino acid substitutions. The more similar two proteins are, the closer they are on a phylogenetic tree. This type of analysis also helps to identify specific amino acids that are critical to the function of a protein – for example, if a specific amino acid is always at the same position in the protein from a variety of unrelated animals. In addition, if there are specific amino acids that are unique to animals with similar physiological conditions – for example, body temperature – this helps to identify which amino acids have evolved for that specific condition.

Figure 6 Comparison of the N-terminus of all known cardiac troponin C homologs. Residues identified as being responsible for the comparatively high Ca^{2+} affinity of trout cTnC are indicated in mauve. Sequences are organized to indicate if they were cloned from ectothermic or endothermic species. The X in place of an amino acid indicates that the residue is not known. Adapted from Gillis TE, Marshall CR, Tibbits GF (2007) Functional and evolutionary relationships of troponin C. *Physiological Genomics* 32: 16–27, used with premission from the American Physiolocical Society.

Interestingly, all ectothermic species (this includes teleost fish, lamprey, and frogs) contain at least two of the four amino acids identified in rainbow trout as being responsible for high Ca^{2+} affinity of cTnC (**Figure 6**). In contrast, cTnC from endothermic species (birds and mammals) do not have these four amino acids at these same positions. As lampreys are the earliest known vertebrates, and fish and amphibians evolved earlier than either mammals or birds, it is suggested that these identified residues (N, I, Q, and D at positions 2, 28, 29, and 30) were present in the earliest forms of cTnC. These residues were then lost through natural selection as the body temperature of the ancestor species of mammals and birds started to increase and become constant.

This suggests that the lower Ca^{2+} affinity of mammalian cTnC is an adaptation to high temperature (37 °C) and high heart rate. Consider a human heart at 37 °C; if it contained a cTnC with the same Ca^{2+} affinity as rainbow trout cTnC, it would likely remain in contracture or beat very slowly as Ca^{2+} would be released at a very slow rate. Remember that rainbow trout cTnC has twice the Ca^{2+} affinity as human cTnC and that as temperature increases the Ca^{2+} affinity increases (**Figure 4**). The heart would remain in contracture as the Ca^{2+} affinity of the protein would be so high that Ca^{2+} would remain bound to the protein. This would result in the continuous formation of cross-bridges between actin and myosin. If a heart is in contracture, the animal dies. It is no surprise, therefore, that the four residues identified as being responsible for the high Ca^{2+} affinity of rainbow trout cTnC are not found in human cTnC.

Cardiac Contractility in Changing Environmental Temperatures

Fish, unlike mammals, expose their heart to a highly variable temperature. Rapid temperature changes can be >10 °C. In addition to Ca^{2+} sensitivity, temperature changes blood and tissue pH. This change in pH is automatic and acts to keep the relative alkalinity ($[OH_2]/[H]$) approximately constant. This relationship, called α-stat regulation, is a change of –0.016 to –0.019 pH units $°C^{-1}$. Therefore, a 10 °C decrease in temperature would cause a ~0.2-unit increase in cellular pH.

This pH change is relevant to cardiac function because an increase in pH increases the Ca^{2+} sensitivity of the heart. **Figure 1** compares the Ca^{2+} sensitivity of rainbow trout cardiac tissue over a range of temperatures when pH is kept constant at 7.0 versus when pH is allowed to change according to α-stat regulation. At 7 °C, the pH difference between the two treatments is 0.2 pH units. The $K_{F1/2}Ca$ of the rainbow trout cardiac tissue at pH 7.2 is 1.6 μM versus 2.8 μM at pH 7.0, which corresponds to a ~1.6

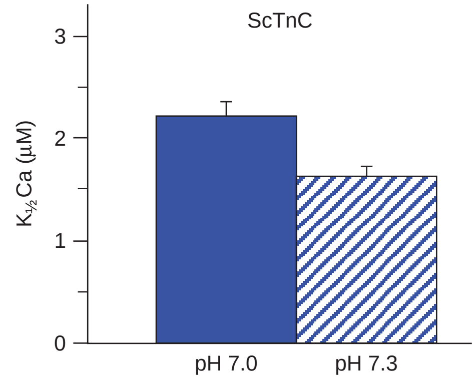

Figure 7 Effect of a 0.3 pH unit increase on the Ca^{2+} affinity of trout cTnC. Ca^{2+} affinity is shown as the $K_{1/2}Ca$, which is the Ca^{2+} concentration (in μM) required to half-saturate the molecule. Measurements were made at 21 °C. The Ca^{2+} affinity of trout cTnC was greater at pH 7.3 than at pH 7.0. Adapted from Gillis TE, Marshall CR, Xue XH, Borgford TJ, and Tibbits GF (2000) Ca^{2+} binding to cardiac troponin C: Effects of temperature and pH on mammalian and salmonid isoforms. *American Journal of Physiology* 279: R1707–R1715.

difference. Therefore, as pH increases with decreasing temperature, the Ca^{2+} sensitivity of the contractile element increases as a result of the pH change, allowing the heart to maintain contractile ability despite the decrease in temperature.

The effect of pH on the Ca^{2+} sensitivity of cardiac tissue is due, at least in part, to a pH effect on the Ca^{2+} affinity of cTnC. A 0.3-pH increase significantly increases the Ca^{2+} affinity of rainbow trout cTnC by ~1.4-fold (**Figure 7**). This increase in Ca^{2+} affinity would make it possible for cTnC to be activated by Ca^{2+} and help the heart to continue beating if a fish swims from warm surface water into colder waters after prey.

Future Directions

There is much to be learned about the molecular mechanisms that regulate cardiac contraction in fish and how these have been adapted to enable cardiac function in the variety of environments in which different fish are found. One current area of interest is the signaling pathways that are used to rapidly change the rate and strength of cardiac contraction. This includes the α- and β-adrenergic pathways. These pathways turned on by the stress response (also called the fight-or-flight response) activate functional proteins called 'kinases' that phosphorylate a number of the cardiac proteins, including cTnI and cTnT. Phosphorylation takes place when a phosphate group is attached to a specific amino acid, usually a serine or tyrosine, thereby adding an additional positive charge to the protein. This acts to change how the amino acids around the phosphate group interact with each other and, as a result, affect the function of the protein. The phosphorylation of cTnI and cTnT in the mammalian heart acts to increase the rate of cardiac contraction. Little is known of how phosphorylation of fish contractile proteins regulates the function of the fish heart.

Glossary

Active tension Increase in muscle tension during activation (during systole).

$[Ca^{2+}]_i$ Free intracellular calcium concentration.

Ca transient ($\Delta[Ca^{2+}]_i$) The term used to describe the transient rise and fall of cytosolic Ca with each contraction–relaxation cycle.

Cardiac output The volume of blood pumped by the heart per unit time; the product of heart rate and stroke volume.

Ejection fraction The end-systolic volume as a fraction of end-diastolic volume, that is, the fraction of blood at the end of ventricular filling that is pumped out during the subsequent contraction. A value of 1 means complete emptying.

Endocardium Inner part (infolding) of the pericardial sac, and is the inner lining of the cardiac chambers.

Epicardium The compact myocardium on the outer side of the ventricle(s).

Intrinsic Inherent, built in.

Myocyte An individual cardiac muscle cell.

Myofilament Either a thick filament made up principally of myosin molecules or a thin filament made up of actin molecules and associated troponin and tropomyosin complexes.

Passive stiffness The resistance of the resting muscle to deformation by an applied force; the inverse of compliance.

Passive tension Muscle tension at rest (during diastole).

pCa_{50} $\log_{10}$ Ca^{2+} concentration that activates 50% of maximal force, used as an index of changes in myofilament Ca^{2+} sensitivity in response to, for example, a change in sarcomere length.

Stroke volume The volume of blood ejected into the aorta by a single contraction of the ventricle(s).

Venous return The return of blood to the heart via the venous system.

Z-Line A dark line which separates the sarcomeres of striated muscle. It is the anchor site of actin filaments from neighboring sarcomeres.

Introduction

How Ca causes the myofilaments (contractile elements) to contract and generate force (or tension) within the cardiac myocyte is discussed in **Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element. It was explained that Ca binds to troponin C (TnC), which initiates a sequence of events that culminate in the myosin (thick filament) heads interacting with actin (thin filament) and generating force via the cross-bridge. From this discussion, it is apparent that there is a direct link between Ca and contractility. Indeed, there is a direct relationship between the amplitude of the Ca transient (**see also Design and Physiology of the Heart**: Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux) and the number of cross-bridges generated between actin and myosin. Because of this, altering the amplitude and rate of the Ca transient effectively regulates the strength and rate of cardiac contraction. This is clearly seen during exercise when adrenergic stimulation increases the amplitude of the Ca transient increasing, in turn, contractile strength as well as cardiac output to meet the elevated demands of the body.

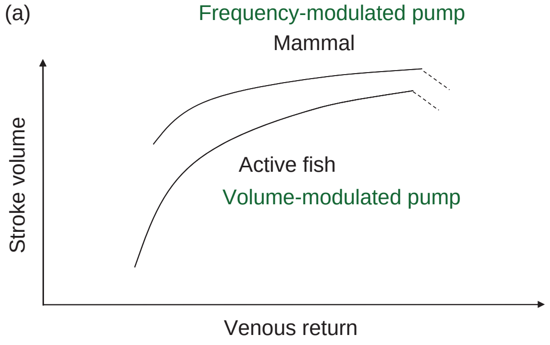
There is, however, another way to increase the strength of contraction, one that does not rely on an increase in Ca. This comes about by increasing the sensitivity of the myofilaments to Ca. Thus, the term ‘myofilament Ca sensitivity’ describes how effective a given amount of Ca is at generating contractile force. If myofilament Ca sensitivity is increased, more force is produced at the myofilaments for the same amount of Ca. Myofilament Ca sensitivity is already higher in fish hearts than mammalian hearts. The mechanisms underlying this inherently high Ca sensitivity in relation to temperature and pH are discussed in **Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element. The focus of this article is on how changes in muscle length (i.e., stretching cardiac muscle) also affect myofilament Ca sensitivity. It is universally accepted that increasing muscle length (up to a point) increases myofilament Ca sensitivity and thus contractile strength. However, the exact mechanisms by which length increases cardiac myofilament Ca sensitivity are still unknown. Elucidating these mechanisms is an active area of research for muscle biomechanics and cardiologists alike.

At the cellular level, the relationship between muscle length and contractile strength is called the 'length–tension (L–T) relationship' or the 'sarcomere length (SL)–tension relationship'. At the level of the whole heart, it is called the Frank–Starling relationship (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping). This article discusses what is known about these relationships in the fish heart and how they regulate fish heart function.

The Frank–Starling Relationship

The relationship between muscle length and muscle contractile strength was first recognized by Otto Frank and Ernest Starling at the turn of the twentieth century. They noticed that the greater the amount of blood in the ventricles at the moment they began to contract (end diastolic volume), the greater the pressure they developed during the contraction (systolic pressure). Thus, the Frank–Starling relationship describes how stretching the heart with increased volumes of blood causes it to contract more forcefully. This mechanism is vital for linking changes in the volume of blood returning to the heart (venous return), with changes in the volume of blood pumped per beat by the ventricle(s) (stroke volume).

The coupling of stroke volume and venous return via the Frank–Starling mechanism is illustrated graphically in **Figure 1(a)**. The figure shows two hypothetical Starling curves: one for an active fish and the other for a mammal. For both curves, as venous return increases, stroke volume increases. It is important to notice two features from **Figure 1(a)**. First, stroke volume increases with increased venous return up until a point and then plateaus. Eventually, stroke volume will drop if venous return continues to increase (dashed line). Second, the fish heart demonstrates a greater response in stroke volume than the mammalian heart over a similar change in venous return. This indicates that fish hearts are more sensitive to the Frank–Starling mechanism than mammalian hearts. This feature of the fish heart has been elegantly demonstrated through the use of an *in situ* heart preparation (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping), which shows how very small increments (0.2–0.3 kPa) in filling pressure (caused by an increased venous return) result in very large (threefold) increases in stroke volume in fish. Much larger increases in filling pressure are required for smaller increases in stroke volume in mammalian hearts.



(b)

$$\begin{array}{ccccc}\text{Cardiac output} & = & \text{Frequency} & \times & \text{Stroke volume}\\ \text{ml min}^{-1} & & \text{min}^{-1} & & \text{ml}\end{array}$$

Figure 1 The Frank–Starling relationship. (a) A schematic representation of the Frank–Starling relationship. (b) The formula for cardiac output showing the roles of heart rate and stroke volume.

Thus, the fish heart is very sensitive to stretch and can operate *in vivo* over much of their Starling curve.

The Importance of the Frank–Starling Relationship to Fish Hearts

The Frank–Starling relationship is important for regulating cardiac function in fish. The reasons for this are at least twofold. First, fish have less neural and hormonal control over their hearts than other vertebrates, such as birds and mammals. This means that intrinsic mechanical regulation can exert a greater influence on heart function. Second, and more importantly, the Frank–Starling relationship is important for fish because they regulate cardiac output via stroke volume. Cardiac output is the product of heart rate and stroke volume (**Figure 1(b)**). Maintaining and adjusting cardiac output to meet changing circulatory demands can be achieved by altering either heart rate or stroke volume (or both). Fish tend to alter stroke volume to a larger degree than heart rate. For example, in a maximally exercising rainbow trout, heart rate increases by ~50%, whereas stroke volume can increase by as much as 300% (i.e., threefold). Increases in stroke volume stretch the cardiac chambers and invoke the Frank–Starling mechanism (i.e., increased contractile force).

The reasons for the greater reliance on volume modulation of cardiac output in fish compared with other vertebrate hearts are not clear. One idea centers around the fact that as ectotherms, body (and thus heart) temperature changes with that of the surrounding aquatic environment. Fish heart rate is profoundly influenced by temperature through direct effects on the pacemaker myocytes (**see also Design and Physiology of the Heart:** Action Potential of the Fish Heart). Cooler temperatures slow down heart rate and warmer temperatures increase heart rate. Thus, controlling cardiac output via heart rate could be difficult for rainbow trout living in, and moving through, a changing thermal environment. With control of cardiac output via heart rate limited by the direct effect of temperature on pacemaker frequency, stroke volume modulation of cardiac output emerges as an important strategy for fish.

It should be noted that the reliance on stoke volume regulation of cardiac output varies with fish species and with activity within one species. Moreover, there are fish that do not modulate stroke volume and rely entirely on varying heart rate to change cardiac output. For example, very active species, such as tuna, have a limited capacity to increase stroke volume during exercise, and often actually decrease stroke volume coincident with an increase in heart rate. The hearts of Antarctic fish (who live in one of the most constant thermal environments on the planet) are known to increase heart rate during exercise with little changes in stroke volume. Nevertheless, in a broad sense, as endothermy emerged during vertebrate evolution, so did the reliance on frequency modulation of cardiac output.

The SL–Tension Relationship

Stretch of the whole heart will result in stretch of the myocytes that make up that heart. For a fish, such as the rainbow trout, a threefold increase in stroke volume (e.g., during maximum exercise) would require a stretch of the underlying cardiac myocytes by ~40%. These changes in myocyte length will affect myocyte contractile force in a manner akin to the Frank–Starling relationship at the whole heart.

The myocyte equivalent of the Frank–Starling relationship is the SL–tension relationship. It states that the force of contraction increases with SL up to an optimum length, beyond which force of contraction drops. The SL–tension relationship from the mammalian heart is illustrated in **Figure 2**. The *x*-axis shows SL and is a cellular correlate to the *x*-axis from **Figure 1**(**a**) showing venous return. The *y*-axis in **Figure 2** is normalized tension and is a cellular correlate of whole heart stroke volume from **Figure 1**(**a**).

Importance of the Sarcomere

To understand the SL–tension relationship, it is important to understand the sarcomere. The sarcomere is the fundamental unit of myocyte contraction. Sarcomeres are recognizable as the familiar banding pattern observed when striated muscle is seen through the light microscope. **Figure 3**(**a**) shows a portion of a ventricular myocyte from a bluefin tuna where the regular banding pattern of the sarcomeres is clearly visible. A schematic of a mammalian sarcomere and its composite proteins is provided in **Figure 3**(**b**). The morphology of the rainbow trout sarcomere is similar to that of the mammalian sarcomere and thin-filament length is approximately 0.95 μm in both rat and rainbow trout ventricular myocytes. A sarcomere is defined as the distance between the Z-lines. The Z-lines are pulled closer together during contraction and move further apart during relaxation. The Z-lines are closer during contraction because actin and myosin interaction generates cross-bridges, which

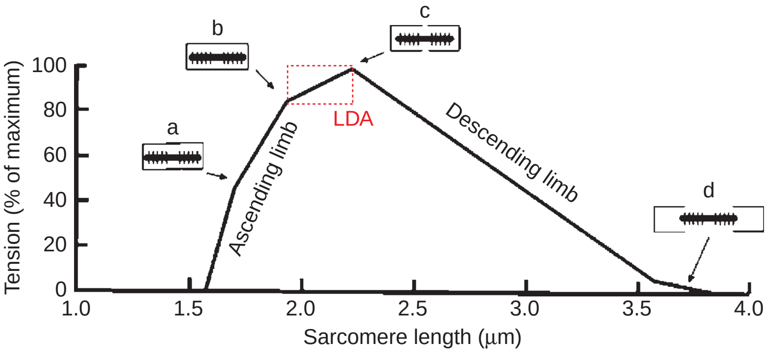


Figure 2 A schematic diagram of the sarcomere length (SL)–tension relationship for mammalian cardiac muscle. The insets (a–d) show the role of myofilament overlap in the length-dependent increase in force. Inset (a) shows the position of actin and myosin at short SLs when myosin comes in contact with the Z-line and there is a rapid decline in tension as SLs decrease (to the left of the arrow). SLs to the left of inset (b) show how tension decreases when the thin filaments from opposite ends of the sarcomere overlap at the M-line. The region between (b) and (c) is the range of SLs where the potential availability of cross-bridges remains constant during sarcomere stretch because the central cross-bridge head-free zone of the myosin filament (M-line) is progressively uncovered. Over this range of lengths, length-dependent activation (LDA) occurs as indicated by the red box. Inset (d) shows how tension declines toward zero when the sarcomere is stretched such that there is no overlap between thick and thin filaments. Adapted from Bers DM (2001) *Excitation–Contraction Coupling and Contractile Force*, p. 27. Dordecht: Kluwer.

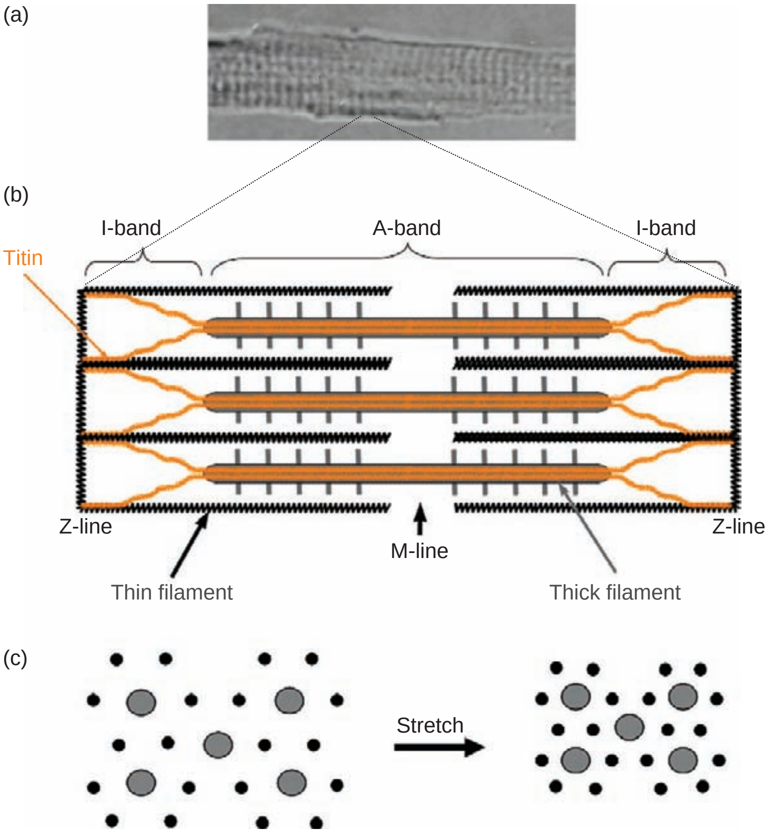

Figure 3 (a) A portion of a ventricular myocyte from a bluefin tuna taken with a light microscope showing the striation pattern of the sarcomeres. The myocyte is ~15 μm in diameter and the images shows 50 μm of its length. (b) Schematic diagram of a cardiac sarcomere. The sarcomere is the fundamental unit of contraction and is defined as the region between two Z-lines. Each sarcomere consists of a central A-band (thick filaments) and two halves of the I-band (thin filaments). The I-band from two adjacent sarcomeres meets at the Z-line. The central portion of the A-band is the M-line, which does not contain actin. The figure shows the positioning of the major filament systems that compose the sarcomere: titin, actin (thin), and myosin (thick) filaments. (c) Pictorial description of the cross section through striated muscle showing the effect of stretch on myofilament lattice spacing. Light gray circles demark thick (myosin) filaments and black circles demark thin (actin) filaments. Adapted from Shiels HA and White E (2008) The Frank–Starling mechanism in vertebrate cardiac myocytes. *Journal of Experimental Biology* 211: 2005–2013.

slide the myofilaments over each other. During relaxation, myosin and actin detach and the Z-lines slide back apart. The role of myofilament overlap in sarcomere shortening is expanded upon in the following section (**see also Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element).

Myofilament Overlap

The distance between Z-lines determines the degree of overlap between thick and thin filaments and thus the potential availability of cross-bridges to generate tension. The insets in **Figure 2** show how changes in SL affect myofilament overlap and thus tension in cardiac muscle. The sarcomeric filaments are drawn schematically in the insets (a–d), where the thick lines with cross-hatching are myosin and the thin lines are actin. Insets (a and b) illustrate how overlap between thick and thin filaments increases during stretch which results in a greater number of potential cross-bridges and thus greater tension development. This phase of the SL–tension relationship is called the ‘ascending limb’. Beyond the length for optimal overlap, additional stretching reduces myofilament overlap, decreasing the probability of cross-bridge formation and decreasing tension (inset d). This region of the SL–tension relationship is called the ‘descending limb’.

A large proportion of the increase in force with increased muscle length on the ascending limb of the SL–tension relationship can be explained by myofilament overlap. Indeed, in skeletal muscle, the majority of the SL–tension relationship is explained in this way. However, in cardiac muscle, other mechanisms contribute to the length-dependent increase in force. A significant increase in active tension occurs over the region of SLs where the potential availability of cross-bridges remains constant. This is shown in **Figure 2** by the increase in tension between insets (b) and (c). Over this SL range, an

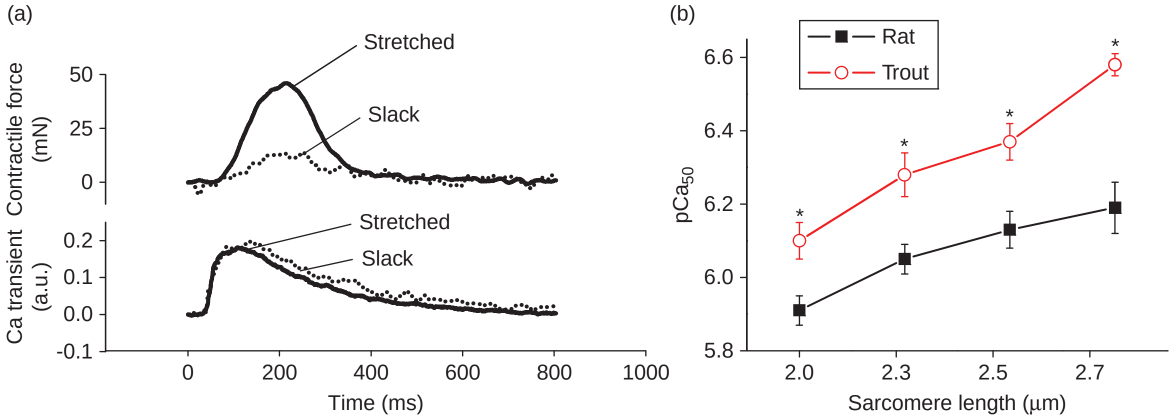

Figure 4 Length-dependent increases in myofilament Ca sensitivity in the trout heart. (a) Simultaneous measurement of changes in force (upper panel) and the Ca transient measured with fura-2 (lower panel) at slack length and after a stretch show how stretch increases force but not the intracellular Ca transient in single trout cardiac myocytes. (b) The sarcomere-length (SL) dependency of myofilament Ca sensitivity in rat and trout permeabilized ventricular myocytes. The pCa for half-maximal activation (pCa_{50}) is an index of myofilament Ca sensitivity of the contractile machinery. The asterisks show the data are significantly different. (a) Shiels HA, Calaghan SC, and White E (2006) The cellular basis for enhanced volume-modulated cardiac output in fish hearts. *Journal of General Physiology* 128: 37–44. (b) Patrick SM, Hoskins A, Kentish J, *et al*. (2010) Enhanced length-dependent Ca^{2+} activation in fish cardiomyocytes permits a large operating range of sarcomere lengths. *Journal of Molecular and Cellular Cardiology* 48: 917–924.

increase in length does not equate to an increase in potential cross-bridge sites, as the central cross-bridge head-free zone of the myosin filament (near the M-line in **Figure 4(a)**) is progressively uncovered. Hence, myofilament overlap cannot fully account for the SL–tension relationship in cardiac muscle: the remainder is due to increased myofilament Ca sensitivity and is referred to as length-dependent activation (LDA).

Myofilament Ca Sensitivity

Stretch of the myocyte increases myofilament Ca sensitivity, which increases contractile force. This is illustrated for the rainbow trout in **Figure 4(a)**. The figure shows simultaneous measurements of the intracellular Ca transient (top panel and **see also Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux) and force production (bottom panel) in a single rainbow trout myocyte at slack length and after a stretch. When the myocyte is stretched, there is an immediate increase in the size of the contraction but no change in the Ca transient. An increase in contractile force in the absence of a rise in $[Ca^{2+}]_i$ indicates that the myofilament sensitivity for Ca has increased. Similar observations occur in amphibian and mammalian cardiac myocytes. Surprisingly, the mechanisms by which stretch increases myofilament Ca sensitivity are still poorly understood.

The stretch-induced increase in myofilament Ca sensitivity is frequently quantified by the $[Ca^{2+}]_i$ required for half-maximal activation of tension (pCa_{50}) at different lengths. pCa_{50} as an index of myofilament Ca sensitivity is explained in **Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element. **Figure 4(b)** compares the pCa_{50} values of rainbow trout and rat cardiac myocytes at a number of SLs. What is important here is that as SL increases in **Figure 4(a)**, so does the Ca sensitivity of the myofilaments as illustrated by the increase in pCa_{50}. It is immediately apparent that the rainbow trout myofilaments are more sensitive to Ca than the rat myofilament at any given SL. This is partially due to differences in TnC between fish and mammals (**see also Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element) and may be required to offset the negative effects of cold temperature on myofilament Ca sensitivity in fish (**see also Design and Physiology of the Heart:** Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element).

The SL–Tension Relationship in the Fish Heart

The SL–tension relationship in the fish myocyte is illustrated in **Figure 5**. **Figure 5(a)** shows a rainbow trout ventricular myocyte held between two carbon fibers. Images show the myocyte at slack length (top, SL 1.80 μm), and following stretches to SLs 2.16 μm (middle) and 2.50 μm (bottom). **Figure 5(b)** shows data from a different rainbow trout myocyte illustrating how stretching a myocyte to SLs, shown by the numbers above each stretch (bottom trace), increases passive and active tension (top trace).

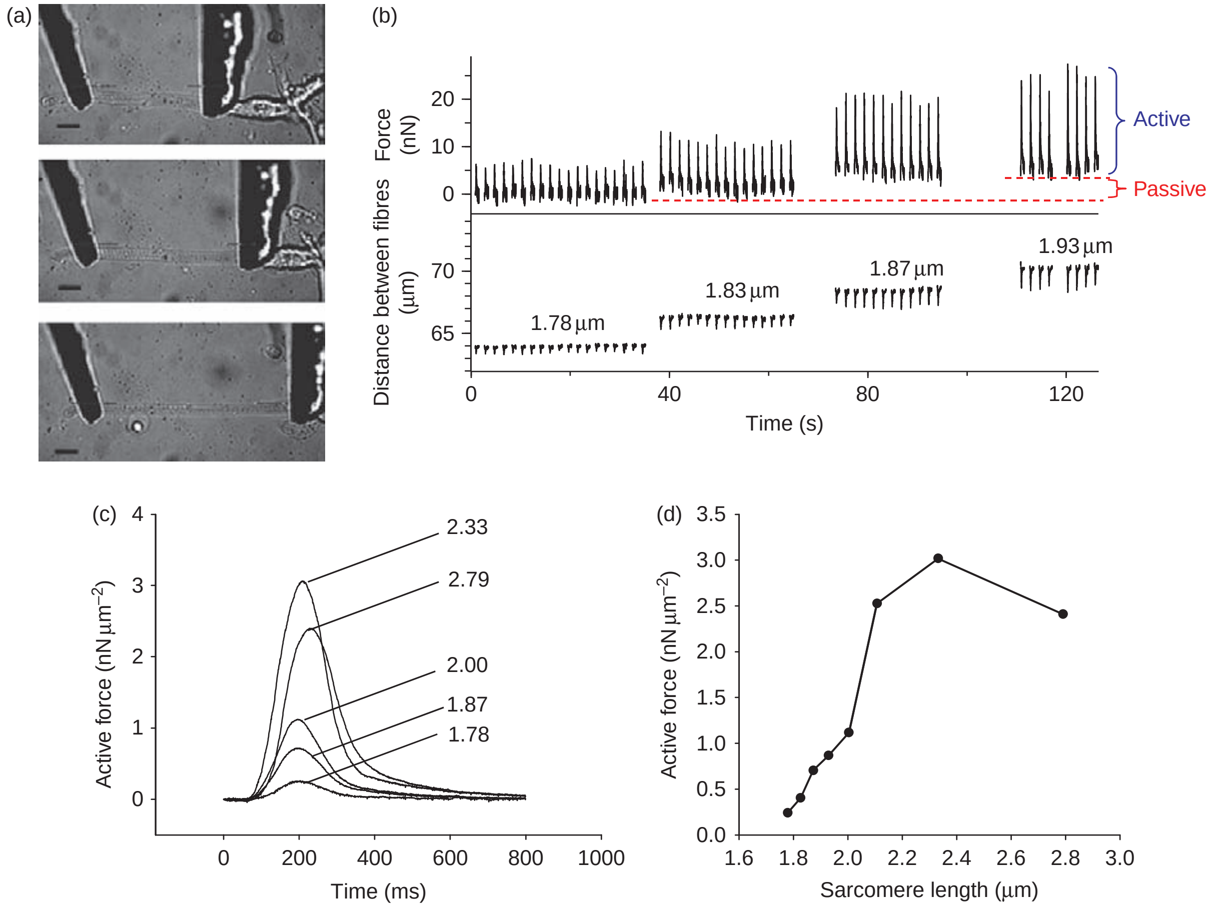

Figure 5 The SL–tension relationship in the trout ventricular myocyte. (a) Stretch of a single rainbow trout ventricular myocyte held between two carbon fibers. Images show the myocyte at slack length (top; SL 1.80 μm), and following stretches to SL 2.16 μm (middle) and 2.50 μm (bottom). Scale = 10 μm (**Video Clip 1**). (b) Data from a different cell showing how progressive stretching increases passive and active tension (upper trace), when the distance between the fibers is increased causing stretch of the sarcomere (lower trace; numbers show SL at each stretch). (c) Data from a different cell which shows contractile force produced by a single rainbow trout myocyte as it is stretched. The figure shows the contractions at each SL (indicated by numbers in micrometers). (d) SL–tension relationship from the same cell. Notice the similarity between the SL–tension relationship in the single trout myocyte and the schematic diagram in **Figure 2**. (a–d) From Shiels HA, Calaghan SC, and White E (2006) The cellular basis for enhanced volume-modulated cardiac output in fish hearts. *Journal of General Physiology* 128: 37–44.

The contraction curves from a different cardiac myocyte at increasing SL are shown in **Figure 5(c)**. Each curve shows the cell contracting and developing force at a given SL, and then relaxing. In **Figure 5(d)**, the amplitude of the contraction is plotted against SL, providing a single rainbow trout ventricular myocyte SL–tension relationship. Notice the similarity to the schematic curve based on mammalian hearts in **Figure 2**. The rainbow trout SL–tension relationship shows an ascending limb where increased SLs increase the force of contraction, a peak, and the beginning of a descending limb.

As the morphology of the rainbow trout sarcomere is similar to that of the mammalian sarcomere (**Figures 3(a)** and **3(b)**), we can assume that similar to mammals, some of the SL–tension relationship is due to changes in myofilament overlap with stretch. However, also similar to mammals, other mechanisms are at work in the fish sarcomere, which enhance the increase in force with increase in length beyond that predicted from myofilament overlap alone. These mechanisms have not been investigated in fish hearts but are discussed in a general way in the following section.

Lattice Compression

When muscle is stretched, in addition to an increase in length, there is a decrease in cross-sectional area (**Figure 3(c)**). This results in compression of the lattice spacing of the muscle (the ordered structure of thick and thin filaments). This compression is thought to encourage the recruitment of strong force producing cross-bridges between the thick and thin filaments. However, the precise role of filament spacing remains controversial in mammalian studies and has not been investigated in fish.

Thin-Filament Activation

Thin-filament activation or cooperativity has also been put forward as a contributor to length-dependent changes in myofilament Ca sensitivity in mammals but has not been explored in fish hearts.

Titin and Passive Tension

Passive tension of the sarcomere offers resistance to stretch. The main determinant of passive tension at SLs on the ascending limb of the SL–tension relationship is the giant elastic protein titin (**Figure 3(b)**). Titin develops passive forces which act to draw the Z-lines together as the sarcomere is stretched. In addition to these longitudinal forces, titin can also produce radial force during stretch as it pulls the thin filament closer to the thick filament, which results in reduced myofilament lattice spacing (**Figure 3(c)**). This may help to explain why passive tension is linked to the length sensitivity of the preparation in both fish and mammals. Titin strain may also increase the likelihood of actin and myosin interaction by increasing the disorder of the myosin heads.

LDA of fish myofilaments has been observed and can be explained, at least in part, by length-dependent increases in myofilament Ca sensitivity. For example, the slope of the relationship between length and pCa_{50}, shown in **Figure 3(b)**, is steeper for fish than for mammals, suggesting that the fish heart does show greater length-dependent increases in myofilament Ca sensitivity than mammals, especially at long SL. This may be important for fish heart function because larger stretches are predicted for the fish heart due to the large volume changes inherent in stroke volume modulation of cardiac output.

Conclusions

During the evolution of the vertebrate heart, the main modulator of cardiac output has shifted from stroke volume in fish, to heart rate in mammals. Thus, in fish, cardiac output is largely volume regulated, meaning that the fish heart is specialized for large distensions during its normal filling-and-emptying cycle. To be able to contract at long lengths, the contractile apparatus in the fish myocytes show greater length-dependent Ca sensitivity than mammalian hearts. This property allows fish myocytes to beat forcefully at the long SLs required to volume-modulate cardiac output.

Glossary

Arterial Adjective pertaining to blood that has been oxygenated.

Arteriosus Pertaining to the outflow tract of the heart leading to capillaries.

Autonomic nervous system A collection of motor neurons (ganglia) ordered segmentally from cranial to caudal levels. The system controls the inner organs (viscera) through reflexes without conscious control.

Autonomic neurotransmitters A group of chemicals released by sympathetic and parasympathetic preganglionic neurons that transmit information to neighboring cells.

Chemical code A precise combination of both peptide and nonpeptide transmitters that identifies different populations of neurons.

Cholinergic system Motor neurons that ramify throughout their target tissues, including cardiac muscle, and release the neurotransmitter acetylcholine.

Coronary circulation A specialized system of blood vessels dedicated to the heart, which normally delivers fully oxygenated blood to at least a portion of the cardiac muscle. A coronary blood vessel refers loosely to any vessel in this specialized circulation, from the coronary artery, through the coronary capillaries to the coronary veins.

Neuropeptides A group of chemicals (co-transmitters) that facilitate cholinergic transmission by mediating slow excitatory postsynaptic potentials.

Nitric oxide synthase/NO system It refers to a gaseous molecule, NO, which is generated by the enzyme NOS, and acts as a neurotransmitter. It is released by cardiomyocytes and myocardial neurons.

Trabeculae A bundle of cardiac muscle fibers that is a characteristic of the spongy myocardium of fishes and other lower vertebrates.

Venous Adjective pertaining to blood that has passed through tissues and has had some of its oxygen removed for metabolism.

Introduction

This article concerns a specialized system of neurons that populate the heart – the intracardiac neurons. These neurons are distinct from the adrenergic and cholinergic neurons that reach cardiac tissues as part of the sympathetic nervous system (**see** section Extrinsic Innervation and Chemical Codes of Autonomic Neurons). Intracardiac neurons recognized in the sino-atrial area suggest the possibility of the heart containing intrinsic circuits that modulate local activities.

Fishes are the most prolific vertebrate group in terms of biomass and number of species, occupying widely differing aquatic environments, which results in different lifestyles and different demands on the heart. Some fishes even breathe air, and this has resulted in the evolution of circulatory changes as extreme as a double circulatory loop in obligate air-breathing lungfish (Dipnoi) and a partial structural division of the ventricle, by a vertical septum and an atrio-ventricular plug, into a larger right and a smaller left side (**see** section The Gross Morphology and Anatomy of the Heart). Consequently, these evolutionary changes are expected to have resulted in alterations in the intracardiac innervation among fishes, as is the case for the sympathetic and parasympathetic cardiac innervation patterns (**see** section Extrinsic Innervation and Chemical Codes of Autonomic Neurons). While the discoveries concerning intracardiac neurons are still in an early stage, certain patterns have already begun to emerge.

The Gross Morphology and Anatomy of the Heart

The piscine circulation features a single ventricle that pumps blood into the gas exchanger (the gill) and then the systemic circulation (the tissues) without further pumping, unlike other vertebrates. The chambered fish heart is enclosed within a pericardial sac and possesses three layers: endocardium, myocardium, and epicardium. It is often called a 'venous heart' because it only pumps venous blood.

Based on the myocardial architecture, the myogenic heart of fish may be divided into four principal chambers arranged in series: the sinus venosus, the atrium, the ventricle, and the bulbus cordis (cous arteriosus) in elasmobranches and dipnoans, and in teleosts, the bulbus arteriosus (see also **Design and Physiology of the Heart:** Cardiac Anatomy in Fishes).

The sinus venosus is the site of a specialized group of autonomous pacemaker cells in many fish and its major functional role is related to the initiation and control of the heartbeat. The excitation of the heart initiates from these cells, which generate spontaneous action potentials (APs). The AP of the pacemaker cells is modulated by temperature, the autonomic nerves, the purinergic system, and possibly by intracardiac neurons.

The atrium is more richly supplied with cardiac muscle when compared with the sinus venosus. It is an irregularly shaped, large muscular, contractile chamber that is situated dorsal to the ventricle in most of the fish. The atrium consists of two parts: a sinoatrial canal and an atrium proper. The atrium communicates with the ventricle through a tubular structure called the atrio-ventricular funnel. The ventricle is a thick-walled chamber of tubular, sac-like and pyramidal shapes (teleosts), or rounded, sac-like (elasmobranchs) contours. The bulbus arteriosus in teleosts and the bulbus cordis (cartilaginous fish) represent the ventricular-outflow tract, but have important auxiliary functions (**see** section Postganglionic Neurons and Neurotransmitter Localization).

The central circulatory system of ordinary fish is essentially symmetrical in sharp contrast to the asymmetrical vascular arrangements seen in the remainder of the vertebrate groups, including lungfish. With the advent of separate pulmonary drainage vessels as seen in lungfish, the heart becomes polarized such that the left side accommodates pulmonary venous blood, either completely or incompletely separated from the right side which pumps the systemic venous blood to the lungs. In the lungfish (Dipnoi), a single ventricle pumps blood, but the heart is quite different from the usual piscine pattern due to the partial separation of the heart for lung-oxygenated and systemic-deoxygenated blood. The development of the divided heart in lungfish is associated with the special pulmonary vascular circuit having a separate return to the left side of the heart, but coupled in parallel with the systemic or the internal gas-exchange circuit on the arterial side.

In the Polypterid heart, the sinus venosus receives blood from the duct of Cuvier, where blood is collected from the inferior hepatopulmonary vein. The wall of the sinus venosus is rather smooth and a scattering of muscular strands is seen in the myocardial tissue and at the junction between the sinus and the atrium.

Extrinsic Innervation and Chemical Codes of Autonomic Neurons

The autonomic nervous system (ANS) pathways are divided into sympathetic and parasympathetic divisions (see also **Brain and Nervous System:** Autonomic Nervous System of Fishes). The ANS in fish is defined simply as that which originates from the cranium, called ' parasympathetic outflow', and that which originates from the spinal cord, termed ' sympathetic outflow'. Preganglionic cell bodies for the parasympathetic outflow are in the brainstem and those for the sympathetic outflow are in the trunk of the spinal cord. Each system contains neurons that have structural similarity, but differ functionally based on their neurotransmitter complement.

The heart of fishes is innervated by the paired cardiac branches of the vagosympathetic trunk. Like other vertebrates, the heart is under autonomic control. The vagus, at its origin, is parasympathetic but receives postganglionic autonomic fibers from the sympathetic chain in the head region, creating the vagosympathetic trunk. The vagus of all groups of fish has cardiac and visceral rami innervating the heart and gastrointestinal tract, respectively. The paired cardiac rami of the vagus arise from the ventral visceral rami, and, in cartilaginous fish and at least some teleost species, they also receive contributions from the most posterior branchial rami. In both teleosts and cartilaginous fish, the cardiac nerves run in the dorsal wall of the ducts of Cuvier to the sinus venosus, where they break up into a ganglionated plexus, extending only as far as the proximal region of the atrium.

The physiological regulation of the cardiovascular system is remote and local. The remote system maintains a constant blood pressure that allows each tissue to adjust its own perfusion through a local regulation of vascular resistance. Various molecules coming from the vasculature (such as the gases CO, NO, and H_2S) provide a variety of signaling pathways in the homeostatic regulation of the cardiovascular function thereby producing vasoactive paracrine signals (see below).

In fish, peripheral autonomic neurons are often globular or ellipsoid in shape and are generally considered unipolar, bearing a single axon but no dendrites. However, recent studies have demonstrated that most sympathetic neurons in goldfish have dendrites and display a complex morphology.

Over the last 25 years, an increasing number of biologically active substances have been identified as transmitters of autonomic neurons. However, comparative studies on the identity of neurotransmitters are often fragmentary, and available information indicates a similarity in the chemical nature among the transmitters in different vertebrate classes. The classical transmitter substances are adrenaline/noradrenaline (A/NA) and acetylcholine (ACh). All preganglionic autonomic neurons, both sympathetic and parasympathetic, use ACh as their fast excitatory transmitter. The most prominent among other transmitters are the neuropeptides. A distinctive combination of these substances may occur in homologous populations of neurons in different species and form the chemical codes. Autonomic neurons may also contain purines, indoleamines, and nitric oxide synthase (NOS), the enzyme that forms nitric oxide (NO) from L-arginine. Thus, neurons can release more than one transmitter, giving rise to co-transmission which accounts for the type of the target tissue that is innervated. These co-transmitters mediate slow excitatory postsynaptic potentials, facilitating cholinergic transmission.

In many fish tissues, blockade of adrenergic and cholinergic transmission results in residual nonadrenergic noncholinergic (NANC) responses. The majority of NANC neurotransmission is due to the release of neuropeptides, adenosine triphosphate (ATP), and NO. However, NANC transmission is apparently absent in the teleost heart with a vagal stimulation after cholinergic and adrenergic blockade. In contrast, NO may be present. Parasympathetic motor neurons utilize ACh or NO, or both, as nonpeptide transmitters, as well as a wide range of co-transmitter peptides, including vasoactive intestinal peptide (VIP).

Cholinergic neurons are present in numerous autonomic pathways as demonstrated by a vast number of pharmacological, histochemical, immunohistochemical, and physiological studies. Immunostaining of choline acetyltransferase (ChAT) with specific antisera is useful to identify cholinergic neurons. Adrenergic neurons are identified using antibodies to tyrosine hydroxylase (TH).

Postganglionic Neurons and Neurotransmitter Localization

Cardiac nervous tissue is most concentrated in a sino-atrial plexus, corresponding to the pacemaker. This plexus consists of a developed network of nerve fibers and nerve cell bodies. These cells are often isolated or clustered into small groups to form microganglia and are not only distributed in the sino-atrial area, but are scattered along the entire atrial canal up to the atrio-ventricular junction. Synaptic contacts and synaptic specializations of these cells with preganglionic vagal fibers have been seen in several fish species (as detailed below). Besides the axo-somatic relationships between the nerve terminals and the somata of the cardiac neurons, a large component of the nervous tissue in the sino-atrial plexus is represented by the postganglionic nonmyelinated outflow originating from the axons of the intramural cardiac neurons, giving rise to numerous nerve terminals mostly concentrated in the sino-atrial junction, the atrial canal, and the atrio-ventricular funnel.

Ray-Finned Fish, Bichirs

Nerve cell bodies are present in the sinus venosus and the sino-atrial junction in the heart of the bichirs. Single and immunolabeling methods have enabled a mapping of these cells in the heart of *Polypterus bichir bichir*. Several populations of neuronal cell bodies have been distinguished using neurotransmitter immunoreactivity. Acetylcholine esterase (AChE), TH, galanin (GA), substance P (SP), vasoactive intestinal polypeptide (VIP), adenylate cyclase-activating peptide (PACAP), and neuronal nitric oxide synthase (nNOS) all occur in nearly every intracardiac neuronal cell body (**Figure 1**). Nerve varicosities showing nNOS and/or TH immunoreactivity are found in close proximity to some neurons or boutons on the nerve cell soma. The AchE and SP double-labeling method shows that the majority of the nerve cells are labeled with SP antibody. Immunoreactivity to SP is found in the preganglionic axons or boutons associated with these neurons (**Figure 1**). Preganglionic axons showing VIP and PACAP (**Figure 1**) immunoreactivity lie on the soma of numerous nerve cell bodies in the sino-atrial ostium.

Lungfish

Immunoreactivity to GA and SP occurs in the intracardiac neuronal cell bodies of the sinus venosus in *Neoceratodus*. These neurons have immunoreactivity for these neuropeptides in their axons. Some neuronal cell bodies seem to receive GA-positive collaterals from other neurons in the sinus. SP does not coexist with TH. The intracardiac neurons do not contain immunoreactivity to ChAT and nNOS. Therefore, GA should be a candidate for mediating the noncholinergic vagal inhibition of the heart of lungfish.

Teleosts

Distribution of specific types of autonomic nerves and the presence of various transmitter substances have been examined in mullet (*Mugil cephalus*) and Nile catfish

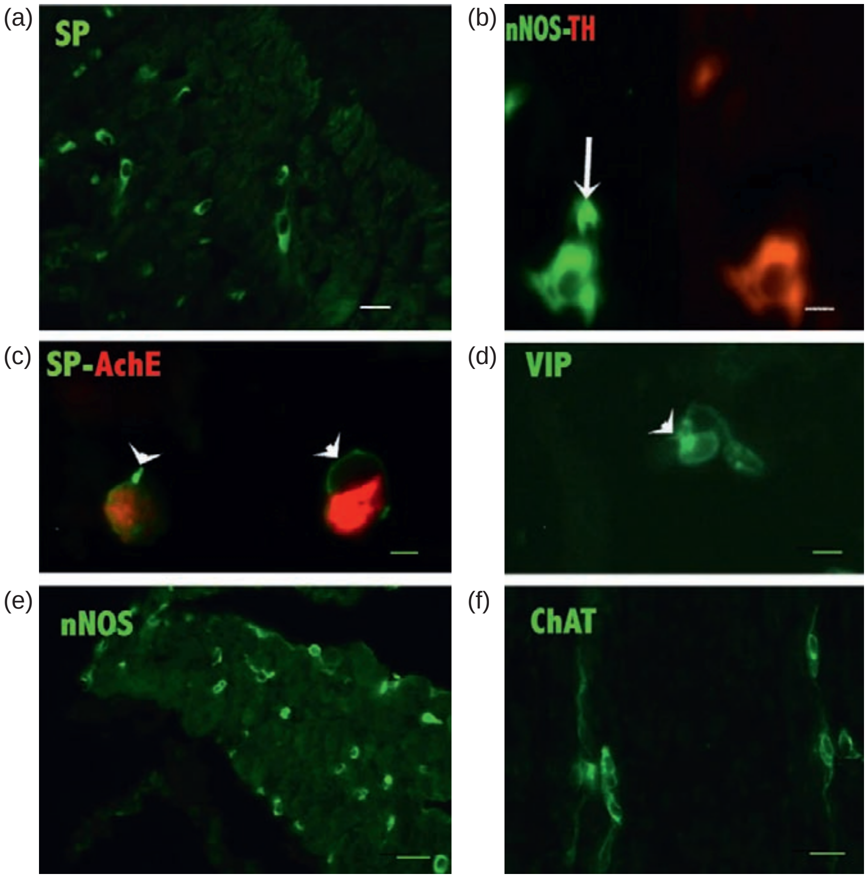

Figure 1 (a) A group of substance P (SP) immunoreactive nerve cell bodies in the sino-atrial tissue of *Polypterus bichir bichir*. (b) Double immunolabeling of neuronal nitric oxide synthase (nNOS) and tyrosine hydroxylase (TH) in the sino-atrial region. Combination of the green and red channel showing the presence of nNOS positive axon (white arrow) lying near the soma of an nNOS positive nerve cell. (c) Double immunolabeling of acetylcholinesterase (AChE) and SP in the sinus venosus showing the presence of SP positive axon (arrowheads) associated with the soma of two nerve cells. (d) VIP immunoreactivity in a nerve cell and axon bearing varicosities near the nerve cell soma. (e) nNOS immunoreactivity of several nerve cell bodies in the sinus venosus of the trout (*O. mykiss*). (f) Unipolar neurons containing immunoreactivity to ChAT in a section of the sinus venosus of the trout (*O. mykiss*), Scale (a–f) = 20 μm.

(*Synodontis nigriventris*). Most intracardiac nerve cell bodies are located in the sinus venosus and in the sino-atrial junction. These are immunoreactive to SP, GA, nNOS, VIP, and PACAP. The presence of a large population of postganglionic nerve cell bodies is demonstrated in sinus venosus using immunolabeling methods with antibodies to nNOS, SP, and ChAT (**Figure 1**). These cells are often intermingled in the nerve plexuses. A nerve plexus consisting of a well-developed network of nerve fibers and nerve cell bodies may possibly correspond to a cardiac pacemaker in the teleosts, but its function in fish cardiac regulation as well as the characterization of the pacemaker tissue are not known.

In view of the antibody reactivity to ChAT and nNOS, cholinergic and nitrergic cell bodies of vagal postganglionic neurons, which are located in an extensive cardiac nerve plexus, may represent a component of the vagal inhibition of the sinus venosus and atria of the fish in general, and should be mediated by noncholinergic mechanisms. However, there have been no pharmacological studies that have clearly demonstrated the presence of inhibitory responses in fish cardiac muscle cells.

In the mullet, the intracardiac neurons form a ganglion consisting of adrenergic and nNOS-immunopositive (nitrergic) nerve cell bodies (**Figure 2**). Double immunolabeling with antibodies against TH and nNOS show immunoreactivity co-localized in these cells. Nerve branches showing TH immunoreactivity enter the sinus venosus. Muscle layers are also innervated by GA and nNOS-immunopositive nerve fibers. Fine varicose substance P-immunopositive fibers are present in the wall of the sinus venosus and the atrium. Bundles of GA-immunopositive nerves are present in the outer compact layer and the spongy layer of ventricular myocardium. Few nerve bundles showing SP-immunoreactivity are found running in the adventitia of the bulbus into the peripheral compact and inner layers of the ventricle.

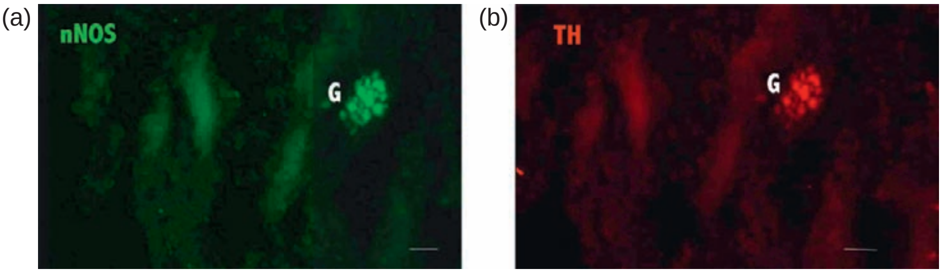

Figure 2 (a, b) Double labeling of nNOS and TH of neurons in a ganglion (G) of sinus venosus in the mullet (*M. cephalus*). Scale = 20 μm.

The compact layer of the myocardium contains coronary blood vessels, which bear a perivascular plexus of TH-immunopositive varicose nerve fibers. In the catfish species (*S. nigriventris*) TH-immunopositive nerve fibers are present in the epicardial coronary vessels.

The Cardiac Pacemaker and Conducting System

A question concerning the lower vertebrate heart is whether it is the site of specialized cardiac pacemaker tissue comparable with that of higher vertebrates. In Gnathostomatous fish, the major functional role of the sinus venosus is related to the initiation and control of the heartbeat. A ring of specialized myocardial cells (sino-atrial node) is situated in the right atrium. An atrio-ventricular node is also placed at the caudal end of the interatrial septum near the coronary sinus and the atrio-ventricular bundle (bundle of His) placed above the interventricular septum. This system is the so-called 'Purkinje system' of birds and mammals. It consists of specialized tissues and their muscle fibers (Purkinje fibers) which are situated sub-endocardially both in the atria and in the ventricle.

There is a general indication that Purkinje fibers similar to those of higher vertebrates are absent in fish hearts. While fish hearts beat in isolation and without neurogenic input (a myogenic heartbeat) and pacemaker potentials have been recorded from cells in the sinus venosus of fish (**see** section The Gross Morphology and Anatomy of the Heart), there is no unanimity among investigators regarding the occurrence of nodal tissues in fish. They have also found an intimate nerve connection at the sino-atrial junction. A muscular continuity in the various chambers of the heart without an interruption by nodes is also a key characteristic. The presence of histologically specialized muscles is also reported. In the eel (*Anguilla vulgaris*) and lungfish (*Protopterus aethiopicus*), specialized pacemaker cells appear at the junction of the sinus venosus and Cuverian ducts. These cells are also located in the atrium of the plaice and the brown bullhead (*Ictalurus nebulosus*), as well as in the atrio-ventricular region. Fish studies have produced evidence that the contraction wave arising from the sino-atrial region successively invades the atrium, the atrio-ventricular funnel, and the ventricular myocardium. A functional equivalent of the Purkinje system has been postulated for the ventricular trabeculae in the zebrafish (*Danio rerio*). The cardiac conducting system of the heart in fish is thought to be neither purely myogenic nor entirely neurogenic, but a complex combination of the two.

Histological studies have concluded that in the sino-atrial region of fish heart, every muscle cell is supplied by at least one nerve profile, thus confirming the role of this part of the heart in initiating and controlling the heartbeats. The innervation of the muscle cells also displays a peculiar arrangement. In addition to the direct neuromuscular contacts, transmission occurs via an intermediate cell interposed between the postganglionic axon and the muscle cell. This type of cell, the so-called 'internucial cell,' plays a key role in the distribution and modulation of the autonomic control of the myocardial cells. The internucial cell is only reported in the nodal tissue of the loach, but not described in other fish species.

Besides the clear recognition of nodal tissue and a specialized network of conduction cells in the fish heart, neurohumoral regulation of such tissues is not clearly understood. Future studies must be addressed to verify whether paracrine substances contained in the ganglion cells contribute to the intrinsic regulation of the heart.

Conclusions

To date, there is very little information on the functions of transmitters and co-transmitters in autonomic cardiac neurotransmission in fish. Besides the inhibitory vagal control and the adrenergic control of the heart, cardiac NANC innervation could be a feature of fish heart. Future studies are needed in order to investigate additional types of neurons involved in the cardiac control as well as the roles of neuropeptides and other putative transmitters in the intracardiac neurons and nerves that directly innervate the pacemaker region.

Glossary

Blood pressure The potential energy of blood within the circulatory system. Blood pressure varies from location to location with the circulation (highest in the central arteries and lowest in the veins), as well as within the cardiac cycle (highest during contraction and lowest during relaxation).

Branchial heart The heart that generates the arterial blood pressure in fishes, and so termed because arterial blood flows first to the gills.

Kinetic energy Energy associated with movement; it is the product of mass and velocity of an object.

Myogenic Originating in the muscle. In the case of a heart, a muscle contraction that does not require outside stimulation.

Potential energy Energy associated with height above a reference point; it is the product of mass, height, and the gravitational constant, *g*.

Vis-a-fronte A term for a supplementary cardiac filling mechanism that uses energy directly from ventricular contraction; literally the force from the front.

Vis-a-tergo A term for a cardiac filling mechanism that uses energy contained in venous blood; literally the force from behind.

Introduction

Other articles have dealt with the return of blood from the venous system and from the secondary circulation back to the branchial heart, where blood is repressurized to create a continuous circulation of blood (**see also Circulation:** Circulatory System Design: Roles and Principles, **Design and Physiology of the Heart:** Physiology of Cardiac Pumping, **Design and Physiology of Arteries and Veins:** Physiology of Capacitance Vessels, and **Design and Physiology of Capillaries and Secondary Circulation:** Secondary Circulation and Lymphatic Anatomy). These articles also acknowledged that fishes can possess an accessory heart, which helps blood return toward the branchial heart. The need for accessory hearts in fishes is in part due to low arterial blood pressures, which leave little potential energy in venous blood once blood has passed through the capillaries (i.e., the energy responsible for *vis-a-tergo* cardiac filling). Indeed, some fishes under certain physiological states have a subambient venous blood (negative potential energy relative to the heart). In these situations, the kinetic energy in the blood and suction by the heart (i.e., *vis-a-fronte* cardiac filling; **see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping) ensure that blood actually flows into the heart.

This status quo does not mean that the venous blood cannot benefit from a boost in its for any toxicants that may have been taken potential energy, which can be provided by an accessory heart. This is especially true for the secondary circulation (**see also Design and Physiology of Capillaries and Secondary Circulation:** Secondary Circulation and Lymphatic Anatomy), which has low arterial pressures in the first place. Therefore, it is hardly surprising that fishes such as eels, with their long tails, and selachian sharks, with their long fins, and hagfish, with their inherently low arterial blood pressure, provide good examples of the accessory hearts found among fishes.

Fishes evolved a variety of structures that act as accessory hearts. In this regard, a heart can be generally defined as a structure that pumps (adds energy to) blood. Accessory hearts are always found on the venous side of the circulation, which is where the lowest blood pressures exist (**see also Circulation:** Circulatory System Design: Roles and Principles). Therefore, accessory hearts could easily be described as auxillary venous pumps that act to steepen the venous blood pressure gradient between capillaries and the branchial heart. A common theme in their design is the presence of valved chambers that are compressed by skeletal muscle, sometimes against skeletal elements.

Among the accessory hearts discovered to date, the portal heart and caudal heart of hagfishes are true hearts in that their associated muscles only power the pump. The other accessory hearts might be better termed as propulsors, because they are powered incidentally by muscles that serve another function such as locomotion and gill ventilation: these include the branchial pump, caudal hearts in other fishes, and the cardinal heart of hagfishes. This article describes five types of accessory hearts. Others may still be discovered.

Portal Heart of Hagfishes

All blood sent to the vertebrate intestine returns to the heart through the liver (**see also Design and Physiology of Arteries and Veins:** Anatomical Pathways and Patterns). This arrangement permits absorbed nutrients to be immediately processed by the liver before entering the general circulation for distribution. Likewise, the liver can act as a critical metabolic barrier for any toxicants that may have been taken by the gut along with the nutrients.

The blood vessels connecting the intestinal circulation to the liver are collectively termed the hepatic portal system, with the major blood vessel being the hepatic portal vein. This vascular arrangement represents one of the few exceptions where two capillary beds are arranged in series without an intervening heart (**see also Circulation:** Circulatory System Design: Roles and Principles). Thus, the pressure remaining in blood after it passes through the intestinal capillaries must carry it through a second, hepatic, capillary bed. The only known exception to this rule is the hepatic portal vein of hagfishes. This situation may not come as a surprise since the arterial blood pressure in hagfishes approaches those that are found in the veins of some animals! The portal heart of hagfish is exceptional in another regard; it is the only known example of cardiac muscle being located outside of the pericardium of any vertebrate.

The portal heart has the shape and structure similar to that of the atrium of the branchial heart (**see also Design and Physiology of the Heart:** Cardiac Anatomy in Fishes). It is comprised of true cardiac muscle that has a trabeculated form and is valved on its inflow and outflow vessels. Being composed of cardiac muscle, it is myogenic and generates its own electrocardiogram when the heart beats (**see also Design and Physiology of the Heart:** Physiology of Cardiac Pumping and Action Potential of the Fish Heart). The electric waves are termed P-wave and T-wave to reflect the contraction and relaxation, respectively. The blood pressure generated by the portal heart is not large (0.10–0.15 kPa), but then similar pressures are generated by the atrium. The ventricle of hagfishes generates arterial pressures that are only 10-times higher.

The Branchial Pumps

The muscles used for gill ventilation can also benefit venous blood flow, that is, that act as a branchial pump.

The Cardinal Heart of Hagfishes

The cardinal heart of hagfishes is not a true heart, as is the case for the portal heart. Instead, the cardinal heart relies on supplementary use of muscles used for gill ventilation and is therefore termed a branchial pump.

Water is propelled through the gill pouches of hagfishes by a velum (**see also Hagfishes and Lamprey:** Hagfishes). Immediately above the velar chamber is the hyoid plate, with an extensive blood sinus (the hypophysio-velar sinus) that is sandwiched between the plate and the more dorsal olfactory organ. Red skeletal muscles inserted onto the hyoid plate move the plate up and down, thereby moving the velum. These ventilatory movements also compress the sinus during each ventilation cycle.

The sinus receives blood from the subcutaneous sinus through a valved vessel. The sinus empties into the anterior cardinal sinus through valved ostium. Therefore, compressions of the sinus result in a one-way flow of blood from the subcutaneous sinus toward the heart.

Branchial Pumps in Other Fishes

The anterior cardinal sinus receives blood from the valved branchial veins and opens into the ductus Cuvier, where there is an ostial valve. These vessels are easily compressed by external water pressure, as generated during each gill ventilation cycle. Furthermore, the valve arrangement is such that compressions direct the resultant blood flow toward the heart. Indeed, ventilation has been observed to expel blood passed these valves. Thus, each ventilation cycle has the potential to propel some of the venous blood from the head region back to the heart. Compression forces would presumably increase with more forceful ventilations when stroke volume increases, say during hypoxia. The synchrony known to occur between the cardiac and ventilation cycles of fishes (**see also Control of Respiration:** Generation of the Respiratory Rhythm in Fish) could be useful in synchronizing venous return with cardiac ejection.

Caudal Pumps

There are three evolutionarily distinct and anatomically different caudal pumps that have been discovered so far in fishes. Their role as an auxillary pump is similar and all are powered by the skeletal muscle.

Caudal Heart of the Hagfish

Within the tail region of hagfish are two, thin-walled, lateral chambers. Each one drains into the caudal vein through a valved ostium. Input into both chambers is through several valved ostia, which provide bilateral connections to the marginal vein and veins from the subcutaneous sinus. This accessory heart, therefore, helps propel blood from both the extensive subcutaneous sinuses and the venous system at the end of the tail.

Two thin sheets of skeletal muscle are arranged on either side of the chambers, separated by part of a median fin skeleton and inserted onto vertebrae. These muscles alternately contract, compressing one chamber and then the other. This results in two pressure pulses in the caudal vein. Since the muscles serve no other function, it is reasonable to refer to the caudal heart of hagfish as a true heart, but one that is powered by skeletal muscle rather than cardiac muscle in the case of the portal heart.

The caudal heart is not continuously active. For example, it starts beating after swimming activity, but contractions gradually fade away with time. Spinal nerves activate the skeletal muscle associated with the caudal heart, which suggests central control. However, reflex loops have not been eliminated as a possible source of activation.

The caudal heart and the cardinal heart of hagfishes are clearly not lymph hearts (like those that are prominent in amphibians). They are connected to the subcutaneous sinuses, which contain plenty of red blood cells (**see also Hagfishes and Lamprey:** Hagfishes). The question of whether they are part of the secondary circulation is still being debated. Some consider the subcutaneous sinuses in hagfishes as a functional forerunner to the secondary circulation of modern fishes (**see also Design and Physiology of Capillaries and Secondary Circulation:** Secondary Circulation and Lymphatic Anatomy). Although the input to the cardinal heart makes such a distinction possible, the situation for the caudal heart is a little more complex.

Caudal Heart in Sharks

The dorsal, lateral, and ventral cutaneous veins of elasmobranchs and teleosts may extend into the tail fin to supply a marginal vein. In the case of sharks, such as the Port Jackson shark (*Heterodontus portusjacksoni*), the carpet shark (*Cephaloscyllium isabella*), and the smooth hound (*Mustelus antarcticus*), the marginal vein passes around the tail fin and collects into threadlike, sinuses that lie alongside the ventral fin skeleton and beneath the caudal vein. Although the exact structure of the sinus varies among species, it always contains numerous, short, valved, ventral vessels that connect to the caudal vein. These sinuses act as caudal hearts (also termed a haemal arch pump).

The caudal heart is compressed by contractions of radial skeletal muscles that insert on the fin spines and, in doing so, extend over the sinus. While activation of these radial muscles by spinal nerves is similar to that in the caudal heart of hagfish, the difference is that these muscles, depending on the species, also produce tail movements during swimming or rippling waves along the fins of stationary sharks. Therefore, compression of the caudal heart is an ancillary use of these muscles.

Caudal Heart in Eels

The last vertebra of an eel has two thin-walled chambers that communicate centrally through a valved ostium and lie ventral between fin rays. The right chamber receives the inflow through a valved connection with the lateral cutaneous vein. The left chamber provides the only outflow through a valved ostium to the caudal vein.

Contraction of skeletal muscles associated with fin spines alternately compresses each chamber against the skeleton, with the right chamber emptying into the left chamber and the left chamber emptying into the caudal vein. These muscle contractions are controlled by spinal nerves, but the muscles are so tiny that fin movements are not always visible. Furthermore, in the case of eels, the caudal heart lies directly above the urophysis, an endocrine gland in the tail of fishes. Urotensin 2, a hormone released by the urophysis, increases the beating rate of the caudal heart in eels.

Caudal heart structures, with a slightly different anatomy to that of eels, are reported for other fishes such as tench (*Tinca tinca*) but without any study of their physiology. Caudal hearts are absent among the Acanthopterygii, the spiny-finned fishes that include the wrasses, the perch, and the flounders.

Summary

Fishes from hagfishes through to eels have evolved structures that act as accessory hearts. These auxillary venous pumps help move blood from the venous system and the secondary circulation toward the branchial heart. Beyond the unique and myogenic portal heart of hagfishes, a valved chamber that is compressed against skeletal elements by the skeletal muscle is a common feature across fishes. However, not all fishes need an accessory heart.

Glossary

Cardiac circulation The venous blood pumped by the heart and contained in the lumen of the cardiac chambers. The cardiac circulation, being venous blood, has variable levels of oxygenation, unlike the well-oxygenated blood of the coronary circulation. In the absence of a coronary circulation, the muscular trabeculae of the spongy myocardium derive their oxygen from the venous blood contained in the lumen of the cardiac chambers. The terms luminal and lacunary oxygen supply are also used in this regard.

Cardiac oxygen demand The amount of oxygen consumed by the heart per unit time. The cardiac oxygen consumption rate may be scaled to either cardiac mass or body mass to permit comparisons among hearts or animals of different size. Cardiac oxygen demand is primarily determined by the amount of work performed by the heart per unit time, which is termed myocardial power output.

Coronary blood flow The blood flowing through the main coronary artery. The flow rate per unit time may be scaled to either cardiac mass or body mass to permit comparisons among hearts or animals of different size.

Coronary circulation A specialized system of blood vessels dedicated to the heart, which normally delivers fully oxygenated blood to at least a portion of the cardiac muscle. A coronary blood vessel refers loosely to any vessel in this specialized circulation, from the coronary artery, through the coronary capillaries to the coronary veins.

Coronary vascular tone The contractile state of coronary vascular smooth muscle. Vascular tone is influenced by various vasoactive hormones, neurotransmitters, and paracrine substances that contract and relax vascular smooth muscle cells. This tonus determines the resistance to blood flow in the coronary circulation. A vasodilatory reserve would mean that the resistance vessels are at least partially constricted and that they can then relax to decrease coronary vascular resistance, thus increasing coronary blood flow.

Myocardium A general term for the cardiac muscle of the heart, which comprises several subtypes, including the compact myocardium and the spongy myocardium of fishes.

Threshold P_{vO_2} A threshold level for venous oxygen partial pressure (P_{vO_2}) below which the trabeculae of the spongy myocardium become hypoxic. Since oxygen diffuses into the trabeculae from the venous blood in the lumen of the heart, P_{vO_2} sets the driving force for oxygen diffusion, whereas the thickness of a trabecula sets the diffusion distance, and the workload of the heart sets the oxygen demand.

Trabeculae A bundle of cardiac muscle fibers that is characteristic of the spongy myocardium of fishes and other lower vertebrates.

Introduction

All muscles, including those of the heart (the myocardium), generate external mechanical work using adenosine triphosphate (ATP) when the muscles contract. Hearts, therefore, need a reliable and sustained oxygen supply to regenerate ATP. The adult mammalian heart has a specialized and dedicated system of blood vessels that deliver fully oxygenated blood to almost the entire myocardium (i.e., a coronary circulation). This circulation is essential for sustained cardiac function because without its coronary oxygen supply the mammalian myocardium dies within minutes. However, fishes have various different arrangements to supply oxygen to the heart that are more analogous to the neonatal mammalian heart. Thus, these various arrangements can be appreciated by considering when and why the coronary circulation develops during mammalian fetal growth.

Early in fetal development, the heart is small and thin-walled; hence, a complex coronary capillary network is not needed for a heart that has a low oxygen demand. Instead, the heart derives oxygen from the venous blood that is being pumped by the heart (oxygen that is contained in the lumen of the heart). The rate of oxygen diffusion from luminal blood into the myocardium is enhanced because the fetal blood is oxygenated by the placenta. As the neonatal heart grows, its walls thicken and a coronary capillary network develops to avoid large diffusion distances for oxygen. Initially, the coronary circulation is associated with only the outer layers of myocardium, but over time it expands to almost the entire heart. Thus, during fetal development, there is a transition from reliance on a luminal oxygen supply to dependence on a coronary oxygen supply.

The hearts of most fish species do not have a coronary circulation and, like in neonates, derive oxygen from the venous blood contained in the lumen of the heart. For those fishes that have a coronary circulation, only a portion of the cardiac myocardium is invested with coronary capillaries. Therefore, fish hearts have either a single (luminal) (**Figure 1(a)**) or a dual (coronary and luminal) myocardial oxygen supply (**Figure 1(b)**). The analogy between fish and fetal hearts breaks down in two important respects. First, the dependence of fish on the coronary circulation is never as great as that seen in mammals. Second, the fish heart pumps oxygen-poor venous blood (**Figure 1(a)**). The term cardiac circulation applies to the venous blood that is pumped by the heart and this venous blood provides oxygen to some or all of the cardiac muscle.

Anatomy

Coronary Circulation in Relation to Ventricular Architecture

As noted in the article on cardiac anatomy, (**see Design and Physiology of the Heart**: Cardiac Anatomy in Fishes) the architecture of ventricular muscle has two morphological arrangements: compact myocardium and spongy myocardium. The outer compact myocardium (also termed compacta) depends on the coronary circulation for its oxygen supply. The inner spongy myocardium (also termed spongiosa) depends primarily on the cardiac circulation for its oxygen supply. The mesh-like arrangement of muscular trabeculae for the spongy myocardium (**Figure 2(a)**) creates a large surface area and small diffusion distances for oxygen exchange.

The compact myocardium varies in thickness among species and with fish development. Consequently, the proportion of compact myocardium acts as an index of the heart's dependence on its coronary circulation. The proportion of compact myocardium is estimated either from histological analysis, or by peeling off and weighing the compact myocardium (**Figure 2(b)**). The compact myocardium is usually expressed as a percentage of ventricular mass.

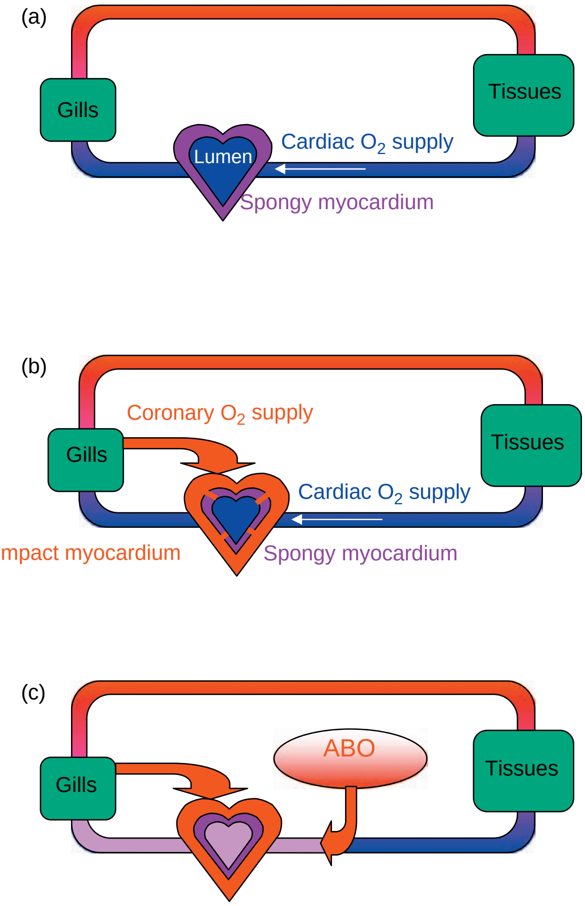

Figure 1 Schematic representation of the circulatory systems, blood oxygenation status (red = fully oxygenated blood; blue = deoxygenated (venous) blood), and composition of the ventricle for (a) fishes with only spongy myocardium, a cardiac circulation, and no coronary circulation, (b) fishes with a coronary circulation to an outer compact myocardium, and (c) air-breathing fishes. Reproduced from Farrell AP, Eliason E, Sandblom E, and Clark TD (2009) Fish cardiorespiratory physiology in an era of climate change. *Canadian Journal of Zoology* 87: 835-851.

As in mammals, the percentage of compact myocardium in fishes also increases with cardiac growth (**Figure 3**), but never to the same extent. For most fish species, the proportion of compact myocardium is typically <50%, but can reach a high of over 60% in athletic tunas and a low of 5% in primitive ratfishes. Therefore, for the majority of fishes, the coronary circulation is probably best described as a supplement to the cardiac circulation in terms of overall cardiac oxygen supply.

Fishes That Have a Coronary Circulation

Phylogeny, physiology, and environment all seem to have played prominent roles in the evolution of coronary circulation in fishes. The coronary circulation was

likely not present when the chambered heart first appeared in vertebrates because extant representatives of the most primitive fishes (hagfishes and lampreys) do not possess a coronary circulation. However, all elasmobranchs examined to date, as well as most other primitive fishes, including sturgeon, holosteans, and lungfishes, possess a coronary circulation. This phylogenetic distribution of the coronary circulation firmly entrenches the idea that the coronary circulation is an old morphological adaptation associated with the vertebrate heart and that the advent of a coronary circulation likely postdates the cyclostomes.

The coronary circulation disappeared repeatedly among teleost fish lineages. Indeed, potentially 50% of all extant vertebrate species may lack a coronary circulation, since ~50% of all species of vertebrates belonging to the Teleostei, and as many as 80% of teleost species lack a coronary circulation. However, an in-depth understanding of the exact phylogenetic distribution of the coronary circulation in teleosts is still lacking.

Across all teleost fishes, it appears that those that have a coronary circulation are either highly athletic (e.g., salmonids and tunas) or tolerant of hypoxic environments (e.g., freshwater eels). The most athletic fishes have the greatest dependence (highest percentage of compact myocardium) on the coronary circulation. Possible explanations are provided below.

What Percentage of the Fish Heart Is Supplied by the Coronary Circulation?

From the perspective of myocardial oxygen supply, fish hearts have four major architectural arrangements. The classification system is as follows:

The 'type I' fish heart has entirely spongy myocardium and a cardiac circulation. Atlantic cod (*Gadus morhua*) and members of the sculpins family are examples of fish with type I hearts. A subtype, 'type Ib', differs in that epicardial coronary vessels are present, but these vessels do not penetrate the myocardium. Plaice (*Pleuronectes family*) is an example of a fish with type Ib heart.

The 'type II' heart has an outer compact myocardium separated from the spongy myocardium by a layer of connective tissue. The coronary vessels in the compact myocardium do not penetrate the spongy myocardium. The coronary veins drain into the atrium near the atrioventricular region (**Figure 4**(**c**)). Rainbow trout (*Oncohynchus mykiss*) and other salmonids are examples of fish with type II hearts.

The 'type III' and 'type IV' fish hearts differ from the type II hearts in that the connective tissue layer is lacking and coronary vessels penetrate the spongy myocardium. Trabeculae appear to have a single, centrally located coronary vessel that empties into the ventricle, suggesting an arrangement analogous to the Thebesian vessels of mammalian hearts. Type III hearts have a lower percentage of compact myocardium (an arbitrary value of <30% of ventricular mass) than type IV hearts. Most sharks and rays are examples of fish with type III hearts. The type IV heart has >30% compact myocardium and known examples are limited to tunas and lamnid sharks. The atrium of type IV hearts of tunas and lamnid sharks also has a coronary circulation, possibly related to the increased atrial wall thickness and diffusion distances of these large fishes.

The coronary circulation also supplies the cardiac muscle associated with the conus arteriosus of primitive fishes including elasmobranchs. The well-developed conal circulation of sharks is less obvious for primitive fishes because the conus arteriosus is often reduced in size.

The coronary vasculature has a dense arrangement, as might be expected for a working muscle, but the regional distribution of coronary vessels within the fish ventricle has received little attention. In rainbow trout, it is suggested that there is one capillary per myocyte fiber.

To summarize, the ventricle of all fish species contains spongy myocardium and this dominant muscle type lacks a coronary circulation in most fish species. Coronary capillaries are always found in compact myocardium. However, complicating these simple arrangements are a limited number of fish species with coronaries in the spongy myocardium and those with epicardial, nonpenetrating coronary vessels.

Origin and Routing of the Coronary Arteries

The coronary artery represents the first branch of the aorta; hence, in mammals the heart is the first organ that receives oxygenated blood. The coronary circulation in fish has an analogous origin in that it represents the first opportunity to route oxygenated blood back to the heart. However, this necessitates a post-gill origin, which makes the origin a little more distant from that of the mammalian heart (**Figure 1**(**b**)) Of course in fish without a coronary circulation, the heart then becomes the last organ to receive oxygen from the circulatory system!

For many fishes, the coronary circulation originates from the efferent branchial arteries in the gills, and it is termed either the cranial hypobranchial or anterior coronary supply. Bilateral vessels carry the oxygenated blood retrograde toward the ventral aorta in gill arches 1, 2, or 3, depending on the species. These vessels unite on the midline of the isthmus often to form a single vessel, commonly termed the hypobranchial artery. The coronary artery forms as a branch of the hypobranchial artery, anterior to the pericardium, which goes on to supply the pectoral musculature.

Within the pericardium, the coronary artery joins the surface of the bulbus arteriosus and may bifurcate caudally to form several arteries en route toward the ventricle (**Figure 4**(**a**)). Alternatively, several coronary arteries may join the conus arteriosus of elasmobranchs, where circumferentially arteries supply the compact myocardium of the conus arteriosus en route toward the ventricle.

A few fish groups (e.g., rays, eels, and marlin) have an additional posterior or caudal coronary supply. This supply is via the coracoid artery, which has its origin on the dorsal aorta posterior to the heart and then passes through the pericardio-peritoneal wall to reach the ventricle. The relative roles of the anterior and posterior coronary supply routes have not been studied.

Superficial coronary arteries are usually visible on the surface of the ventricle (**Figure 4**(**b**)). Similarly, superficial coronary veins are also visible draining toward the atrioventricular junction, where the coronary circulation drains into the atrium. These large distribution vessels, as well as the extensive capillary network in the compact myocardium of rainbow trout, are easily visualized with plastic corrosion casts of the coronary circulation (**Figure 4**(**c**)).

(b) A schematic representation of the arrangement of the coronary artery on the bulbus arteriosus and ventricle. (c) A vascular cast of the coronary vessels of a salmon with all tissue digested away leaving only the vessels visible. The upper opening is the ventricular–bulbar canal and the lower opening is the atrioventricular canal. (a) Courtesy of Dr. R. Seymour. (b) Courtesy of Dr. M. Axelsson.

Histology of the Coronary Artery

The histological structure of the fish coronary artery is similar to that of the mammalian coronary artery and other arteries. The main tissue layers, from inside to outside, are endothelium, internal elastic membrane or lamina, the media consisting of circular or spirally arrayed vascular smooth muscle and elastic fibers in the interstitium, and an outer adventitial layer consisting largely of connective tissue. The media of the fish coronary artery is considerably thinner than in mammals. This reduced amount of vascular smooth muscle likely reflects the lower coronary arterial blood pressure (and hence vessel wall tension) in fish.

Coronary arteriosclerotic lesions develop in the main artery of salmon. These lesions increase appreciably in their prevalence and severity as salmon grow and mature. The coronary lesions in salmon are primarily composed of vascular smooth muscle and a disrupted elastic lamina, and lack the fatty deposits that are typical of atherosclerotic plaques in human coronaries (**Figure 5**). The exact etiology and consequences of coronary arterial lesions in fishes are unknown. Vascular damage may initiate coronary lesions in salmonids – this is in line with the fact that there is a particularly high prevalence and severity of lesions in adult migratory salmon that often undergo long, stressful, and energetic upstream river migrations to reach their spawning grounds. Elasmobranchs appear to be free of these coronary lesions in the main coronary artery, but lesions are reported in the arterial branches on the surface of the ventricle.

Physiology

Regulation of Coronary Blood Flow

The primary function of the coronary circulation is to supply oxygenated blood to and remove wastes from cardiac muscle. Consequently, coronary blood flow is

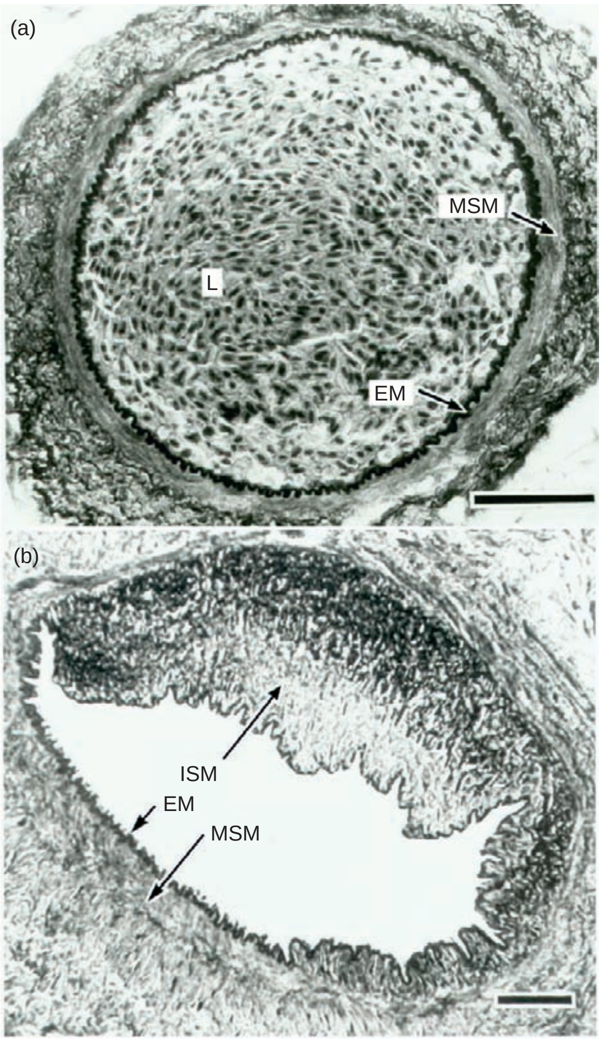

Figure 5 Histological cross sections of the main coronary artery of an Atlantic salmon to illustrate (a) the normal structure of the arterial wall and (b) a large arteriosclerotic lesion composed of intimal smooth muscle (ISM) that obstructs the lumen of the coronary artery. Scale = 50 μm. EM, elastic membrane; L, lumen of the vessel filled with nucleated red blood cells; MSM, medial smooth muscle. Adapted from Saunders RL, Farrell AP, and Knox DE (1992) Progression of coronary arterial lesions in Atlantic salmon (*Salmo salar*) as a function of growth rate. *Canadian Journal of Fisheries and Aquatic Sciences* 49: 878–884.

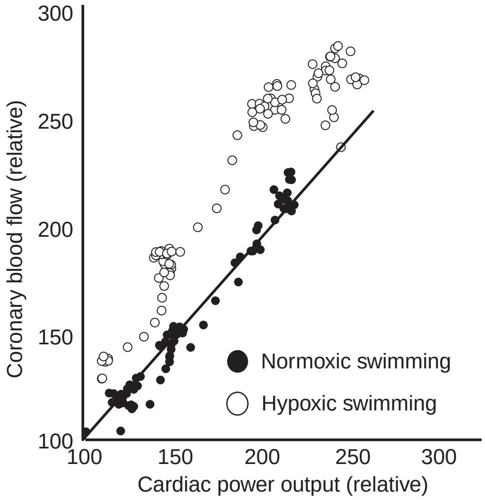

Figure 6 The relationship between cardiac power output and coronary blood flow in resting and exercising salmon. Adapted from Gamperl AK, Axelsson M, and Farrell AP (1995) Effects of swimming and environmental hypoxia on coronary blood flow in rainbow trout. *The American Journal of Physiology* 269: R1258–R1266; Figure 3.

closely matched with the work performed by the heart to pump blood through the circulatory system. Coronary blood flow has been estimated as 0.6–3.0% of cardiac power output, and 0.2–0.4 ml $\min^{-1} g^{-1}$ ventricular mass. As the heart works harder during exercise, it requires more oxygen to pump a greater quantity of blood at a faster rate and at a higher blood pressure. Thus, coronary blood flow increases by almost threefold when salmon swim fast (**Figure 6**). However, this increase in coronary blood flow during exercise does not quite match the increase in cardiac oxygen demand as measured by the increase in cardiac power output. Therefore, it is likely that either oxygen extraction from the coronary blood supply increases or the heart becomes mechanically more efficient, or some combination.

Compared with the cardiac circulation, the coronary circulation of athletic fishes provides a much more reliable myocardial oxygen supply during exercise. This is because when locomotory muscles work harder during exercise, they extract more oxygen from arterial blood, leaving less oxygen in the venous blood returning to the heart (i.e., in the cardiac circulation). It is the partial pressure of oxygen in venous blood (P_{vO_2}) that drives oxygen diffusion into the trabecular muscle. Therefore, the decrease in P_{vO_2} during exercise occurs precisely when there is an appreciable increase in myocardial oxygen demand; any imbalance between oxygen supply and demand would render the trabecular muscle hypoxic. In addition, the heart rate increases with exercise, which means that venous blood is contained in the lumen of the heart for a shorter time, leaving less time for diffusion of oxygen into the trabeculae.

Coronary blood flow also increases appreciably when salmon are exposed to hypoxic water (**Figure 6**), but in this case the workload of the heart remains unchanged. However, the oxygen supply to both the compact and the spongy myocardium is potentially compromised because arterial and venous oxygen partial pressures are reduced by hypoxia. The fish heart beats slower during hypoxia (hypoxic bradycardia), allowing more time for diffusion of oxygen from the lumen into the trabeculae.

The primary determinants of coronary blood flow are dorsal aortic blood pressure (the driving force) and coronary vascular resistance (which is determined by coronary arterial vascular tone). While arterial blood pressure is under reflex control in fishes (**see also Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System and Central Control of Cardiorespiratory Interactions in Fish), dorsal aortic blood pressure can still increase by 50% under stressful situations. However, even an increase in arterial blood pressure of this magnitude cannot account for a two- to threefold increase in coronary blood flow. Therefore, the large increases in coronary blood flow seen during exercise and hypoxia must involve corresponding decreases in coronary vascular resistance.

Coronary vascular resistance is determined by vascular tone (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). Coronary vascular tone is decreased by stimulation of beta-adrenergic receptors and increased by stimulation of alpha-adrenergic and muscarinic cholinergic receptors. These adrenergic effects might be mediated by the sympathetic innervation present in the fish ventricle (via release of the sympathetic neurotransmitter noradrenaline) and by catecholamines (the hormones adrenaline and noradrenaline) released into the circulation during stressful hypoxia and exercise. However, when catecholamines are injected into the fish coronary circulation, an alpha-adrenergic vasoconstriction dominates and this leads to an increase, and not a decrease, in coronary vascular resistance. Thus, the decreases in coronary vascular resistance observed during exercise and hypoxia must involve either other vasoactive compounds or a large coronary vasodilatory reserve.

A vasodilatory reserve would come about because the coronary vasculature is under tonic vasoconstriction, possibly involving a sympathetic tonus. Many compounds affect the vasoactivity of the main coronary artery (e.g., endothelin and prostaglandin $F_{2\alpha}$ are particularly potent vasoconstrictors), but their roles in controlling coronary vascular resistance are unclear. Acetylcholine is unlikely to be involved because it is released only as a neurotransmitter from the parasympathetic vagus nerve and cardiac vagal innervation is restricted to the sinus venosus and atrium in fish.

Coronary blood flow is in phase with the cardiac cycle, being lowest during ventricular systole and highest during diastole, as in the mammalian heart. This is because muscles such as myocardium physically compress capillaries during contraction. Accordingly, each ventricular contraction slows down coronary blood flow.

The amount of coronary blood flow to the spongy myocardium has never been measured, but is presumed to be small. Whether vasoactive agents regulate the relative distribution of coronary blood flow between the compact and the spongy myocardium in type III and IV hearts is unknown.

Limitations on the Myocardinal Oxygen Supply

The coronary circulation clearly evolved in fishes as a supplement to the cardiac circulation, which implies that myocardial oxygen supply may become limited under certain situations. As noted earlier, exercise is a potential situation where oxygen supply from the cardiac circulation to the trabeculae may become limited. Thus, a coronary circulation represents a more dependable cardiac oxygen supply for athletic fishes, which generate high blood flow and blood pressure with a resulting higher cardiac oxygen demand compared with less-active fishes. Even so, environmental hypoxia compromises cardiac oxygen supply to the compact and the spongy myocardium. Consequently, while environmental hypoxia and exercise are clearly implicated in the evolution of coronary circulation, identifying the exact conditions when oxygen supply to the fish myocardium might be limited will require more information than is currently available on cardiac oxygen supply and demand.

Since it has been calculated that venous oxygen content is more than sufficient to meet the needs of the fish heart, even during maximum cardiac effort of a swimming salmon, there is presumably a threshold P_{vO_2} at which oxygen cannot diffuse fast enough into the trabeculae to meet demands. The threshold P_{vO_2} will then depend on the oxygen demand of the heart (determined by myocardial power output), the thickness of the trabeculae, the heart rate (the inverse of blood residence time in the lumen of the heart), the environmental oxygen conditions, and the shape of the hemoglobin dissociation curve. All these parameters vary considerably among fish species; hence, it is impossible to generalize as to an exact P_{vO_2} at which oxygen diffusion from the cardiac circulation might limit trabecular function.

Given that cardiac oxygen demand is about 3 times higher during exercise than that during hypoxia (based on a threefold increase in cardiac power output when salmon swim), one might expect the difference in threshold P_{vO_2} driving diffusion to be 3 times higher during exercise than that during hypoxia. (A caveat here is that the heart rate slows during hypoxia (potentially favoring oxygen diffusion) but accelerates during exercise (potentially hampering oxygen diffusion).) In salmonids, P_{vO_2} decreases to as low as 0.8 kPa during environmental hypoxia and P_{vO_2} usually remains >2.0 kPa during maximum prolonged swimming. These P_{vO_2} values may turn out to be the threshold P_{vO_2} values for these two different cardiac work conditions.

An Alternate Way of Increasing Oxygen Delivery to the Fish Heart

The physiology of air-breathing fishes is detailed in other articles (**see also Air-Breathing Fishes**: Circulatory Adaptations for Air-Breathing Fishes; Respiratory Adaptations for Air-Breathing Fishes; The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction) and so this article considers only the cardiac benefit of air breathing. Oxygenated blood from an air-breathing organ (ABO) generally returns directly to the heart, where it mixes fully or partially with systemic venous blood (**Figure 1**(**c**)), thereby raising the overall P_{vO_2} in the lumen of the heart. This has a clear benefit in terms of the myocardial oxygen supply via the cardiac circulation.

Despite such an obvious benefit, many air-breathing fishes possess a coronary circulation. This suggests that the benefit of air breathing was insufficient to select for the loss of a coronary circulation, an event that neverthe less has occurred in water-breathing teleosts.

It has been proposed that air breathing evolved in fishes as a means of supplementing the heart with oxygen during exercise rather than hypoxia. Air breathing would certainly moderate the decrease in P_{vO_2} that occurs when fish swim, especially because exercise can increase the air-breathing frequency. However, not all air-breathing fishes increase the air-breathing frequency during exercise. Given that most air-breathing fishes increase the air-breathing frequency during hypoxia, both environmental hypoxia and exercise were likely important driving forces for the evolution of air breathing, at least from the perspective of the heart.

Glossary

Anastomose To join, plural anastomoses. An anastomosis is a connection joining two blood vessels. This can result from two or more vessels coalescing to form a single vessel, or it can be a shunt created when an artery connects directly to a vein (arteriovenous anastomosis).

Bifurcate To branch evenly. Commonly used to describe the branching of an artery or arteriole into two smaller arteries or arterioles of equal diameter.

Caudal peduncle The fleshy part of the tail anterior to the tail fin.

Cyclostomes Jawless fish including hagfish and lamprey.

Elasmobranch The subclass of fishes (Elasmobranchii) found within the class Chondricthyes that includes sharks, skates, and rays, making up the Chondricthyes or cartilaginous fishes. Their bones are made up of cartilage rather than calcium found in all other vertebrates.

Lentiform body A countercurrent vascular network in the eye of some fish that is used to concentrate oxygen to supply the retina.

Myotome Blocks of white muscle in fish used for burst swimming. When cooked, they separate as flakes.

Pectoral girdle Structures associated with the paired pectoral fins in the anterioventral body, usually just posterior to the operculum of a fish. The pectoral fins are homologous to the forelimbs of tetrapods.

Pelvic girdle Structures associated with the paired pelvic fins. These are located posterior, and generally ventral, to the pectoral fins. Pelvic fins are homologous to the hindlimbs of tetrapods.

Perfuse To pump blood or fluid through a tube or blood vessel.

Pericardial cavity The cavity containing the heart. It is usually found dorsal to the pectoral girdle.

Peritoneal cavity The body cavity containing visceral organs such as the liver, kidney, spleen, and stomach and intestines.

Physoclist A fish with a completely enclosed swimbladder.

Phystostome A fish with the swimbladder connected to the esophagus via a pneumatic duct.

Systemic All tissues of the body except the respiratory tissues.

Urophysis A small neuroendocrine gland at the caudal end of the spinal cord.

Fish Vascular Anatomy

The fish circulatory system consists of two major vascular beds, the respiratory gill (or branchial) and the systemic circulations. The gill and systemic vascular beds are in series. A four-chambered heart pumps blood through a brief arterial network into the gills for oxygenation. From there, a second, more complex arterial network delivers oxygenated blood from the gills to systemic tissues. The venous system returns the deoxygenated blood from systemic tissues and nonrespiratory gill tissue back to the heart. This basic design is common to all fish with surprisingly few, and generally minor, exceptions. Therefore, in this article, the general vascular architecture of a bony fish, the rainbow trout (*Oncorhynchus mykiss*), is described in detail as the general vascular model. A few phylogenetic variations in cyclostomes and elasmobranchs are also described. The most significant exceptions to the general fish model are found in the form of the varied anatomical pathways in air-breathing fish (**see also Air-Breathing Fishes**: The Biology, Diversity, and Natural History of Air-Breathing Fishes: An Introduction), the presence of rete mirable in tunas and some sharks (**see also Design and Physiology of Arteries and Veins**: The Retia), and the enigmatic secondary circulation (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy).

The pre-gill and post-gill arterial vasculature in the head is illustrated in **Figure 1**. The systemic arterial vessels are illustrated in **Figure 2**. The trunk segmental arterial and venous vessels are shown in **Figure 3**. Systemic venous vessels are illustrated in **Figure 4** and major venous vessels in the head in **Figure 5**.

Arterial System

Pre-Gill Arteries

The muscular ventricle (V) pumps blood through the bulboventricular valve (BV) and into the bulbus arteriosus

Classe des Sciences Mathematiques et Naturelles Serie B: Sciences Naturelles* III: 241–261.

(B) in teleosts or conus arteriosus in most other fish (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes). The bulbus is typically a pear-shaped vessel with thick elastic walls and may be lined with a dozen or more longitudinal septa. The bulbus is over 30 times more compliant than the mammalian aorta and because it may be able to store up to 100% of the stroke volume, it serves an important role in dampening ventricular pulse pressure. The bulbus is well endowed with vascular smooth muscle and connective tissue (elastin and collagen) and it has a physiological role in storing the energy of cardiac contraction and thereby dampening the arterial pulse pressure (**see also Design and Physiology of the Heart**: The Outflow Tract from the Heart and Physiology of Cardiac Pumping). It remains to be determined if this has a physiological role in affecting compliance and therefore arterial pulse pressure. The septa, however, clearly add structural integrity to the bulbus. The conus arteriosus of elasmobranchs and other subteleostean fish, such as bowfin (*Amia calva*) and gar (*Lepisosteus* sp.), occupies a similar position within the pericardial cavity and presumably has a similar function. However, the conus has true cardiac muscle surrounding the connective tissue (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). The conus has its own pacemaker and, in some fish, it initiates as well as conducts an action potential, typically down the length of the conus away from the heart. The conus usually has numerous valves. After passing through the bulbus or conus, the blood leaving the heart enters the ventral aorta (VA), which at this point is still within the pericardial cavity.

The ventral aorta passes anteriorly out of the pericardial cavity and branches to give rise to the afferent branchial arteries that deliver deoxygenated blood to the gill arches. There are four pairs of gill arches in bony fish, and, in some fish, pairs of independent afferent branchial

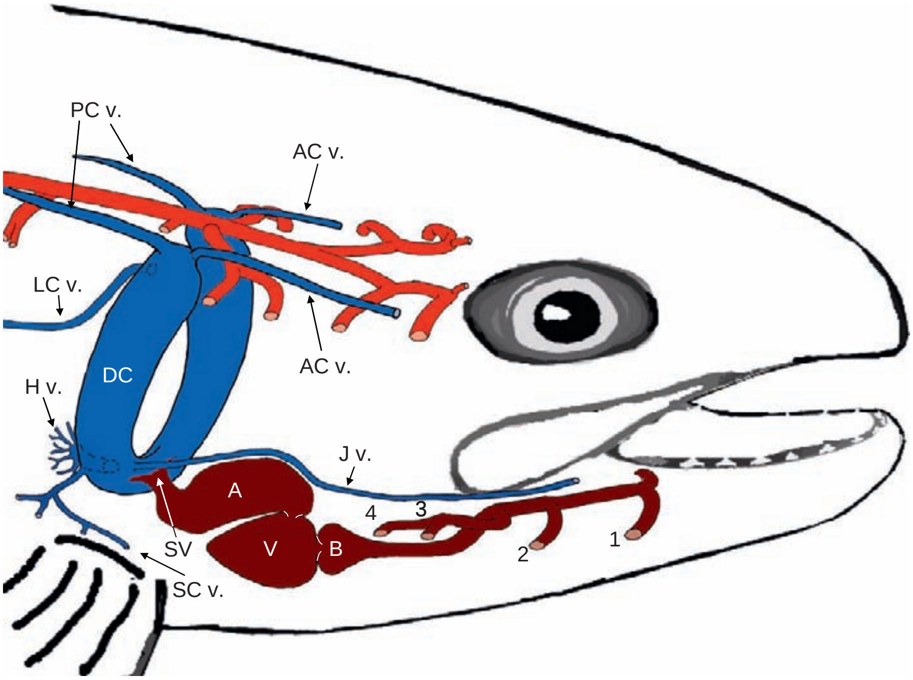

Figure 4 Central venous system in the rainbow trout head. **See Figure 1** for abbreviations.

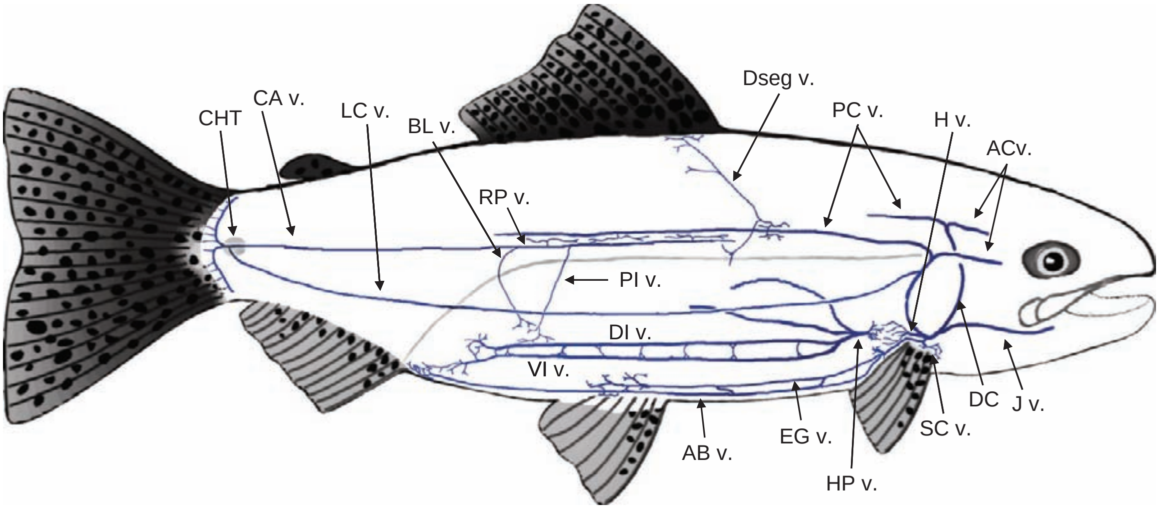

Figure 5 Major systemic veins in the rainbow trout. **See Figure 1** for abbreviations.

arteries successively supply the fourth through the first pair of gills. In other fish, such as the rainbow trout, the first pair of vessels to arise from the ventral aorta turn posteriorly and then bifurcate, with the most posterior branch forming the fourth afferent branchial artery (4) and the other the third (3). The main trunk of the ventral aorta continues anteriorly, and, after giving rise to a pair of afferent branchial arteries that supply the second gill arches (2), bifurcates to form the first pair of afferent branchial arteries (1). The afferent branchial arteries enter the gill arches and ultimately form the microcirculation of the gill (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy and **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics).

Post-Gill (Systemic) Arteries

Post-gill arterial vessels supply the systemic (body) circulation. Most of the gill blood supply exits via the efferent branchial arteries that emanate from the posterio-dorsal aspect of the gill arches. A comparatively minor circulation

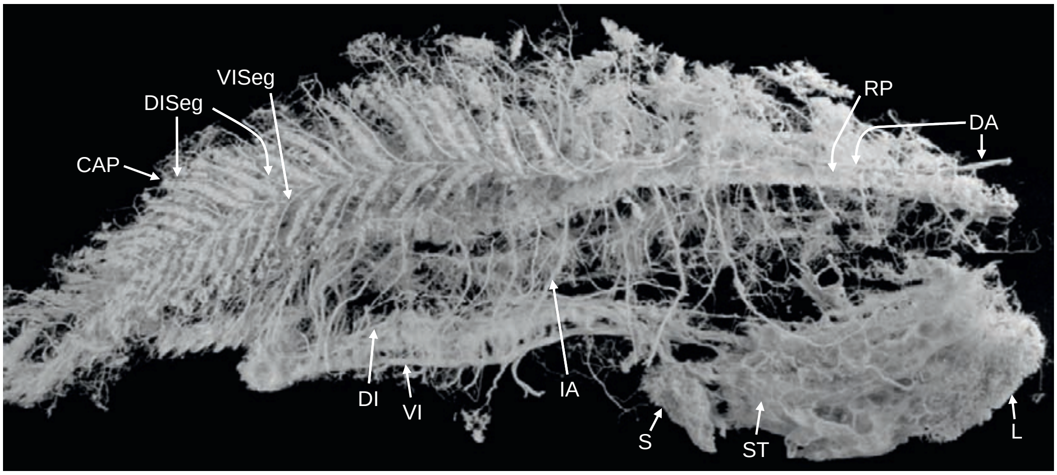

Figure 6 Vascular corrosion replica of the systemic circulation of rainbow trout. The dorsal aorta (DA) and celiacomesenteric artery (not visible) were perfused with liquid methyl methacrylate. After polymerization, the tissue was digested away leaving a vascular replica. This figure shows the dorsal and ventral intersegmental (DISeg and VISeg) and intercostal (IA) arteries and the extensive capillary networks (CAP) they supply. Also visible is the renal portal (RP), liver (L), stomach (S), spleen (SP), and dorsal and ventral intestinal (DI and VI) circulations. **See Figure 1** for abbreviations.

also exits via the anterio-ventral and ends of the gill arches through extensions of efferent branchial arteries. This latter circulation is usually limited to supplying the ventral jaw and, if present, the coronary circulation. The gill also has its own systemic circulation (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy and **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics).

Posterio-dorsal post-gill arteries

Arteries in the head

The efferent branchial arteries that arise from the posterio-dorsal regions of the gill arch supply the bulk of the systemic circulation. Although efferent branchial arteries from all four arches are interconnected into a common manifold, additional vessels, the carotids and hyoidean, typically emanate from the first arch efferent branchial artery (1′) and form the major supply network to the anterior head region. The main portion of the efferent branchial artery from the first gill arch turns posteriorly and becomes the lateral dorsal aorta (LA) and is soon joined by the efferent branchial artery from the second gill arch (2′). The two lateral aortas then anastomose to form the anterior segment of the dorsal aorta (DA). Efferent branchial arteries from the third (3′) and fourth (4′) gill arches on either side of the fish frequently anastomose to form a single vessel, often called the epibranchial artery, prior to joining the dorsal aorta. Efferent branchial arteries that arise from the first pair of gill arches directly supply the systemic circulation in the head region (anteriorly) and also connect posteriorly to efferent branchial or epibranchial arteries from other gill arches (an epibranchial artery is formed by the anastomosis of two efferent branchial arteries from adjacent gill arches). Systemic arteries do not arise directly from efferent branchial or epibranchial arteries of the second through fourth pair of other gill arches, or from the lateral dorsal aortas. Some fish may have a single anterior dorsal aorta in lieu of the paired lateral aortas.

The internal (IC) and external (EC) carotid arteries, and the hyoidean artery (HY) originate from the first gill arch efferent branchial arteries, usually as the latter makes its posterior turn. The internal carotid travels anterio-dorsally to the brain. The cephalic circle in the brain (BR) is formed by the union of posterior branches of the internal carotids from both sides of the head. The orbito-nasal artery (ON) arises from the internal carotid about midway along the carotid and travels anteriorly. One branch, the nasal artery (N), continues to supply the olfactory organ, the other becomes the optic artery (OT) and continues on to the retina and lentiform body of the eye. The external carotid, or orbital artery, courses dorsally from the efferent branchial artery before branching anteriorly and posteriorly to perfuse the more superficial structures of the head. The hyoidean artery travels anteriorly to the anterior head region.

Arteries to the trunk

The dorsal aorta traverses the longitudinal axis of the body ending in the caudal peduncle anterior to the caudal (tail) fin. While this entire vessel is often referred to as the dorsal aorta, posterior to the peritoneal cavity, it is technically the caudal artery (CA). The dorsal aorta travels just beneath the vertebra and above the dorsal surface of the kidney. As the dorsal aorta diminishes in diameter (there is progressive loss of blood to segmental arteries) and leaves the peritoneal region to become the caudal artery, ventral processes of the spine become fused forming the hemal arch and the caudal artery travels within this arch (the hemal canal), along with the caudal vein and several secondary veins. Longitudinally, both the dorsal aorta and caudal artery take on a characteristic undulating form due to their close association with the vertebrae. In some fish, including rainbow trout, the dorsal wall of the dorsal aorta and caudal artery tightly adhere to the vertebrae and the vessel cannot be dissected free. In other fish, such as eels (*Anguilla*), the vessel is more readily isolated from surrounding tissue. In addition, in some fish such as the rainbow trout, there is a longitudinal elastic ligament in the lumen of the dorsal aorta. This ligament is attached to the dorsal wall of the vessel via the basioccipital bone and forms a dorso-ventral vertical septum that nearly completely divides the long axis of the vessel for up to a quarter of its length. Although its exact function is unclear, it most likely helps propel blood down the dorsal aorta when the trunk undulates during active swimming.

A pair of segmental arteries arise from the dorsal aorta shortly after the union of the lateral aortas and anterior to the anastomosis of the epibranchial arteries with the dorsal aorta (not shown in **Figure 1**). Paired subclavian arteries (SC) arise from the lateral wall of the dorsal aorta just posterior to the anastomoses of the epibranchial arteries. The subclavian arteries run ventrally and supply the pectoral girdle, pectoral fins, and adjacent musculature. Branches of the subclavian arteries may connect directly to the epigastric arteries (EG) or may communicate with them via the coracoid artery (CC). The subclavian arteries often anastomose anteriorly, with the hypobranchial circulation (see below). As the dorsal aorta travels posteriorly from the origin of the subclavian arteries, it gives rise to numerous segmental arteries. The celiac and mesenteric arteries supply the anterior (stomach) and posterior (intestines) viscera, respectively. In some fish, such as rainbow trout, these vessels may arise as a single vessel, the celiacomesenteric artery (CM), but even in the same strain of trout, some individuals may have separate vessels. Small renal arteries (RA) perfuse the kidney and one or two small posterior intestinal arteries (PI) supply the posterior gut (see also **Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation).

Segmental arteries

Segmental arteries rise in association with each vertebra, often in alternating myosepta. These vessels supply blood to the red and white muscle and possibly skin, although the secondary circulation may perfuse the superficial epithelium in the skin. There are three groups of segmental arteries: dorsal, lateral, and ventral. Dorsal and lateral segmental arteries (DSeg and LSeg) and their corresponding veins (DSeg v. and LSeg v.) travel in the septa between myotomes and small branches leave periodically to enter the myotomes and perfuse the muscle fibers and skin. Ventral segmental arteries and veins, more commonly known as the intercostal arteries (ICos) and veins (ICos v.), follow a slightly different pathway but serve a similar purpose.

Dorsal segmental arteries leave the dorso-lateral wall of the dorsal aorta and travel dorsally, briefly skirting laterally around the vertebra (Vb) *en route*. They then accompany the dorsal spines and continue to the dorsal surface. Dorsal segmental arteries of rainbow trout are paired, whereas in many other fish, one of the pair is reduced. Midway along their route, they give rise to perpendicular secondary muscular arteries (SM) that branch profusely to perfuse the dorsal musculature. Further dorsally, tertiary muscular arteries (TM) branch to perfuse the muscle beneath the dorsal fins.

Lateral segmental arteries arise from the dorsal segmental arteries at the level of the ventral border of the vertebrae and run transversely through the horizontal myosepta of the axial muscles to a point just beneath the red muscle. Here they divide into three branches, forming the dorsal, lateral, and ventral intersegmental arteries (DISeg, LISeg, and VISeg). The dorsal intersegmental branch travels dorsally between the muscle and skin, roughly following the path of the myotomes and its fine terminal branches anastomose with the tertiary arteries of the dorsal segmental vessels. The ventral intrasegmental branch follows a similar ventral-ward course and its terminal branches ultimately anastomose with terminal vessels of the epigastric artery (EG). Numerous branches along the length of both dorsal and ventral intersegmental arteries supply the underlying myotomes and superficial skin. The lateral intersegmental artery is considerably shorter and smaller in diameter than the other two and it continues laterally to perfuse the red muscle. The intercostal (ventral segmental) arteries leave more ventrally from the dorsal aorta and briefly travel perpendicularly toward the ribs and then follow the ribs ventrally. Small branches along their length supply the ventro-lateral muscles of the trunk, peritoneum, and ribs. The distal fine branches also anastomose with the epigastric vessels. Intercostal arteries are smaller than the lateral segmental arteries.

Paired epigastric arteries travel longitudinally along the ventral aspect of the fish between the peritoneum and abdominal muscles and link the pectoral and pelvic girdles. They are not true segmental vessels but have numerous capillary anastomoses with the subclavian, intercostal, and ventral intersegmental arteries.

Visceral arteries

The celiacomesenteric artery travels posterioventrally, usually passing to the right of the esophagus, and soon divides into the celiac (anterior) and mesenteric (posterior) branches, although these are also commonly called the intestinal (IN) and gastrointestinal (GI) arteries, respectively. In some fish, the gastrointestinal artery may originate some distance posterior to the intestinal. Other than a few segmental arteries that supply the very posterior gut, the celiacomesenteric artery is the only major visceral artery in rainbow trout.

The intestinal artery travels ventrally and gives rise first to the hepatic artery to perfuse the liver (H) and then turns posteriorly and branches to form the duodenosplenic artery (DS) that perfuses the pyloric cecae and spleen, and ventral intestinal artery (VI) that perfuses the ventral intestine. The branches from the gastrointestinal artery include paired gonadal arteries to the gonads (GO), gastric arteries to the dorsal stomach (GA), gastrosplenic arteries to the stomach and spleen (GS), and dorsal intestinal arteries (DI) to the dorsal aspect of the intestine. In a number of instances, small terminal arteries from different sources anastomose to form a collateral arterial circulation. This is seen in the union of the gastrosplenic and duodenosplenic arteries in the spleen, the gastric and duodenosplenic in the stomach, the dorsal and ventral intestinal arteries along the intestine, and one or two segmental arteries, the posterior intestinal arteries, that travel from the distal dorsal aorta to the rectum and very posterior intestine and anastomose with both dorsal and ventral intestinal arteries. These segmental arteries are unlike the intercostal arteries in that they pass ventrally through the midline of the kidney and travel directly through the peritoneal cavity *en route* to the intestine.

The swimbladder (**see also Design and Physiology of Arteries and Veins**: The Retia and **Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes) in physostomes, such as the rainbow trout and eel, is perfused by the swimbladder artery (SA), which branches off the celiacomesenteric artery. This vessel branches into a capillary network in the resorbent portion and then onward, via retia forms a capillary bed in the secretory end. In physoclist fish, the celiac and intercostal arteries supply the secretory and resorbant tissues, respectively. The kidney is supplied by numerous small renal arteries that arise either directly from the dorsal aorta, from segmental arteries, or from the venous renal portal system, as described next.

Anterio-ventral post-gill arteries

Extensions from the efferent branchial arteries of the first, second, and sometimes third and fourth gill arches exit the anterio-ventral portion of the arch and supply the lower jaw, pseudobranch (in rainbow trout), and the heart if the fish has a coronary circulation (**see also Design and Physiology of the Heart**: The Coronary Circulation). Efferent branchial arteries are paired in the anterio-ventral arch because the artery forks around the afferent branchial where the latter enters the gill arch. The lateral, outside fork of the efferent branchial from the first gill arch becomes the mandibular artery (MA). Side branches of this artery supply the lower jaw, whereas a main branch, now the afferent pseudobranch artery (AP), makes an abrupt hair-pin turn and proceeds ventro-posteriorly and then dorsally, following the arc of the operculum, to supply the pseudobranch (P). *En route*, a number of smaller arteries branch from the afferent pseudobranch artery and supply the operculum. In non-salmonids, the afferent pseudobranch artery may originate from the posterio-dorsal arteries via the cephalic circle. The pseudobranch is drained by the efferent pseudobranch artery (EP), which becomes a singular ophthalmic artery (OP) ultimately forming the choroid artery (CH) that perfuses the choroid gland of the eye (**see also Design and Physiology of Arteries and Veins**: The Retia). A short transverse commissural vessel (C), about mid-way between the pseudobranch and choroid, connects the two ophthalmic arteries from the opposite sides of the head.

Ventral extensions from the medial (inside fork) of the efferent branchial arteries from the second pair of gill arches unite with each other to form the median hypobranchial artery (HB). This artery travels posteriorly along the ventral surface of the ventral aorta and it bifurcates as it passes under the bulbus to form the left and right coronary arteries (CO). One or more small branches of the coronary artery may continue posteriorly to anastomose with branches from the subclavian artery.

Venous System

It is common in vertebrate circulatory systems for veins to be closely associated with the respective artery whose blood they return. By convention, these veins are given the same name as their corresponding artery and, unless noteworthy, are not repeated. There are, however, a few exceptions such as the jugular, cardinal, and abdominal veins. These vessels are described below. In addition, there are several aspects of the fish venous system not common to all vertebrates. These include the renal portal system and the venous caudal heart (**see also Design and Physiology of the Heart**: Accessory Hearts in Fishes). These are also described in greater detail later.

Valves are absent from fish arteries (other than those associated with the bulbo-ventricular opening and the conus arteriosus), whereas venous ostial valves are common. These valves, located at the opening of tributary veins into longitudinal veins, are plentiful and prevent retrograde (reverse) flow. They are especially useful during contraction of skeletal muscles and, by virtue of their one-way conduction, act as skeletal-muscle pumps and assist venous return during swimming. Parietal valves are found within longitudinal veins of higher vertebrates and act as anti-gravity valves to prevent blood from being pulled away from the heart by gravity into dependent veins (those lower than the heart). Parietal valves are not found in fish, presumably because they live in a nearly neutrally buoyant environment.

Central Venous System

The central venous system is comprised of the ductus Cuvier (DC) and the large longitudinal (axial) veins that return blood from the head and trunk into the sinus venosus (SV) which lies inside the pericardial cavity. The ductus Cuvier is a U-shaped vessel embedded in the transverse septum, the tissue that separates the pericardial and peritoneal cavities. The opening between the ductus and the sinus venosus is located ventrally near the bottom of the U. From one to several hepatic veins (H v.) also enter the sinus venosus in this region from the peritoneal side. The anterior and posterior cardinal veins (AC v. and PC v.) drain into the dorsal horns of the ductus. In some literature, the ductus may be called the common cardinal vein. Prominent ostial valves are located at the junction of the anterior cardinal veins with the ductus Cuvier, but not between the ductus Cuvier and the sinus venosus.

Venous Drainage of the Head

Three principal veins drain the head, a singular jugular (J v.) and paired anterior cardinals. The jugular vein lies in the midline of the lower jaw, dorsal to the ventral aorta and ventral to the esophagus. The jugular drains the thyroid gland, pharyngeal muscles, and tissues of the lower jaw, the venous drainage from the anterio-ventral ends of the gill arches, and a portion of the pericardium. The jugular vein drains directly into the sinus venosus slightly to the right of the midline. The anterior cardinal veins are the central extensions of the orbito-nasal veins (not shown in **Figure 3**) and drain the snout, olfactory rosettes, eyes, braincase (via anterior, medial, and posterior cerebral veins), and other tissues in this region. The cardinal veins drain into the sinus via the ductus Cuvier.

Venous Drainage of the Trunk

By definition, a portal system contains two vascular networks (typically capillary beds) in series. Two portal systems are unique to fish: the renal portal system and the pseudobranch (see earlier). Another major portal system, which is common to all vertebrates, is the hepatic portal system.

Renal portal system

Much of the venous return from the trunk musculature and skin, and nearly all of it from the post-abdominal region and tail fin, passes through the renal portal system before returning to the heart. Segmental veins in the post-abdominal trunk and primary veins from the caudal fin drain into the central caudal vein (CA v.) located in the hemal arch. This vein also receives flow from secondary vessels in the caudal fin and lateral cutaneous veins (LC v.) via the caudal heart (described below), as well as from the urophysis. As the caudal vein approaches the kidney, it anastomoses with the bladder vein (BL v.) and, within the kidney, a branch from the caudal vein connects with the posterior intestinal vein (PI v.). The bladder may also be connected directly to the posterior cardinal vein via a second vein that passes through the gonads. The direction of flow in these two branches is unclear – toward or away from the caudal vein. If it is away from the caudal vein, it may be an additional portal system in parallel with the renal portal vessels. Nevertheless, the majority of caudal venous blood enters the kidney and in the kidney, the vein ends and blood percolates through the renal parenchyma and around the renal tubules.

Some segmental veins also directly contribute to the renal portal system. In the abdominal region of the trunk, the dorsal and lateral segmental veins anastomose and a short common vessel delivers blood to the renal parenchyma, as do the intercostal veins.

Renal portal blood and post-glomerular renal arterial blood are then collected into the posterior cardinal vein as it passes through the kidney and the blood is delivered to the ductus Cuvier. Commonly, the left posterior cardinal vein is either considerably reduced, or nonexistent, and the right posterior cardinal vein assumes a central position. It then serves as the main conduit for venous return.

Hepatic portal system

Essentially all drainage from the intestines, spleen, and liver (known as the splanchnic or visceral region) ultimately flows into the short hepatic portal vein (HP v.), which then enters the liver and supplies blood to the liver sinusoids. There are numerous interconnections among splanchnic vessels that form a diffuse system with a number of pathways for venous return. For instance, the gastrosplenic vein connects the splenic vein with the lateral gastric vein, the duodenosplenic vein connects the spleen with the pyloric cecae and the duodenum, and venous anastomoses within the spleen form a gastro-dudeno-splenic loop that has several connections with the hepatic portal vein. The dorsal and ventral intestinal veins (DI v. and VI v.) are similarly connected with each other through circumferential veins that encircle the intestine. The dorsal and ventral intestinal veins travel along the respective borders of the intestine and directly anastomose with the hepatic portal vein. Although the hepatic-arterial and hepatic-portal blood mix in the liver sinusoids, the diameter of the celiacomesenteric artery is considerably larger than the hepatic artery and the majority of blood flow through the liver is venous. Blood from the sinuses is collected into one or several very short hepatic veins that drain into the ductus Cuvier.

Cutaneous veins

There are four noticeable longitudinal vessels that run beneath the skin, one each on the dorsal and ventral margins of the fish and one on each side of the fish, essentially beneath the lateral line. Although these vessels appear to be simple return vessels, there are a number of unresolved issues regarding their connections with other vessels: the direction of flow, and why the blood in them often has very few red blood cells. It has been proposed that these may be lymph vessels or veins of the secondary circulation (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy), for a detailed discussion on these possibilities). The more obvious connections to the central venous system are described next.

The abdominal vein extends ventrally from the anus along the ventral midline to the region of the pectoral fins, although there are also reports that a branch continues on to the tail. Near the pectoral fins, the abdominal vein turns laterally and anastomoses with either the left epigastric (EG v.) or subclavian (SC v.) vein or it may drain directly into the ductus Cuvier. The abdominal vein anastomoses repeatedly with the epigastric veins and in the pelvic region with the iliac vein. The dorsal vein follows a similar course beneath the dorsal skin. In the region of the dorsal fin, it often divides into three branches, two of which travel lateral, and one medial, to the fin rays.

Lateral cutaneous veins connect at the caudal end with the caudal heart (CHT) and anteriorly are likely to drain into the ductus Cuvier, although the actual connections remain unclear. The caudal heart is basically a sac-like structure with a vertical baffle that divides the heart into two lateral chambers (**see also Design and Physiology of the Heart**: Accessory Hearts in Fishes). Presumably, it acts as a booster pump to move blood into the caudal vein from the low-pressure secondary veins draining the caudal fin. Spinal nerves alternately contract a sheet of skeletal muscle on either side of the caudal heart, which alternately compresses the baffle into one chamber then the other and forces fluid into the caudal vein. This helps compensate for incompressibility of the caudal vein as the walls of this vessel are imbedded in the bony hemal arch and insulated from muscular contraction. Swimming movements may also contribute to the activity of the caudal heart. Caudal hearts are generally quite small (~1–2 mm in adult rainbow trout) and because their capacity must be limited, their overall importance remains unclear. Furthermore, in non-swimming fish, much of the flow through the lateral cutaneous veins appears to be forward and fluid is delivered to the heart via an anastomosis between the cutaneous vein and the ductus Cuvier.

Hagfish

The vascular anatomy of the most primitive extant fish, the hagfish (class Myxine), is basically similar to that described earlier for teleosts with only a few notable exceptions. Hagfish have more pairs of gills than teleosts, anywhere from five to as many as fifteen pairs, and thus they have more afferent and efferent arteries as well as a distinct gill vascular organization. Other modifications include a single medial anterior dorsal aorta in addition to the paired lateral aortas, a portal heart on the hepatic portal vein that is comprised of true cardiac muscle, complete with its own electrocardiogram. They also have both caudal and anterior cardinal hearts that are powered by skeletal muscle. These are analogous to, but structurally different from, the caudal heart of teleosts. Hagfish do not have a bulbus or conus arteriosus, and they lack a spleen and a renal portal system. Perhaps the most striking feature, however, is the sinus system especially the capacious subcutaneous sinus (**see also Hagfishes and Lamprey**: Hagfishes; **Design and Physiology of the Heart**: Accessory Hearts in Fishes, and **Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy). There are numerous small vascular sinuses associated with a variety of tissues, and these ultimately drain into the subdermal blood space that almost completely surrounds the fish from head to tail. This sinus system has been likened to the primitive lymphatic system or the secondary circulation of teleosts.

Elasmobranchs

The elasmobranchs, sharks and skates and rays, typically have five, but may have up to seven, pairs of gill arches and, like hagfish, there are additional branchial arteries to accommodate these gill arches. However, unlike the hagfish, vascular supply to the gills is very similar to that of teleosts. The elasmobranchs lack an operculum and swimbladder, and their conus arteriosus is extensively valved. Most other vascular modifications are relatively minor.

Glossary

Abductor muscle A muscle that pulls two objects apart.

Adductor muscle A muscle that pulls one object toward another.

Anastomose To join, plural anastomoses. An anastomosis is a connection joining two blood vessels. This can result from two or more vessels coalescing to form a single vessel, or it can be a shunt created when an artery connects directly to a vein (arteriovenous anastomosis).

Bifurcate To branch evenly. Commonly used to describe the branching of an artery or arteriole into two smaller arteries or arterioles of equal diameter.

Buccal cavity The mouth (oral) cavity at the anterior end of the fish in front of the gills.

Chemoreceptors Type of cell that is specialized to detect chemical stimuli and convert them into signals within the nervous system.

Countercurrent Flowing in opposite directions. Used for an arrangement of vessels (e.g., blood vessels or kidney tubules) such that fluid flows in one direction in one vessel that lies close to another vessel in which the flow is in the opposite direction. This arrangement allows the transfer of molecules or heat from one vessel to another in such a ways as to maintain a gradient along the countercurrent vessels.

Filament The functional unit of the gill containing the respiratory lamellae, ionocytes, mucus cells, and pavement cells. It was formerly called the primary lamella.

Gill raker Projections from the gill arch that prevent particulate material from damaging the gills, and also direct food into the esophagus.

Hemibranch A 'half' branch (gill arch) with only one row of filaments.

Holobranch Two hemibranchs on the same gill arch form one holobranch.

Intrabranchial septum Tissue that runs between, and is attached to, the filaments of both hemibranchs on a gill, thereby restricting their movement.

Lamellae Also known as secondary lamellae, these are attached in rows to the gill filaments. They are the primary sites for gas exchange in fish gills. Each lamella is made up of two epithelial layers separated by pillar cells. Oxygen is taken up by erythrocytes flowing inside the lamellae from water flowing between the lamellae.

Pseudobranch A reduced mandibular gill arch, in elasmobranchs the spiracular gill, in teleosts located on the inside of the operculum. In teleosts with ocular oxygen secretion, blood is supplied to the eye only via the pseudobranch.

Introduction

The fish gill is the primary site for respiration, osmoregulation, acid–base balance, nitrogen excretion, and metabolism of circulating hormones. These diverse and specialized activities are reflected in the anatomical diversity and specialization of the gills. Compared to air, water is 800 times more dense and 60 times more viscous, has 1/30th the capacity to hold oxygen, and allows oxygen to diffuse at 1/8000th the rate. Gill architecture has achieved a delicate balance between a tissue that is thin enough to promote transepithelial transfer of a variety of molecules, yet strong enough to withstand the viscous and often abrasive aquatic environment.

The Gill Arch

The gill develops in the embryo from a series of paired pouches in the lateral walls of the mouth cavity (more commonly called the buccal cavity; **see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Models and Mechanisms. These pouches form a water pathway from the mouth to the exterior, and the tissue between them becomes the gill arch and supports the gill filaments. In bony fish (teleosts), the gill arch is a relatively simple bow-shaped structure whose ends are attached to the dorsal and ventral surfaces of the buccal cavity and with the curved portion projecting posterio-laterally (**Figures 1**(**a**) and **1**(**b**)). Teleosts have eight gills arranged in pairs with four pairs on either side of the buccal cavity. The pseudobranch, an additional, vestigial gill hemiarch, is also present in most teleosts (notable exceptions being the catfish). The pseudobranch is covered by a thick epithelium; its physiological function is not known.

The gill arch is supported by three bones, which, starting from the ventral aspect, are the hypobranchial (Hb), ceratobranchial (Cb), and epibranchial (Eb) bones (**Figure 1**(**a**)). These bones are hinged to provide flexibility necessary for jaw movement during feeding and respiration. They also serve as the mechanical anchor for the filaments. Gill rakers typically project from the arch on the opposite side of the filaments (**Figures 1**(**a**) and **1**(**b**)). They serve as filters to protect the delicate filaments from large particulate matter, which can also be food that they help funnel into the esophagus. The arch also provides a matrix for gill blood vessels, most notably the afferent and efferent branchial arteries (**Figures 1**(**c**), **2**(**a**), **2**(**b**), *2*(**c**), and **3**(**a**)) and brachial veins.

Each arch supports paired rows of long blade-like filaments. Each row of filaments is called a hemibranch (**Figures 1**(**d**) and **2**(**a**)), and two hemibranchs that share the same arch form a holobranch (**Figure 2**(**a**)). Filaments of one hemibranch alternate with the filaments of the adjacent hemibranch along the arch. Filaments from the two hemibranchs on a single arch face different water channels (gill slits), whereas hemibranchs from adjacent arches (the posterior hemibranch of one arch and the anterior hemibranch of the next arch) share a common water channel. The tips of filaments from adjacent hemibranchs lining the same water channel nearly touch each other and this maximizes water flow across the filament surface (**Figures 2**(**a**) and **2**(**b**)). A cartilaginous rod runs the length of the filament to provide mechanical support (**Figure 3**(**a**)).

In some fish, the filaments are only attached to the gill arch at the filament base. Adductor and abductor muscles mechanically connect the cartilaginous rod in the filament to the arch. The contraction of the abductor muscles spreads the hemibranchs farther apart, whereas the contraction of the adductor muscles moves the tips of the filaments of the hemibranchs on the arch closer to each

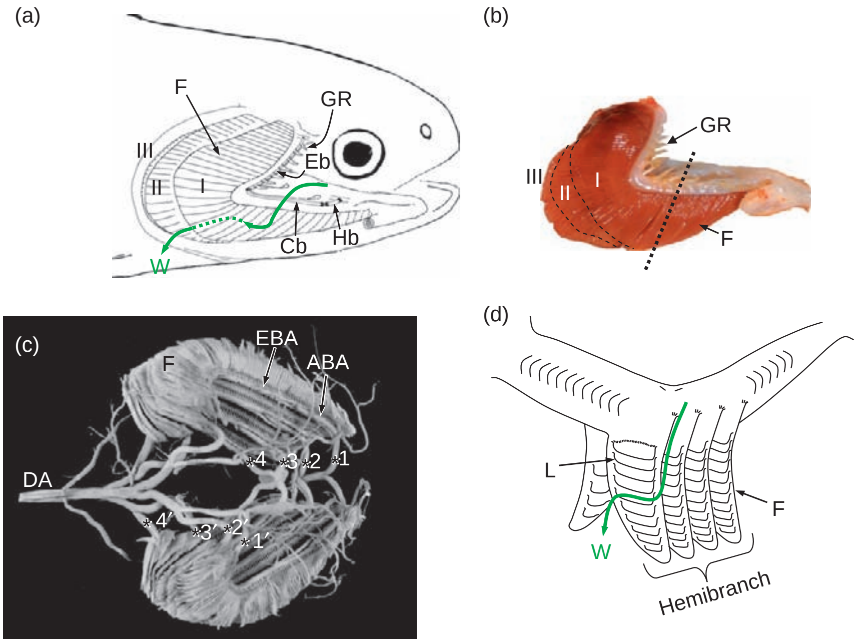

Figure 1 General orientation of the gills. (a) Eight gills line the buccal (mouth) cavity of the fish, four on each side. Three gills, I, II, and III, on the right side of the fish are shown in the figure. The gill arch supports the filaments (Fs) and gill rakers (GRs). Three bones in the arch, hypobrachial (Hb), ceratobrachial (Cb), and epibrachial (Eb), provide strength and are hinged, permitting the gills to move with the jaw during ventilation. Water flows past the gill rakers, over the arch, and between the filaments (green arrows, W). (b) Gills removed from a fish showing three of the four gills (I, II, and III, separated by dashed lines). Dotted line indicates plane of cross section through the arch viewed in **Figure 2**. (c) Dorsal view of a vascular corrosion replica of catfish gills, anterior to right. 1–4, afferent branchial arteries (ABAs) deliver blood to corresponding gill arches (asterisk directly on vessel to left of number); 1′–4′ efferent brachial arteries (EBAs) drain blood from the corresponding gill arches and deliver it to the dorsal aorta (DA). (d) Schematic of a single gill arch showing the relationship of the filaments (Fs) of one hemibranch and the direction of water flow (W; green arrow) between the filaments of one hemibranch and across the respiratory lamellae (L). GRs on the ventral portion of the arch are not shown.

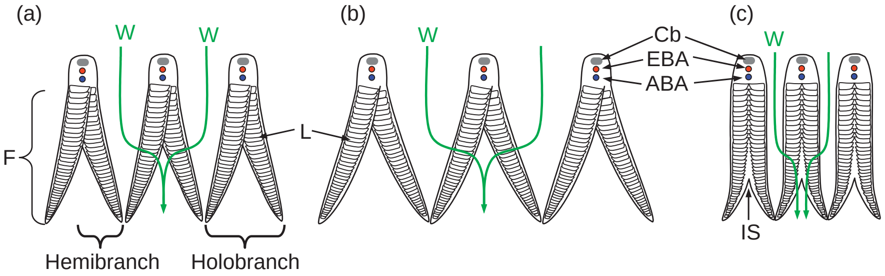

Figure 2 Cross section through three adjacent gill arches showing the freedom of movement of filaments in gills lacking an intrabranchial septum (IS; a, b) compared to the restriction imposed by the IS (c). Filaments on each side of the gill form a hemibranch and two hemibranchs on a single gill arch form a holobranch. Water flows between hemibranchs of adjacent gill arches, passes across the respiratory lamellae (L), and exits between the hemibranchs on the same gill arch. Other abbreviations: Cb, ceratobranchial bone of arch skeleton; ABA, afferent branchial artery; EBA, efferent branchial artery.

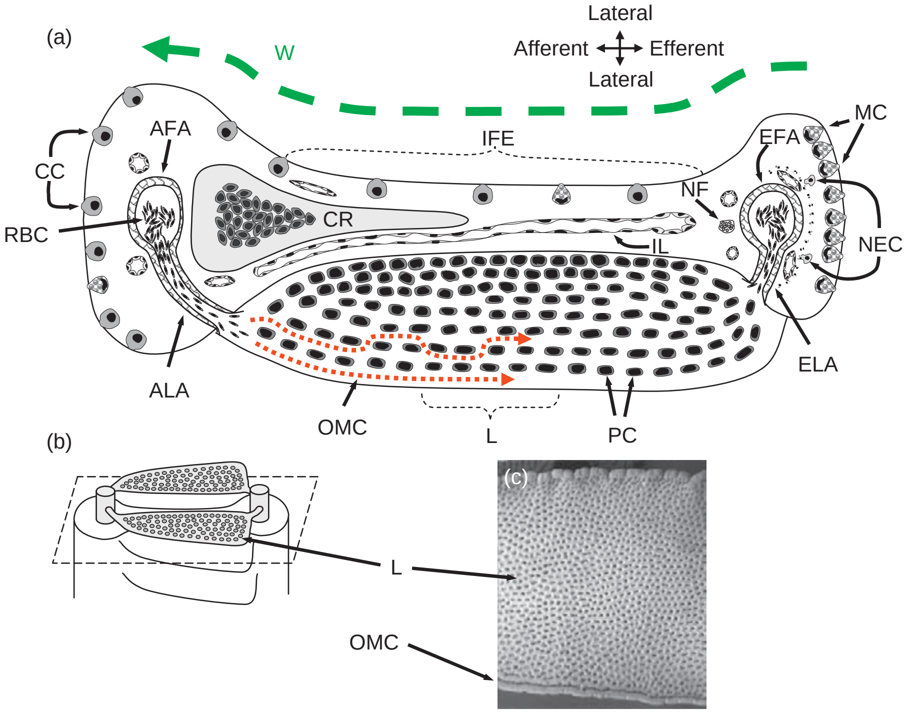

Figure 3 (a) Cross section through a gill filament including a planar section through one respiratory lamella (L); inset (b) shows plane of section. Blood (red blood cells; RBCs) from the afferent filamental artery (AFA) passes through the afferent lamellar arteriole (ALA) and enters the lamellar sinus where it percolates around the pillar cells (PCs) or travels around the periphery of the lamella through the outer marginal channel (OMC). Blood leaves the lamella via the efferent lamellar arteriole (ELA) and is drained from the filament via the efferent filamental artery (EFA). Water flow (W; dashed green arrow) is countercurrent to lamellar blood flow (dotted red arrows). A cartilaginous rod (CR) runs the length of the filament and provides structural support. Ionocytes (chloride cells, CCs) are most prevalent in the epithelium along the afferent edge of the filament and in the interlamellar filamental epithelium (IFE), that is, the filamental epithelium between the lamellae. Mucus cells (MCs) and an occasional sensory neuroepithelial cell (NEC) are more common along the efferent edge of the filament, although the MC can be found throughout the filament. One or several nerve fibers (NFs) are often found near the EFA. Only a portion of the extensive interlamellar vasculature (IL) is shown. (c) Scanning electron micrograph of a lamellar vascular corrosion replica shows the dilated OMC; the numerous dark holes were once occupied by pillar cells.

other (**Figures 2**(**a**) and **2**(**b**)). This motion allows for expansion and contraction of the buccal cavity during respiration and it keeps the filament tips of hemibranchs lining a common water channel in close contact with each other. This creates an effective sieve and forces water to flow across the respiratory surfaces of the gill. Without this apposition, water would too easily flow past the gills without contacting the respiratory exchange surface, creating an anatomical dead space for respiratory water flow.

Other fish have an intrabranchial septum (IS) between, and attached to, the filaments of adjacent hemibranchs on the arch (**Figure 2**(**c**)). The extent of the IS limits the flexibility of the filaments. In fish such as tuna, elasmobranchs, and a few others, the intrabrachial septum extends all the way to the body wall (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics).

Gill Filament

The filament is the functional anatomical unit of the gill and on it are all of the cells and tissues necessary for the various homeostatic activities. The number of filaments on a gill arch increases as fish grow. For example, a 0.35-g rainbow trout (*Onchorhynchus mykiss*) has around 770 total filaments, which increases to approximately 1600 in a 400-g trout. The filament number also varies somewhat from arch to arch; usually, there are more filaments on the first or second arch and often more on the anterior than on the posterior hemibranch.

The filament is a long, flattened knife-blade-like structure that supports numerous respiratory (secondary) lamellae while offering minimal resistance in the respiratory water current. A cross section through the filament is shown schematically in **Figure 3**. By convention, the orientation of the filament is defined by the major blood vessels; the afferent end is nearest the afferent filamental artery (AFA), and the efferent end nearest the efferent filamental artery (EFA). Filaments appear somewhat dumb-bell in shape when viewed in cross section, expanded at the afferent and efferent ends, while the thinner tissue in between supports the respiratory lamellae.

Mechanical support to the filament is provided by a cartilaginous rod near the AFA that extends from the gill arch to the tip of the filament. In some fish, thin spines project perpendicularly from the rod toward the EFA. Presumably, they help stabilize the efferent edge of filament against the incoming water current. The movement of the cartilage rod is controlled by striated and smooth muscle in the arch and base of the filament (see earlier).

The main nerve bundle in the filament nerve usually runs parallel to and near the EFA (**Figure 3**). Additional smaller nerves are found along the AFA. These nerves carry sensory information from cells monitoring the position of the filament (proprioceptors), chemical composition of the water or blood (chemoreceptors), or noxious stimuli (nocioceptors) (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmosensing and **Control of Respiration**: Oxygen Sensing in Fish). Other nerves go to the adductor and abductor muscles and to blood vessels (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes).

Respiratory Lamellae

Respiratory lamellae are thin plate-like structures that spread the blood out into a thin sheet with a minimal diffusion distance between the blood and water. Lamellae project at right angles from both sides of the filament. The outer (free) margins of lamellae from adjacent filaments on the hemibranch nearly interdigitate. This forces respiratory water to flow between the lamellae and over the lamellar surface. In nearly all fish, lamellar blood and respiratory water flow in opposite directions, that is, countercurrent (**Figure 3**(**a**)). This close apposition of adjacent lamellae and countercurrent blood–water flow optimizes gas-exchange efficiency.

Lamellar shape may vary between species and even along a single filament. Most lamellae, however, are in the form of a right triangle with the edge of the lamella facing the incoming water (efferent side) as the right arm. Presumably, this maximizes oxygen loading of the blood just prior to exiting the lamella.

Lamellar pillar cells define the vascular space. They are spool-shaped cells with a large central nuclei and broad cytoplasmic flanges that radiate out from the top and bottom of the cell. The flanges connect pillar cell to pillar cell and in so doing create a flat vascular sinusoid between them (**Figures 3–5**). True endothelial cells are only found at the very outer margin of the lamellar sinus, and they help form the so-called outer marginal channel for blood flow (**Figures 4** and **5**).

The two layers of basement membrane that overlie the pillar cells are connected to each other by numerous collagenous columns (**Figure 5**). This prevents the lamella from ballooning out under the high intravascular pressure. The pillar-cell plasma membrane wraps around these columns, much like a tree growing around a wire fence (**Figure 5**(**b**)). Thus, even though the column remains outside the cell, it is effectively separated from the plasma and cannot initiate a blood clot. Typically, there are 4–10 columns per pillar cell. Myosin filaments within the pillar cell may provide additional mechanical support or they may help regulate blood flow.

Epithelial Cells

At least seven types of cells populate the gill epithelium: pavement, ionocyte, mucus (chloride cells), neuroepithelial, taste, rodlet, and undifferentiated. Pavement cells (**Figure 6**(**a**)) are simple squamous cells. They are relatively thin, often hexagonal, and their surface contains microridges or microvilli believed to help trap a protective coat of mucus. Pavement cells are the most numerous epithelial cells (over 95%) and their primary function is to form a relatively impermeable barrier between the water and tissue. The cell nucleus of lamellar pavement

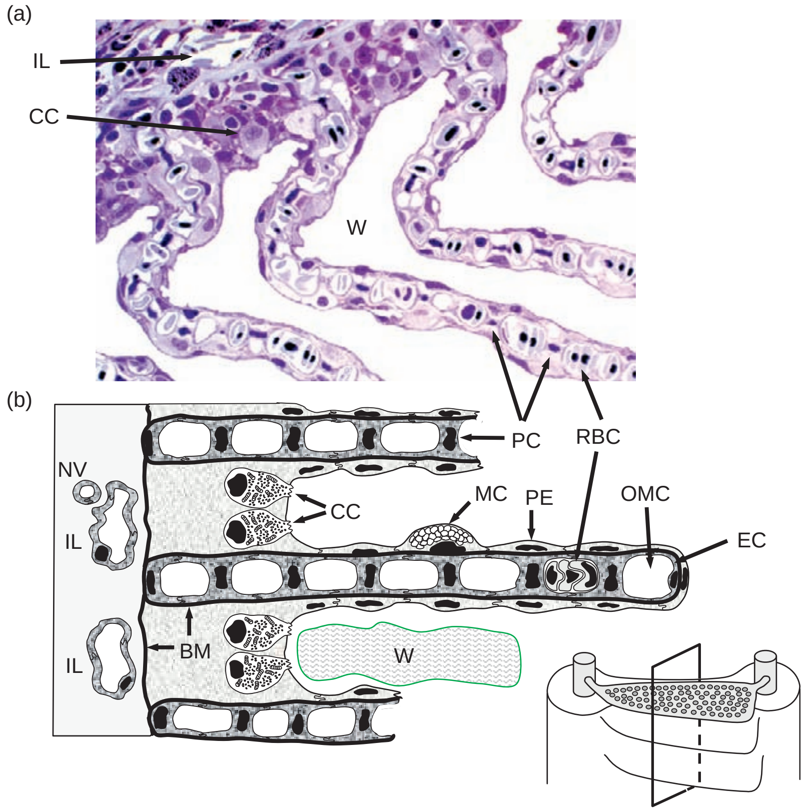

Figure 4 Cross section through several respiratory lamellae ((a), light micrograph; (b), schematic); inset shows plane of section. The lamella consists of two surface layers of pavement cell epithelium (PE) that cover a planar sheet of pillar cells (PCs). Cytoplasmic flanges from adjacent PC form the vascular space (VS), which is occupied by red blood cells (RBCs). The thick nuclear region of the PE is aligned with the pillar-cell body to minimize the blood–water diffusion distance. True endothelial cells (ECs) are only found around the periphery of the outer marginal channel (OMC). Chloride cells (CCs) are common in the interlamellar filamental epithelium but may also be found on the lamella (not shown) along with occasional mucus cells (MCs). The basement membrane (BM) forms a continuous sheet over the lamella between the PE and PC and along the filament interior to the inner margins of the lamella. Filamental nutrient vessels (NVs) and interlamellar (IL) vessels lie beneath the BM of the filament. W, water. Modified from Olson KR (1991) Vasculature of the fish gill: Anatomical correlates of physiological function. *Journal of Electron Microscopy Technique* 19: 389–405.

cells often lies directly above the body of the pillar cell and the thinner, anuclear, region above the pillar-cell flanges and vascular space. This minimizes the diffusion distance between water and blood.

Mucus cells (also called goblet cells) are scattered over the gill arch, filament (they are especially prevalent on the edge of the filament facing the water current), and basal regions of the lamella (**Figures 3** and **6**(**b**)). Mucus secreted by these cells flows over the surface of the gill, and, in addition to its lubricating function, has been reported to have some antibacterial properties. Mucus may even act as a semipermeable barrier to electrolytes. The number and/or size of mucus cells and the rate of mucus secretion may be increased by adaptation to high salinity (seawater), ion-poor water, mechanical abrasion, or a variety of waterborne contaminants. Other cells, called granular cells, embedded in the epithelium may secrete mucus intermittently.

Ion-transporting cells (ionocytes or chloride cells) are most prevalent on the body, or alamellar, portion of the filament, especially along the afferent margin of the filament and in the interlamellar filamental epithelium, that is, the filament epithelium between adjacent lamellae (**Figures 3** and **4**). If ionocytes are present on the lamellar epithelium, they are most commonly located near the filament. Ionocytes are rarely observed on the more lateral areas of the lamella, although they may appear here as well under certain conditions, such as excessively low environmental sodium and chloride. Ionocytes in freshwater fish typically project a broad microvillous surface (**Figure 6**(**c**)) whereas those from saltwater fish are recessed within the crypt just beneath the epithelium and are also associated with accessory cells (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts, and Mechanisms of Ion Transport in Freshwater Fishes). Ionocytes are rarely found along the efferent margin of the filament. All ionocytes have two striking features important for ion regulation: abundant mitochondria and a basolateral membrane that is so extensively invaginated that all but the apical region of the cell appears to be filled with a tubular reticulum.

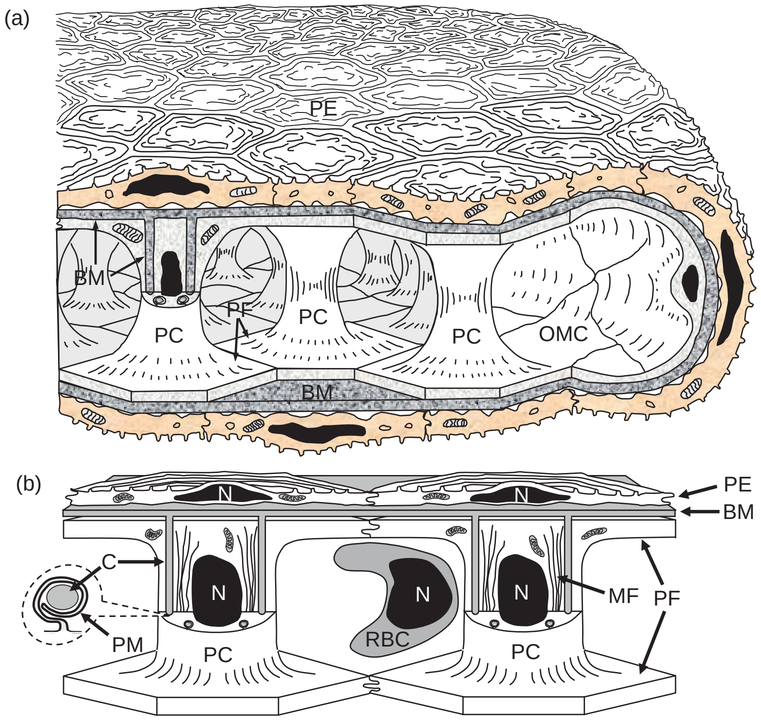

Figure 5 Schematic of a respiratory lamella and pillar cells. Cytoplasmic flanges (PF, arrows) extend from pillar cells (PCs) and surround the vascular space. The basement membrane (BM) separates the PC from the pavement epithelium (PE). The outer marginal channel (OMC) is shown on the right in upper panel. The two layers of BM are connected by numerous columns (C; N) and the PC plasma membrane (PM) wraps around the columns. Myosin filaments (MFs) in the pillar cell provide additional structural support and may be contractile. RBC, red blood cell.

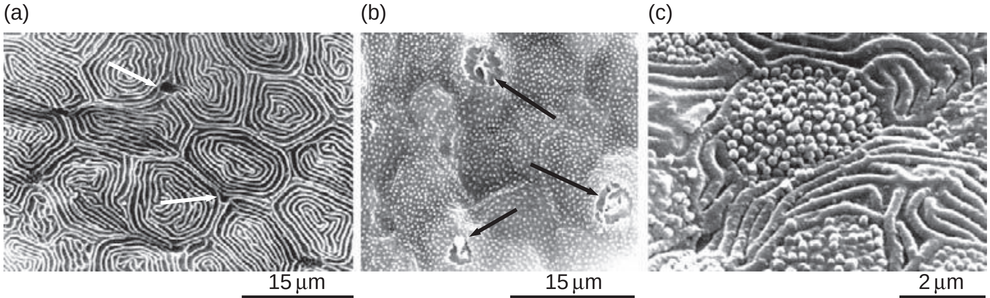

Figure 6 Scanning electron micrographs of gill epithelial cells. Whorled pavement cells (a) are common on arch support tissue and filament body and often interspersed with recessed mucus cells (arrows). (b) Surface mucus cells. A mucus droplet is being secreted from the cell near bottom of micrograph. (c) Microvillous chloride cells of freshwater fish are distinct from adjacent ridged pavement epithelial cells. Modified from Olson KR (1996) Scanning electron microscopy of the fish gill. In: Dutta HM and Munshi JSD (eds.) *Fish Morphology: Horizons of New Research*, pp. 31–46. Lebanon, NH: Science Publishers.

Neuroepithelial cells are also thinly scattered along the efferent margin 50–100 µm beneath the epithelium (**Figure 3**). They serve as chemoreceptor cells and monitor the oxygen tension in both water and blood (**see also Control of Respiration**: Oxygen Sensing in Fish). Interstitial and undifferentiated cells are found throughout the body of the filament. Undifferentiated cells in the interlamellar area are precursor cells for new chloride cells. Undifferentiated cells embedded in the area of the inner margin of the lamella differentiate into lamellar pillar cells, and the lamellae essentially grow outward from the filament as the fish grows.

Taste buds are generally restricted to the arch support tissue and gill rakers; they are rarely found on filaments and are absent from lamellae. Taste buds have two types of sensory cells, light and dark, and a single taste bud may have 10–25 of each (**see also Smell, Taste, and Chemical Sensing**: Morphology of the Gustatory (Taste) System in

Fishes). Rodlet cells are thinly dispersed on the gill arch, body of the filament, interlamellar filamental epithelium, and basal areas of the lamellae. Rodlet cells appear to be secretory; however, their specific function is unknown.

Gill Vessels

Gill Arch

The arrangement of gill vessels is shown schematically in **Figure 7**. The afferent branchial artery (ABA) enters the anterioventral end of the arch and travels approximately one-quarter to one-third of the length into the arch before branching, one branch turning anteriorly and the other, main branch, continuing ventrally. AFAs arise repeatedly from the ABA and travel to the tips of the filaments. The filament is drained by EFAs and filamental veins. EFAs join the efferent branchial artery (EBA) and exit the arch to become the systemic arterial circulation. This is known as the arterio-arterial pathway. Filamental veins drain into one of the several branchial veins and blood is returned directly to the heart, thus completing the arteriovenous pathway.

The EBA lies anteriodorsal to the ABA except in the anterior end of the arch where it branches in order to pass around the ABA. Here, each branch only drains filaments from its respective hemibranch. The lateral (outside) branch from the first gill arch EBA exits the arch and supplies the jaw, and, in some fish, the pseudobranch. The medial (inside) branch from the second and sometimes third and fourth gill arches also exit the arch and form the hypobranchial (systemic) arterial system that delivers blood to the lower jaw and the heart. These small anterior branches carry only a fraction of the cardiac output. Most of the arterio-arterial flow exits the arch via a single posterio-dorsal EBA; these become the epibranchial arteries of the systemic circulation.

The largest veins in the gill arch (branchial veins) usually travel close to the ABA. They exit the arch from both anterio-ventral and posterio-dorsal ends and drain into the jugular or anterior cardinal veins, respectively. Nutrient supply to the arch tissues, including gill rakers, comes from numerous small arterioles that arise from either the EBA or the EFAs near their junction with the EBA. These arterioles anastomose repeatedly with each other to form the nutrient arteries. Nutrient vessels ultimately drain into the branchial veins. The vascular anatomy of the systemic arterial and venous circulations is described in the article **Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns and the origin of the gill nutrient vessels is described in the article **Design and Physiology of Capillaries and**

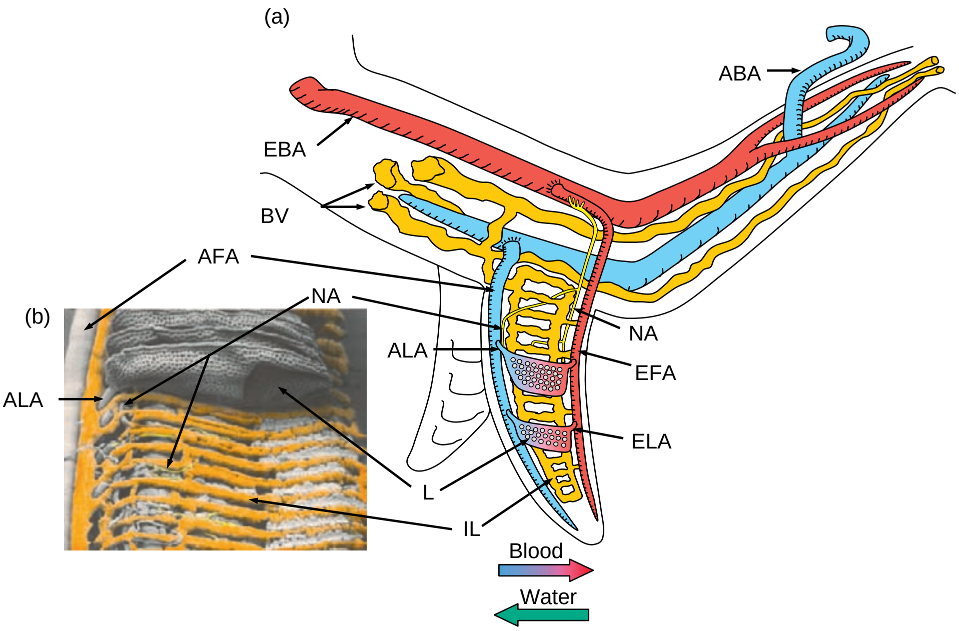

Figure 7 Blood vessels in the gill. (a) The afferent brachial artery (ABA) delivers blood to, and distributes it along, the gill arch. Afferent filamental arteries (AFAs) distribute blood to the respiratory lamellae (L) via afferent lamellar arterioles (ALAs). Oxygenated blood leaves the lamellae through short efferent lamellar arterioles (ELAs), and from there passes into the efferent filamental arteries (EFAs) and then into the efferent branchial artery (EBA). Small nutrient arteries (NAs) originate from the EFA near the base of the filament and reenter the filament. The intra-lamellar vasculature (IL) forms an extensive sinus with the filament that ultimately drains into the branchial veins (BV) in the gill arch. (b) Scanning electron micrograph of a vascular corrosion replica of the filamental circulation. Secondary Circulation: Secondary Circulation and Lymphatic Anatomy.

Gill Filament

There are three main vascular networks in the gill filament: respiratory, nutrient, and interlamellar. The respiratory pathway consists of the AFA, afferent lamellar arteriole, lamella, efferent lamellar arteriole, and EFA (**Figures 3–5** and **7**). Afferent lamellar arterioles are typically much longer than the efferent lamellar arterioles. The vascular space around the outer margin of the lamella is called the outer marginal channel (**Figures 3**(**a**), **3**(**b**), **3**(**c**), and **5**(**a**)). This pathway is larger in diameter than elsewhere in the lamella. There is some debate over whether the outer marginal channel increases the efficiency of gas exchange because the red cells are exposed to the exchange surface on three sides instead of two, or whether it acts as a shunt to minimize untoward water and salt exchange. Around 15–20% of the lamellar vasculature is embedded in the body of the filament and is not available for gas exchange. The innermost vascular channel of the lamella is called the inner marginal channel, although the pillar cells are packed so close together in this region that neither it is dilated nor it is a direct route across the lamella. This vascular space may, however, be important in metabolizing blood-borne molecules (**see also Integrated Control and Response of the Circulatory System**: Hormone Metabolism in the Circulation).

After percolating through the lamella, blood is collected into a short efferent lamellar arteriole that subsequently anastomoses with the lateral wall of the EFA. From here, most of the blood (>90%) drains from the filament into the EBA and continues on to the systemic circulation (**Figure 7**). A highly innervated smooth-muscle sphincter in the EFA, just prior to its anastomosis with the EBA, may be important in regulating blood flow through the filament.

The alamellar body of the filament is perfused by two circulations, a nutrient system and an extensive interlamellar vasculature. Both of these vascular networks lie beneath the basal membrane that envelops the filament (**Figure 4**(**b**)). Nutrient arteries originate from the wall of the EFA near its base or from the EBA (**Figure 7**). These arteries start as small, tortuous arterioles and they repeatedly re-anastomose with each other to form progressively larger nutrient arteries to supply both the arch and filaments. The filamental nutrient artery usually travels singularly (or rarely branched) along and medial to the EFA. Upon entering the filament, one or several branches from the main nutrient artery travels across the filament and these branches then proceed toward the filament tip either through the middle of the filament or along the AFA. In some instances, narrow arterioles arise directly from the medial wall of the peripheral EFA and directly supply nutrient capillaries.

The second vascular system in the filament is the interlamellar system. These vessels have a thinner wall but larger diameter than the nutrient capillaries (**Figure 4**(**b**)). Interlamellar vessels traverse the body of the filament in register with, but between and medial to, the inner margins of the respiratory lamella (**Figures 7**(**a**) and **7**(**b**)). An interlamellar system is found on both sides of the filament along the AFA and around the cartilage support rod. Toward the efferent border of the filament, interlamellar vessels from the two sides come together and form a common system. Often, extensions of the interlamellar vessels wrap around both afferent and EFAs. Interlamellar vessels are supplied by narrow-bore arterioles from the medial wall of the EFA, or by nutrient arterioles. In a few fish, such as eel, *Anguilla anguilla*, and catfish, *Ictalurus punctatus*, a portion of the interlamellar system is supplied by narrow-bore arterioles from the AFA or afferent lamellar arteriole; these vessels are called prelamellar arteriovenous anastomoses (AVAs). However, prelamellar AVAs are rare in most fish. The interlamellar system has also been considered to be part of the secondary circulation (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy). The function of the interlamellar system is unknown.

Innervation of the Gill Arch

Gill nerves (branchial nerves) enter the gill arch via the posterio-dorsal end. These nerves may travel together as a single branch, or in two to three bundles in the arch, usually between the arch skeleton and either the EBA or the basal extension of the EFA. These fibers supply the arch tissues and penetrate into the filaments. Teleost gills are innervated by cranial nerves IX (glossopharyngeal) and X (vagus). These nerves are classified as somatic sensory, visceral sensory, and visceral motor. All are of dorsal root origin and majority of them are sensory. The first gill arch is innervated by the glossopharyngeal and vagus nerves; the remaining arches are innervated by the vagus nerve. Spinal autonomic (sympathetic) nerves travel with the cranial nerves to the gills. Additional details on gill innervation can be found in the article **Brain and Nervous System**: Autonomic Nervous System of Fishes.

Glossary

Adrenergic A general term pertaining to processes or structures related to catecholamines. For example, neurons that release noradrenaline as transmitter; catecholamines binding to adrenergic receptors (adrenoceptors), and adrenergically activated (catecholamine-activated) physiological processes.

Adrenoceptor A receptor located in the cell membrane that binds the hormones adrenaline and noradrenaline (see adrenergic receptor).

Arterioles Muscular blood vessels that form the terminal end of the arterial circulation. They offer the greatest impediment to blood flow by virtue of their relatively narrow diameter. Their diameter is controlled by neural and endocrine signals and by local factors released from the endothelium or nearby tissue.

Cannula A tube placed into a blood vessel to measure blood pressure or provide a site for injection of drugs. It is sometimes referred to as a catheter as well.

Catecholamine Any of a class of amines derived from a catechol that acts as chemical messangers (a hormone or neurotransmitter). The main catecholamines are dopamine, adrenaline, and noradrenaline and these are secreted by neurons of the autonomic nervous system or specific chromaffin cells of the head kidney.

Cholinergic A general term pertaining to processes or structures related to acetylcholine. For example, neurons that release acetylcholine as transmitter. Nicotinic and muscarinic receptors are cholinergic receptors because they bind acetylcholine. Cholinergic synapses are found in both the central and peripheral nervous systems.

Chromaffin cells Cells from the sympathetic-adrenal lineage that synthesize and store catecholamines as well as release them into the blood (via the extracellular fluid).

Heme A large molecule that consists of an iron atom contained in the center of a large heterocyclic organic ring called a porphyrin. It is found in hemoglobin, myoglobin, and cytochromes.

Metarterioles The smallest arterioles and the location of much of the local regulation of blood flow through capillaries.

Perfuse To pump blood or fluid through a tube or blood vessel.

Precapillary sphincters A single smooth muscle wrapped around a metarteriole at the terminal end of the arterial tree and at the entrance to a capillary network.

Introduction to the Arterial System

The resistance vessels derive their name from the fact that they offer the greatest impediment to blood flow. These vessels are usually small arteries and arterioles. Control of their diameter regulates blood flow through tissues and can profoundly impact arterial blood pressure. Resistance vessels are found in both the gills and the systemic circulations; this article emphasizes the latter. Resistance vessels are under the influence of two control systems. The remote control system operates more or less uniformly throughout the body to regulate arterial blood pressure. The local system adjusts blood flow and its pattern of tissue flow to metabolic distribution through tissue capillaries to match tissue metabolic demand. Usually, the larger resistance vessels operate predominately under the influence of the remote system and the smaller arterioles, the local system.

Anatomy of Resistance Vessels

Much of the resistance to blood flow in mammalian tissues is located in small ($<300\,\mu\text{m}$ diameter) vessels. This is assumed to be the case in fish as well. Collectively, these vessels include small arteries, arterioles, and metarterioles.

Resistance arteries and arterioles (~300–30 μm) are characterized by an abundance of smooth muscle wrapped circumferentially around the vessel that allows exquisite control of their diameter. The terminal end of the arteriole (~30–5 μm) has just a single smooth muscle cell encircling it at the very entrance to a capillary bed and is called the precapillary sphincter. Like all fish blood vessels, they are lined by a single layer of endothelial cells and they have less elastic tissues than the larger arteries. Larger arteries may be heavily innervated, but the degree of innervation becomes progressively less in smaller vessels and nerves are usually absent from the smallest arterioles.

Hemodynamics: The Importance of Vascular Resistance on Blood Pressure and Blood Flow

As described in the article **Circulation:** Circulatory System Design: Roles and Principles, central arterial blood pressure is obtained by rearrangement of Darcy's law: $\Delta P = F/R$, where ΔP is the difference between arterial and venous blood pressure, F equals blood flow, which in this case is cardiac output, and R equals vascular resistance. Vascular resistance $R = 8l\eta/\pi r^4$, where 8 and π are geometric constants, and l, η, and r are the vessel length, blood viscosity, and vessel radius, respectively. Thus, arterial blood pressure is directly proportional to cardiac output and inversely proportional to the fourth power of vessel radius. The arterial blood pressure is dispersed equally throughout the body and it is kept relatively constant by a control system that is integrated at the level of the central nervous system. Consequently, the remote control is achieved predominantly through neural reflexes and hormones.

Tissue blood flow is also obtained by a rearrangement of Darcy's law: $F = \Delta P/R$, where flow now is the blood flow through a tissue and ΔP is the difference between arterial and venous blood pressure. Under normal circumstances, arterial pressure is regulated within relatively narrow limits and thus tissue blood flow becomes inversely proportional to the fourth power of vessel radius. As tissue blood flow must be regulated by the needs of individual tissues, it is regulated predominately through local factors, usually metabolic signals, that provide an index of the tissue's metabolic need. As a result, factors that increase arterial or arteriolar resistance decrease blood flow downstream, and increase arterial pressure upstream.

Remote Control of Vascular Resistance

Neural Control

The anatomy and physiology of the fish autonomic nervous system is described in the article **Brain and Nervous System:** Autonomic Nervous System of Fishes. Most systemic blood vessels are innervated by adrenergic (sympathetic) nerves, but they may be lacking in gill vasculature of cyclostomes and elasmobranchs. Only gill blood vessels are innervated by cholinergic nerves. In general, sympathetic nerve stimulation increases systemic vascular resistance and thereby decreases blood flow to those vascular beds where the resistance was increased. This is achieved predominately through activation of α-adrenoceptors located on the vascular smooth muscle cells.

Fish vessels are also innervated by nonadrenergic, noncholinergic (NANC) nerves. Their neurotransmitters include nitric oxide (NO), serotonin (5-hydroxy-tryptamine), purines, and peptides such as vasoactive intestinal peptide (VIP), substance P, tachykinins, and others. The effects of neuronal release of these messengers *in vivo* is an area of active investigation.

Hormonal Control

Catecholamines

Vascular smooth muscle in blood vessels may also receive adrenergic stimulation via the circulating catecholamines, namely epinephrine and norepinephrine (**see also Hormonal Responses to Stress:** Catecholamines). These hormones are released in varying amounts directly into venous blood from chromaffin cells commonly located near the great veins in the trunk, especially the posterior cardinal vein. Chromaffin cells are also found in the hearts of some lower fish. Vascular chromaffin cells are homologous to those that release catecholamines from the mammalian adrenal medulla. The concentration of plasma catecholamines is generally quite low (1–10 nM) and this may not be sufficient to affect vascular resistance, or at best it may provide only a low level of stimulation. Whether or not vascular smooth muscle is stimulated depends on the affinity and type of its adrenergic receptors, as well as the catecholamine concentration in the blood. Severe stress, however, can increase catecholamine release and blood concentrations by 10–100 times, which can significantly increase vascular resistance.

Renin–angiotensin system

The potent vasoconstrictor molecule angiotensin II (ANG II) is formed from the step-wise metabolism of a circulating protein, angiotensinogen, by the enzyme renin, to the inactive 10-amino-acid peptide, angiotensin I, and subsequent metabolism by angiotensin converting enzyme to ANG II. The effects of ANG II appear to be somewhat limited to resistance vessels as large arteries and veins are often insensitive to the hormone. ANG II has two effects on blood vessels. It directly stimulates vascular smooth muscle cells to contract; it also contracts vessels by stimulating norepinephrine release from the adrenergic nerves. In some fish, the indirect effects of adrenergic nerve stimulation are even greater than direct effects. The renin–angiotensin system has been demonstrated in teleosts, elasmobranchs, and lampreys. In teleosts, the renin–angiotensin system is often tonically active in regulating arterial blood pressure. Thus, if the renin–angiotensin system is chemically blocked with the inhibitor that prevents formation of ANG II, such as captopril, blood pressure would decrease without any other change. The renin–angiotensin system does not appear to be tonically active in elasmobranchs.

Natriuretic peptides

Peptides that belong to the family of natriuretic peptides (NPs), including atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), C natriuretic peptide (CNP; up to four subtypes), and ventricular natriuretic peptide (VNP), have been identified in bony fishes. Hagfish have a single, unique NP and only CNP has been found in elasmobranchs. All NPs are potent vasodilators, and they effectively relax vascular smooth muscle and decrease vascular resistance.

Arginine vasotocin

Arginine vasotocin (AVT) is similar to the mammalian arginine vasopressin (also known as the antidiuretic hormone, ADH). AVT is a potent vasoconstrictor, although it has been shown to relax the hepatic vein of the gar.

Bradykinin

Bradykinins (BKs) are somewhat similar to angiotensins in their structure and biosynthesis. Although bradykinins typically produce vasodilation in mammals, in fish they have both vasodilatory and vasoconstrictory effects. In addition to directly stimulating smooth muscle, bradykinins also stimulate the release of vasodilatory prostaglandins from the endothelium.

Urotensins

The urotensins are members of an ancient family of neuropeptides. Urotensin-I (U-I) produces an indirect α-adrenoceptor-mediated increase in systemic resistance and blood pressure when injected into fish. However, U-I has the opposite effect of relaxing blood vessels *in vivo* or lowering blood pressure *in vivo* when the α-adrenoceptors are blocked. Urotensin II (U-II) is a potent vasoconstrictor of arterial vessels in all fish and its actions are independent of α-adrenoceptor activation. U-II does not appear to affect veins in isolated preparations.

Adrenomedullin

Adrenomedulins (AMs) are a family of vasodilator peptides in mammals. Five AMs have been identified in fish, and some of these are proposed as circulating hormones of head-kidney origin. When injected into fish, they produce a profound drop in blood pressure and appear to be more effective on systemic arteriolar resistance than on gill resistance. Regulation of endogenous AM secretion and its effect on cardiovascular function in fish has not yet been investigated.

Local Control of Vascular Resistance

Metabolites

Local consumption or production of metabolic substrates has direct effects on vascular smooth muscle, thereby coupling blood flow to metabolic needs. A drop in oxygen partial pressure (P_{o_2}), which accompanies an increase in metabolism if blood flow is not increased accordingly, produces vasodilation in many vascular beds and thereby provides a local mechanism to match local capillary blood flow to local metabolism. The notable exception is the gill where hypoxia produces vasoconstriction. An increase in metabolism also increases carbon dioxide (CO_2) production and decreases pH (an increase in H^+ concentration). Both CO_2 and H^+ produce vasodilation. Other vasodilators that are associated with an increase in metabolism, such as adenine nucleotides and other intermediates in oxidative phosphorylation (ATP, ADP, and AMP), appear to be vasodilators in fish, as they are in mammals, but they have been poorly studied in fish.

Paracrine-Mediated Responses

Paracrine signals, liberated by the endothelium, vascular smooth muscle, or even surrounding tissue, diffuse through the interstitial space and stimulate adjacent vascular smooth muscle. Many of these signaling molecules may be more potent than neural or endocrine messengers.

Arachnidonic acid metabolites

Metabolites of arachnidonic acid include the prostaglandins, leukotrienes, and thromboxane. These paracrine signals are released by the vascular endothelium and affect adjacent vascular smooth muscle. Molecules that cause vasodilation are known as endothelium-derived relaxing factors (EDRFs) and those that constrict are known as endothelium-derived contracting factors (EDCFs). Prostaglandin E_2 (PGE_2) and I_2 (PGI_2, prostacyclin) are well-known EDRFs, although PGI_2 has been shown to constrict some experimental preparations. Thromboxane A_2 and its analogs are consistent EDCFs.

Endothelin

Endothelin-1, also released from the endothelium, constricts most, but not all, systemic vessels in experimental preparations. It is one of the most potent constrictors of gill resistance vessels known.

Gasotransmitters

Three gases, nitric oxide (NO), carbon monoxide (CO), and hydrogen sulfide (H_2S), were all originally thought to be toxic molecules but have since been shown in mammals to be important signaling molecules in the cardiovascular system as well as in other tissues. They have been given the name gasotransmitters to reflect their actions parallel with the neurotransmitters. NO is produced by the vascular endothelium and may be secreted by nerves, CO can be produced by both endothelial and vascular smooth muscle cells, whereas all tissues (vascular and extravascular) can produce H_2S. All of these gasotransmitters are rapidly inactivated upon their formation, and, therefore, function primarily as paracrine/autocrine signals. Evidence is emerging that, in many respects, the metabolism and effects of these gasotransmitters are similar in fish.

NO is a potent dilator of fish blood vessels and it inhibits constrictions produced by most stimuli including catecholamines, angiotensin II, AVT, and endothelin-I. In mammals, NO is synthesized by both the endothelium and perivascular nerves, and synthesis from the amino acid L-arginine is under the control of endothelial nitric oxide synthase (eNOS) and neuronal nitric oxide synthase (nNOS), respectively. The presence of nNOS and neuronally mediated release of NO in fish vessels has been well documented. Although there are conflicting reports, most evidence to date suggests that eNOS is not present in fish endothelial cells and that NO is not an EDRF.

CO is produced from the heme of proteins such as hemoglobin, myoglobin, and cytochromes by the action of the enzyme heme oxygenase (HO). Three heme oxygenases have been identified in mammals but only heme oxygenase-2 (HO-2) appears to be an important enzyme in regulating CO production in the vasculature. CO is a vasodilator in mammals and, like NO, activates soluble guanylyl cyclase, which enzymatically produces cyclic guanosine monophosphate (cGMP) and brings about a reduction in intracellular calcium and relaxation. CO also vasodilates fish vessels by increasing cGMP and there is some evidence that there is tonic production of CO in fish. Little else is known of this potentially important vasoactive molecule.

Considerable evidence is accumulating in support of H_2S as an important signaling molecule in fish vessels. H_2S is synthesized from L-cysteine by the enzyme cystathionine γ-lyase (CGL also known as GSE) or cystathionine β-synthase, or from 3-mercaptopyruvate by the enzyme 3-mercaptopyruvate sulfurtransferase (3-MST). All three enzymes have been identified in fish vessels. The effects of H_2S on fish vessels are quite variable; H_2S contracts some vessels, relaxes others, and may even produce biphasic or multiphasic contractions and relaxations. These effects are, for the most part, independent of the endothelium. One consistent observation regarding the effects of H_2S is that they are identical to those produced by hypoxia. It has been proposed that H_2S is the initial oxygen-sensing step, that is, the oxygen sensor in the vasculature. Isolated fish vessels and fish tissues have been shown to produce H_2S when oxygen levels are low but not when oxygen is increased. Recent studies have also shown that H_2S acts solely as a paracrine/autocrine signaling molecule and that it does not exist in the circulation.

Factors That Affect Vascular Resistance

The collective response of the cardiovascular system to stimuli such as exercise, hypoxia, and temperature involves the integration of numerous local and remote factors that regulate vascular resistance. It is often difficult to separate these factors experimentally.

Exercise

Swimming in fish is generally classified as either burst (sprint) or sustained. Burst swimming is brief, anaerobic activity of white muscle and is quite often accomplished without substantial changes in peripheral vascular resistance. Sustained swimming is aerobic and necessitates adjustments in vascular resistance to maintain both adequate perfusion of metabolically active tissue and decreased perfusion of less critical tissues in order to maintain arterial blood pressure (**see also Integrated Response of the Circulatory System:** Integrated Cardiovascular Responses of Fish to Swimming). During sustained swimming, blood flow to skeletal muscle can increase more than fourfold as vascular resistance decreases through local regulatory mechanisms. At higher swimming speeds, blood flow to the gastrointestinal tract is often decreased through remote mechanisms (**see also Design and Physiology of Arteries and Veins:** The Gastrointestinal Circulation). This increase in vascular resistance in the gastrointestinal tract ensures that the heart can pump sufficient blood to maintain, or even slightly elevate, arterial blood pressure.

Temperature

In most fish, as temperature increases so does metabolic rate and this decreases vascular resistance through local mechanisms (**see also Integrated Response of the Circulatory System:** Integrated Responses of the Circulatory System to Temperature). Conversely, a drop in water temperature cools the fish and decreases metabolism, thereby increasing resistance. At very low ambient temperatures, such as those encountered by Antarctic fish, blood viscosity increases and this increase in viscosity will effectively increase vascular resistance. The red-blooded Antarctic icefish solved this problem by remodeling blood vessels to reduce their vascular resistance (they have a larger diameter). Other Antarctic icefish decrease blood viscosity by eliminating red blood cells. While this substantially reduces blood viscosity, these hemoglobin-less icefish must have a considerably higher cardiac output in order to maintain adequate oxygen delivery with blood lacking red blood cells.

Hypoxia

Acute hypoxia in fish, produced experimentally by lowering water P_{O_2} from 100 to 30–50 mmHg, produces reflex fall in heart rate and cardiac output in most fish (**see also Integrated Response of the Circulatory System:** Integrated Responses of the Circulatory System to Hypoxia). In teleosts, arterial blood pressure increases due to activation of the sympathetic nervous system and an increase in peripheral vascular resistance. In elasmobranchs, arterial blood pressure falls indicating that the remote system responses are not sufficient to maintain blood pressure. The crucian carp (*Carassius carassius*) is unique in its ability to maintain normal autonomic control after 5 days of complete anoxia.

Hypovolemia

A decrease in blood volume (hypovolemia) brought about either through hemorrhage or through a dehydrating environment (often accompanying moving from freshwater and saltwater) decreases blood pressure (hypotension), which in bony fish brings about a reflex increase in peripheral vascular resistance. This is usually mediated through activation blood pressure receptors (baroreceptors) located in the gill, which then reflexively activate the sympathetic nervous system. This response may be supplemented by increased production of ANG II or secretion of AVT. Baroreceptor reflexes are greatly reduced or absent in elasmobranchs.

Methods for Measuring Arterial Resistance in Fish

A number of methods have been developed to measure vascular resistance or vasoactivity in fish vessels. These include *in vitro* techniques using isolated blood vessels or perfused organs, or *in vitro* methods to measure vascular resistance in unanesthetized fish.

Isolated Blood Vessels

Myography is the most commonly employed technique to measure vasoactivity in isolated blood vessels. With this procedure, a small (0.5–2 mm diameter) blood vessel is

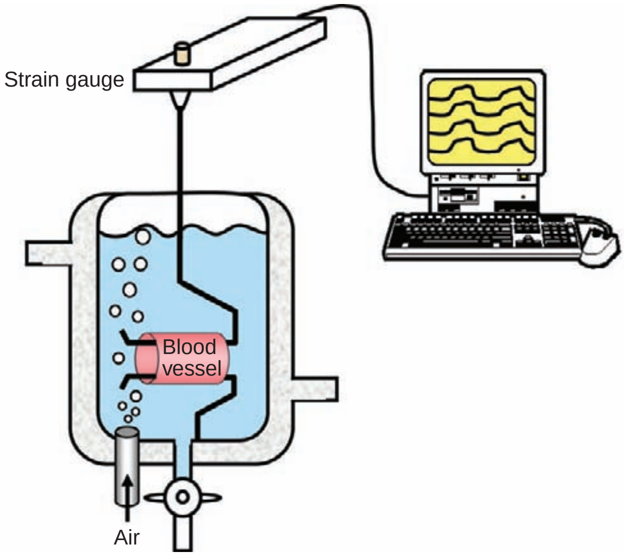

Figure 1 Method for measuring the response of isolated blood vessels using myography. The myograph chamber consists of a water-jacketed vessel that can be filled with physiological buffer and aerated with appropriate gas mixtures. A small piece of a blood vessel is mounted between two wire hooks (dark black lines); the bottom (immobile) hook is attached to the chamber and the upper hook is connected to a sensitive strain gauge. Contraction or relaxation of the vessel is sensed by the strain gauge and the signal is sent to a physiological recorder for data archiving and video screen for observation. Hormones or compounds of interest can be added to the chamber to determine their vasoactivity.

placed between two thin wires, one of which is immobile and the second is connected to a sensitive strain gauge to record slight displacements of the vessel wall (**Figure 1**). The vessel is placed in a temperature-controlled, water-jacketed myograph chamber and aerated with appropriate gas mixtures (typically, room air for fish). Hormones or drugs of interest are added to the chamber and the response (contraction or relaxation) is archived to a computer and displayed on a monitor. The limitation of this system is that it is useful for conductance arteries and can be modified for smaller vessels but does not work well for resistance-size arterioles.

Perfused Organs

The perfused organ technique is useful for measuring vascular resistance of organs or tissues at the level of resistance arterioles. With the constant-flow technique (**Figure 2**), a blood vessel supplying the tissue of interest is cannulated and physiological saline is infused through the tissue with a peristaltic roller pump (as shown in **Figure 2**) or syringe. A pressure transducer connected to the infusion cannula provides information on the input pressure, and vascular resistance is obtained from the equation $R = \Delta P/F$, where ΔP is the difference between input pressure measured with the pressure transducer and venous pressure, which is generally assumed to be zero. F is the flow delivered by the pump. In an alternate method, the constant pressure technique, the physiological saline drains into the tissue through a reservoir elevated above the fish. The height of the reservoir is adjusted to give a constant hydrostatic pressure. Flow is determined by either measuring the change of volume in the reservoir above the fish or collecting the venous effluent draining the fish.

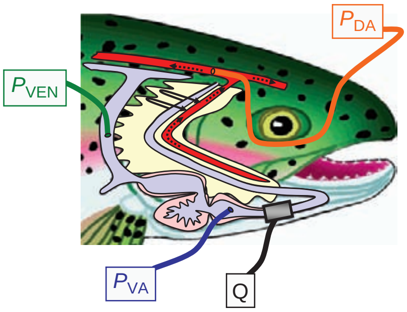

Figure 3 Placement of the pressure cannulas and flow probe for measuring gill and systemic vascular resistance in unanesthetized fish. Ventral aortic pressure (P_{VA}) is recorded from a cannula (blue line) placed in either the bulbus arteriosus (as shown here) or ventral aorta anterior to the flow probe. Dorsal aortic pressure (P_{DA}) is recorded from a cannula (red line) placed through the roof of the mouth and into the dorsal aorta and venous pressure (P_{VEN}) is obtained from a cannula (green line) inserted into the ductus Cuvier. Cardiac output (Q) is measured with a flow probe placed around the ventral aorta (black line).

Intact Fish

Measuring vascular resistance in unanesthetized fish is the most technically challenging procedure. Under anesthesia, blood pressure cannulas are placed in the ventral aorta to record central arterial blood pressure (P_{VA}), the dorsal

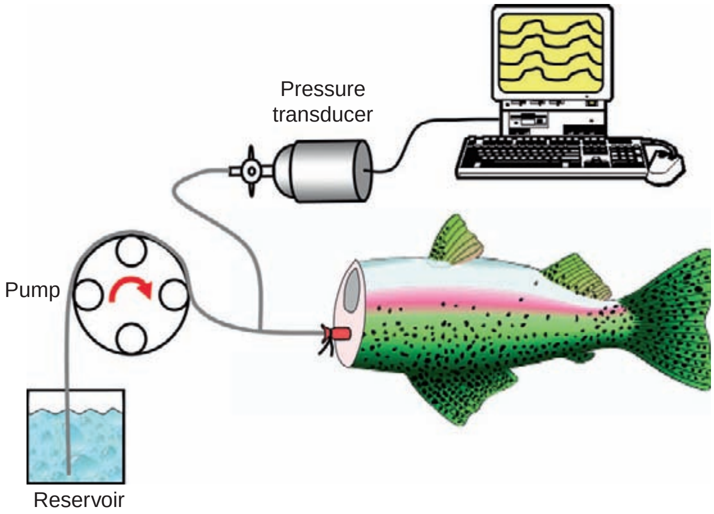

Figure 2 Method for measuring vascular resistance using a perfused organ or tissue. The organ of interest (in this example the trunk of a fish) is cannulated, and a roller pump pumps a physiological saline, containing the compounds of interest from a reservoir into the fish; a pressure transducer connected to the inlet cannula monitors perfusion pressure and the signal is sent to a computer for archiving or a video monitor for observation. Vascular resistance (R) is determined from the equation $R = \Delta P/F$, where ΔP is the difference between input pressure measured with the pressure transducer and venous pressure, which is generally assumed to be zero. F is the flow delivered by the pump.

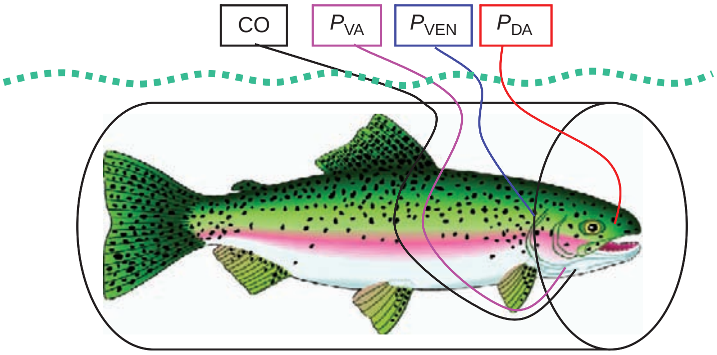

Figure 4 Method for measuring gill and systemic vascular resistance in unanesthetized fish. The fish is instrumented as shown in **Figure 3**. Gill resistance (R_G) is calculated from the equation $R_G = (P_{VA} - P_{DA})/Q$, and systemic resistance (R_S) is calculated from the equation $R_S = (P_{DA} - P_{VEN})/Q$.

aorta to record systemic arterial blood pressure (P_{DA}), and the ductus Cuvier to record central venous pressure (P_{VEN}). A flow probe is placed around the ventral aorta to measure cardiac output (Q; **Figure 3**). The fish is then revived and returned to the water, usually with minimal restraint, while pressure and flow parameters are measured at rest, following either injection of drugs or during other experimental manipulations such as swimming. Gill resistance (R_G) is calculated from the equation $R_G = (P_{VA} - P_{DA})/Q$, and systemic resistance (R_S) is calculated from the equation $R_S = (P_{DA} - P_{VEN})/Q$. Typically, all of these parameters are recorded simultaneously (**Figure 4**).

Glossary

Capacitance The relationship between the volume of fluid in a closed container and its pressure.

Compliance The ability of a blood vessel to stretch and relax. It is defined mathematically as the slope of the change in volume of the vessel divided by the change in pressure, i.e., $\Delta V/\Delta P$.

Edema The accumulation of excess fluid in the space between cells (interstitial space) but outside of the blood vessels.

Euryhaline A fish that can live in both freshwater and saltwater.

Fahraeus effect The observation that hematocrit in small vessels is significantly lower than that in large vessels.

Fahraeus–Lindqvist effect The condition in small blood vessels where viscosity becomes less dependent on hematocrit.

Hematocrit The proportion of blood volume that is occupied by red blood cells.

Hydraulic pressure Pressure imparted on a solution by a piston or pump. This is equivalent to the blood pressure generated by the heart or by vascular smooth muscle.

Hydrostatic pressure Pressure due to the height of a column of fluid directly above the reference point.

Mean circulatory filling pressure The pressure that will exist throughout the cardiovascular system when blood flow has stopped and blood pressure has equilibrated throughout. This pressure is due to the volume of blood in the cardiovascular system and the tension exerted on it by the walls of the blood vessels. This tension is generated by stored energy as well as active tension developed by vascular smooth muscle

Osmotic pressure The hydrostatic pressure produced by the different concentrations of two solutions on opposite sides of a semi-permeable membrane.

Ostial valve A one-way valve in a small vein near the location where it empties into a larger vein. These valves prevent the backflow of blood into the periphery.

Parietal valve A one-way valve in long veins of mammals that prevents the backflow of blood due to gravity.

Resistance The sum of the impediments to fluid flow. Resistance is increased by increased vessel length and fluid viscosity and decreased by increased vessel radius.

Stressed blood volume The volume of blood in the cardiovascular system that distends the vessel walls and creates a positive pressure. Stress blood volume is equal to the total blood volume minus the unstressed blood volume.

Tone The active compression of a blood vessel due to contraction of smooth muscle in the blood vessel wall.

Transmural pressure The pressure difference between the inside and the outside of a vessel.

Unstressed blood volume The volume of blood that fills the dead space of the cardiovascular system without distending the vessels or creating internal blood pressure. This volume is possible because blood vessels do not collapse down to zero volume and therefore can contain blood at zero pressure. This volume is often two-thirds of the total blood volume.

Introduction to the Venous System

The venous system has historically been the least appreciated, if not least understood component of the cardiovascular system. The most obvious function of the veins is to provide a conduit for the return of blood from the capillaries back to the heart. However, studies initially performed in mammals, and more recently in fish, have clearly shown that the venous system is more than a passive participant in blood flow. It is now clear that the veins play an important role in the regulation of cardiac output due to their ability to increase or decrease blood flow into the heart. This is achieved in part through active regulation of the diameter of veins as well as passive factors such as surrounding muscular contractions and elastic recoil of the vessels. As the name implies, most of the blood in the circulatory system is contained in the venous capacitance vessels. This volume is not static, however, and can be mobilized through active and indirect processes according to the fish's needs. The following sections describe these features in detail.

Functions of Veins

The venous system serves three important functions. Veins provide a conduit for blood to flow from the capillaries back to the heart, they act as a storage site for a substantial portion of the blood volume, and by regulating blood flow returning to the heart they profoundly affect cardiac output.

Anatomy

Tiny capillary-size venules drain blood from the capillaries. Through repetitive anastomoses they form progressively larger veins that ultimately drain into the large horseshoe-shaped ductus Cuvier. The ductus Cuvier connects directly to the first chamber, the sinus venosus, of the heart (**see also Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns and **Design and Physiology of the Heart**: Cardiac Anatomy in Fishes). Compared to arteries and arterioles, veins and venules are typically very thin–walled because they contain less smooth muscle and elastic tissue. Veins and venules are also larger in diameter than their corresponding arteries and arterioles. Therefore, they offer less resistance to blood flow (**see also Circulation**: Circulatory System Design: Roles and Principles). This means that the loss of blood pressure across the venous circuit is relatively small, generally no more than several mmHg. As a result, blood can leave the capillaries under low blood pressure and still have sufficient potential energy to return to the heart (**see also Integrated Control and Response of the Circulatory System**: Central Control of Cardiorespiratory Interactions in Fish and **Design and Physiology of the Heart**: Accessory Hearts in Fishes). Any elevation in venous pressure naturally increases capillary pressure, which would cause unwanted leakage of blood plasma across the capillary wall and into the interstitial space. Excessive leakage can produce edema (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange).

In mammals, 70–80% of the blood volume in the systemic circulation resides in the veins. The percent blood volume in the fish venous circulation is unknown, but it is also likely to be considerably larger than the volume of blood in the arteries and capillaries combined given the much larger diameter of the venous compared with arterial vessels. This is undoubtedly the case for certain sharks and rays, which have large central veins. The large volume of blood in the veins represents a pool of blood that the heart can draw on immediately whenever cardiac output increases. In fact, the passive elastic recoil and active contraction of veins can change the blood pressure filling the heart and thereby directly affect cardiac output (**see also Circulation**: Circulatory System Design: Roles and Principles and **Design and Physiology of the Heart**: Physiology of Cardiac Pumping).

Unlike arteries, where valves are absent, veins have one-way valves that ensure movement of blood toward the heart. Mammalian veins have two types of valves, parietal and ostial (**Figure 1**(**a**)). Parietal valves are found in the lumen of longitudinal veins. They are especially important in countering the effects of gravity. The hydrostatic pressure generated by gravity results in a larger venous transmural blood pressure which tends to pool blood at the extremities and limits the flow of blood returning to the heart. The one-way parietal valves prevent backflow of blood downward in the legs when standing, and also limit the expansion of veins because of their connective tissue. Parietal valves are not found in fish veins, presumably because gravitational effects are essentially nil in an aqueous environment (**Figure 1**(**b**)).

This important difference between the venous anatomy of fish and mammals is shown in **Figure 1**(**b**), which illustrates the effects of gravity on the pressure across the wall (transmural pressure) of a vein in a terrestrial animal (air) and one that lives in water. In air, the hydrostatic pressure in a vertical column of fluid increases as a function of the depth of the fluid column (**see also Circulation**: Circulatory System Design: Roles and Principles). Thus, the hydrostatic pressure in the lowest (most dependent) segment of the vessel is the greatest. With minimal external pressure to oppose

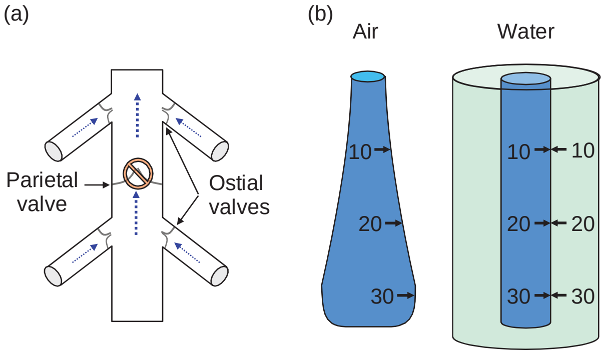

Figure 1 Anatomical and physical properties of veins. (a) Valves in veins ensure one-way blood flow. Ostial valves are found where small veins drain into larger ones and they prevent backflow of blood into the side branches. Parietal valves in the lumen of mammalian veins prevent backflow of blood due to gravity. Parietal valves are not found in fish. (b) Effects of hydrostatic pressure on veins of terrestrial and aquatic animals. In terrestrial animals the hydrostatic blood pressure increases with the length of the veins, and because there is no hydrostatic pressure outside these vessels there is increased venous distention in the lower regions. In fish the intravascular hydrostatic pressure is offset by hydrostatic pressure of the surrounding water and there is no net venous distention (b) Adapted from Satchell GH (1991) *Physiology and Form of Fish Circulation*. New York: Cambridge University Press.

the internal pressure, the wall of the vessel becomes progressively distended proportional to the transmural pressure, which in this case is the hydrostatic pressure. Any venous blood pressure adds to this hydrostatic pressure to increase the total transmural pressure. To offset this distending pressure, terrestrial animals constrict the smooth muscle layer surrounding the veins to create an external pressure. In a submerged vessel, on the other hand, the increase in hydrostatic pressure in the dependent segment of the vessel is essentially offset by an increase in external hydrostatic pressure from the environment. Thus, the transmural pressure is zero and the vessel cannot distend. As this is the case for fish, it was once thought that fish veins did not need to constrict and they were essentially passive conduits for the return of blood to the heart. However, recent studies have clearly shown that fish veins do indeed constrict and this plays an important role in regulating venous pressure, venous return to the heart, and cardiac output. In fishes, ostial valves are typically found in the lumen of smaller veins near their anastomosis with a larger vein (**Figure 1**(**b**)).

The Fahraeus Effect and the Physiology of Venules and Small Veins

Small veins and venules exhibit a number of characteristics that distinguish them from larger veins. It is well known that as blood passes through progressively smaller vessels into the microcirculation, the hematocrit of blood contained in arterioles, capillaries, and venules that are 200–300 μm diameter or less also decreases. This is known as the Fahraeus effect. This effect can also be produced simply by passing blood through small glass tubing. In mammalian vessels, hematocrit can be decreased from 45% in arteries and veins to 10% or less in the microcirculation. (**see also Circulation**: Circulatory System Design: Roles and Principles).

It has also been shown from studies on mammals that as much as 30–40% of the blood volume is found in the small venules and that these vessels are quite compliant. The importance of the capacitance characteristics of these small vessels is evident when blood is rapidly lost from the vasculature during hemorrhage. Following hemorrhage, the reduced blood volume means that mean circulatory filling pressure is lower and the drop in the mean circulatory filling pressure collapses these vessels. This mobilizes plasma-rich blood from the microcirculation back into heart and provides a near-instantaneous transfusion of blood into the central circulation. This simple biophysical effect can sustain cardiac output until other reflexes set about restoring fluid volume. These responses have also been demonstrated in fish following hemorrhage and show that the fish microcirculation, especially the venules, is functionally similar to that of mammals.

Physiological Significance of Regulation of Venous Tone and Compliance

As described in **Circulation**: Circulatory System Design: Roles and Principles, factors that increase venous pressure increase venous return and cardiac output and, conversely, factors that decrease venous pressure decrease both venous return and cardiac output. With respect to the veins, the major factors that influence the venous blood pressure are blood volume, venous compliance, and venous tone.

An increase in blood volume will increase venous pressure simply because blood vessels cannot expand indefinitely. However, under most circumstances fish do not rapidly alter their blood volume despite the fact that they are continuously faced with water loss (in seawater) or water gain (in freshwater) as a result of large osmotic differences between their blood and the environment (see below and **see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). In fact, fishes have excellent regulation of blood volume, with the only exception being hemorrhage. Instead, the mechanical properties of veins, namely venous tone, provide the most important mechanism for rapidly adjusting cardiac output. In fact, as described above, the venous system is important in responding to rapid changes in blood volume that may occur through hemorrhage. Thus, control of venous capacitance and fishes is extremely important, although studies thus far are limited.

Venous capacitance curves, which are frequently derived from unanesthetized animals, provide the most accurate assessment to date of venous responses (see the section titled 'Techniques for measurement of venous compliance and tone'). A typical capacitance curve is shown in **Figure 2**. Experimental points generated from the relationship between mean circulatory filling pressure (x-axis) and blood volume as a percent of total (left y-axis) or actual blood volume (right y-axis) define the capacitance characteristics of the venous system. Venous compliance ($\Delta V/\Delta P$) is the slope of the capacitance line, which is typically measured relative to the normal blood volume (black line, A). Rotation of this line counterclockwise reflects an increase in compliance (blue line, B); compliance is decreased when the line is rotated clockwise. Intersection of the compliance line with the y-axis at 0 mmHg mean circulatory filling pressure provides the unstressed blood volume, which in **Figure 2** is ~67% of the total blood volume or 24 ml kg^{-1} body weight. The difference between total blood volume and unstressed blood volume is the stressed volume, 33% of total, or 11 ml kg^{-1} body weight. In this example, we assume that the total blood volume was 3.5%. Although a number of studies have indicated that some treatments may affect venous compliance (i.e., rotate the compliance curve), there is no experimental evidence on isolated veins that indicate that vascular compliance can be actively increased or decreased. Apparent changes in compliance most likely are the result of a change in blood volume (see below).

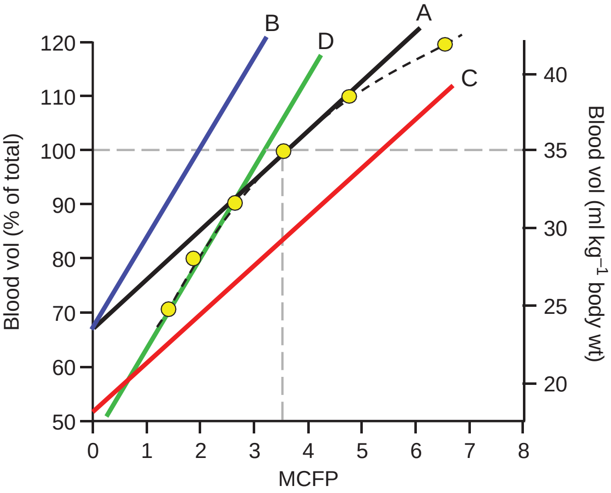

Figure 2 Typical capacitance curve for a rainbow trout. The data points (yellow circles) show the experimentally obtained relationship between mean circulatory filling pressure (MCFP) and blood volume. The slope of the line passing through the capacitance curve at normal (100%) blood volume (line A) is the *in vivo* compliance and the intersection of this line with blood volume at 0 MCFP is the unstressed blood volume, in this case 67% of total blood volume or 24 ml kg^{-1} body weight. The stressed volume is 100–67% or 33% of the total blood volume (11 ml kg^{-1} body weight). An increase in compliance (blue line, B) rotates the compliance curve counterclockwise but does not change the unstressed volume. An increase in vascular tone (red line, C) shifts the compliance curve downward increasing the stressed volume without a change in slope. It can be seen from the figure that if blood volume remains constant, an increase in vascular compliance will lower the mean circulatory filling pressure and decrease cardiac output, whereas an increase in tone will increase mean circulatory filling pressure and increase cardiac output. A decrease in compliance or a decrease in tone will have the opposite effect. If blood volume is decreased experimentally or by hemorrhage, the compliance curve will be shifted to lower blood volumes (green line, D) indicating that compliance has increased, because the veins are now more collapsed, and the unstressed volume has decreased, which reflects the fact that some of the blood has been removed.

The unstressed blood volume, by definition, fills the dead space in the vasculature (as blood vessels cannot passively collapse down to zero volume) and creates no internal pressure. Therefore, it does not contribute to venous pressure. Only the stressed volume is of physiological importance in establishing venous pressure and thereby regulating venous return to the heart and cardiac output. A decrease in blood volume following hemorrhage decreases the stressed volume. For this reason, and in the absence of any regulation of venous smooth muscle, blood loss can have catastrophic consequences on cardiac output. Active constriction of smooth muscle in the veins or external compression of venous vessels that often accompanies contraction of the surrounding skeletal muscle produces a parallel downward displacement of the compliance curve and in doing so shifts blood from the unstressed into the stressed compartment. This increases venous pressure and ultimately cardiac output. Dilation of the veins has the opposite effect and will decrease cardiac output. Some fish hearts create suction during cardiac contraction (via-a-fronte filling; **see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping) and this creates a larger pressure gradient to fill the heart independent of the venous blood pressure.

Physiological Factors That Affect the Capacitance Curve and Therefore Cardiac Output

Hormones and Drugs

Several hormones or drugs that are known to raise arterial blood pressure or increase cardiac output also decrease venous capacitance through a downward displacement of the compliance curve (**Figure 2**), that is, the veins become stiffer. This change in venous compliance has the effect of shifting blood volume from the unstressed into the stressed compartment, thereby increasing mean circulatory filling pressure. Hormones in this list include epinephrine (adrenaline) in rainbow trout (*Oncorhynchus mykiss*), the air breathing fish (*Synbranchus marmoratus*), and the dogfish shark (*Squalus acanthias*), as well as arginine vasotocin (AVT) in rainbow trout. Epinephrine appears to act through α-adrenoceptors (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes and **Hormonal Responses to Stress**: Catecholamines) as synthetic drugs that are specific for α-receptors have similar effects. Furthermore, blockade of α-adrenoreceptors decreases the mean circulatory filling pressure in resting fish, which clearly suggests that there is a continuous stimulation of veins by the sympathetic nervous system (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes). This continuous contraction of the veins is sometimes called venous tone, which refers to a constant level of tension developed in the vessel wall.

Drugs that relax blood vessels by stimulating β-adrenoceptors have the opposite effect, that is, they produce an upward displacement of the capacitance and decrease blood in the stressed compartment.

Endothelin-1, a peptide hormone, also increases blood pressure in rainbow trout but it increases venous pressure by decreasing venous compliance (which may be due to fluid retention and volume expansion). Other hormones that are known to increase arterial blood pressure, such as norepinephrine (noradrenaline) and angiotensin II, do not affect vascular capacitance. This indicates that the action of these hormones is achieved through an increase in arterial vascular resistance (**see also Circulation**: Circulatory System Design: Roles and Principles).

Atrial natriuretic peptide (ANP) decreases arterial blood pressure and lowers mean circulatory filling pressure by decreasing venous compliance. Because ANP also promotes rapid loss of water by the kidneys, it is likely that this hormone affects venous compliance indirectly through a reduction in blood volume. The nitric oxide (NO) donor sodium nitroprusside (SNP) also decreases arterial blood pressure, but has no effect on vascular capacitance. Thus, SNP appears to act only on the arterioles.

Exercise

The increase in cardiac output commonly associated with exercise in fish is typically accompanied by an increase in central venous pressure. Furthermore, in both the rainbow trout and European sea bass (*Dicentrarchus labrax*), exercise increases mean circulatory filling pressure. This suggests that the contracting skeletal muscles compress the veins and decreased vascular capacitance. However, this has never been measured directly because of the technical difficulty measuring vascular capacitance in exercising fish.

Temperature

In many fish cardiac output increases as temperature increases. Studies have shown that when temperature is increased from 10 to 16° C, mean circulatory filling pressure also increases in rainbow trout, presumably to enhance venous return, but only up to 13° C. These responses, however, may be species specific as there only appears to be a slight increase in venous tone associated with warming in the Antarctic fish (*Pagothenia borchgrevinki*).

Hypoxia

It has been shown in rainbow trout that moderate hypoxia (lowering water P_{O_2} to approximately 65 mmHg) decreases venous capacitance as a result of an α-adrenergic venous constriction. This is brought about predominantly through an increase in circulating catecholamines (**see also Hormonal Responses to Stress**: Catecholamines). However, profound hypoxia/anoxia relaxes veins through a direct effect on vascular smooth muscle, and this ultimately overrides the effect of any adrenergic stimulation.

Adaptation to Freshwater, Saltwater or High-Salt Diet

Unlike terrestrial animals where loss of body water and salt is a pervasive occurrence, water and salt balance in fish can vary with the environment (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). In freshwater, where the ambient osmolarity is 1 mosm l^{-1} or less and blood osmolarity is nearly 300 mosm l^{-1}, there is strong osmotic gradient for water uptake and these animals must continually regulate against chronic volume expansion. Volume expansion is even more of a problem in freshwater fish fed a high-salt diet as the excess salt increases the tendency to accumulate water. In a saltwater environment where osmolarities are around 1000 mosm l^{-1}, yet plasma osmolarity remains close to 300 mosm l^{-1}, the water and salt gradients are reversed and there is a tendency for volume depletion. The relationship between blood volume and venous capacitance has been studied in euryhaline rainbow trout because of their ability to thrive in all three environments. When freshwater trout are adapted to saltwater, their blood volume decreases as predicted.

This decreases their vascular capacitance and as shown in **Figure 3**(**a**), chronic reduction in blood volume also decreases mean circulatory filling pressure. When freshwater rainbow trout are fed, a diet with excess salt their blood volume increases which in turn increases mean circulatory filling pressure. These alterations in vascular capacitance remain for extended periods, but the long-term effect on cardiac output is unclear.

Passive Responses: The Importance of Venous Compliance

The elastic properties of the veins may also passively contribute to physiological responses. This is perhaps most notable if blood is rapidly removed from the circulation and there is insufficient time for reflexes to restore the lost volume. If blood is removed from the arterial circulation, arterial blood pressure will fall which in turn decreases capillary blood pressure and venous blood pressure. Because of the elastic (compliance) properties of the veins, the drop in venous blood pressure will cause a passive collapse of the veins which in turn shifts the capacitance curve to a new setpoint. This results in the mobilization of blood from the venous compartment toward the heart as illustrated in **Figure 3**(**b**). In this example a 1-mmHg drop in venous pressure mobilizes approximately 12% of the vascular volume (4.2 ml kg^{-1} body weight). A 2-mmHg drop in mean circulatory filling pressure will mobilize almost 25% of the blood volume.

The Importance of the Pericardium

The pericardium is important in venous return in that it helps establish the vis-a-fronte pressure which is a negative pressure created by the contracting heart inside the rigid pericardial vault (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). When the pericardium is opened due to surgery, or as part of an experimental protocol, vascular capacitance decreases due to active venoconstriction to offset the loss of the cardiac suction. While these events do not occur under physiological circumstances, the changes associated with opening the pericardium during experimental procedures need to be understood and accounted for.

The Venous System in Hagfish

Hagfish have one of, if not the largest blood volume per body weight of any vertebrate, some 2–4 times that of mammals or bony fish. As much as 30% of this may reside in the subcutaneous sinus, a large capacious vascular space that lies beneath the skin. It is not known if blood can be mobilized from or stored in this space and thereby affect cardiac output.

Techniques for Measurement of Venous Compliance and Venous Tone

Venous Compliance *In Vitro*

Compliance of a system such as a blood vessel is defined as the change in volume for a given change in pressure

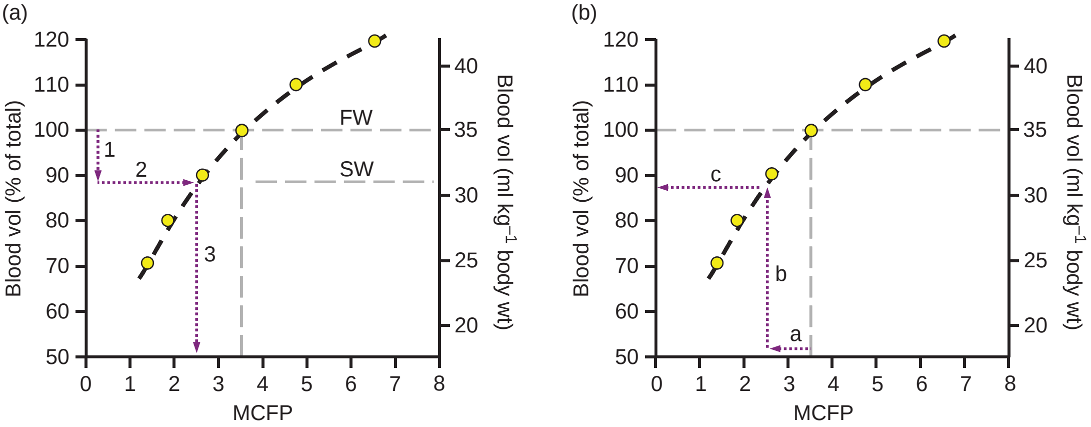

Figure 3 Capacitance curves for a trout showing the effects of freshwater saltwater adaptation (a) and hemorrhage (b). (a) The water–blood osmotic gradients of a fish in freshwater (1–300 mosm l^{-1}) produce chronic volume overload, whereas in saltwater these osmotic ingredients (1000–300 mosm l^{-1}) produce chronic hypovolemia. Thus, the blood volume of a saltwater trout is chronically reduced and this reduces mean circulatory filling pressure (MCFP; lines 1–3). (b) Mobilization of blood volume following acute hemorrhage. In this example, hemorrhage from an artery reduces blood flow into the venous system which in turn lowers venous pressure by 1 mmHg (line a). The vascular capacitance now shifts to a new equilibrium point (line b) that can only be achieved if the venous blood volume is reduced by approximately 12% (4.2 ml kg^{-1} body weight). This 4.2 ml kg^{-1} body weight of blood that is mobilized by the passive recoil of the venous compartment helps sustain cardiac output until the lost volume can be restored. Typically, this blood is mobilized from the microcirculation.

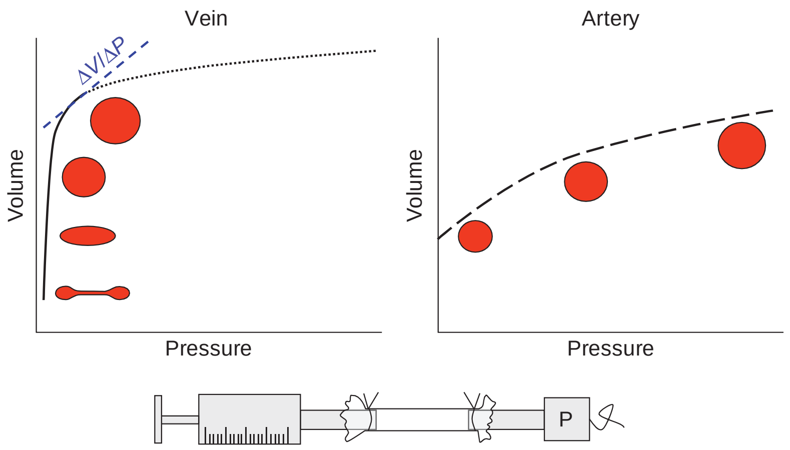

Figure 4 Compliance curves for an isolated vein and artery. Compliance is calculated as the slope of the volume–pressure relationship (Δ*V*/Δ*P*; blue line). Because veins collapse at low pressures, they are initially quite compliant; once distended, their compliance dramatically decreases. Dotted portion of line is obtained at superphysiological pressures. Arteries are considerably (1/25) less compliant than veins but they do not collapse at low pressures. Diagram beneath compliance curves illustrates the method for measuring compliance of isolated vessels. Pressure (*P*) in the vessel is measured as known volumes of fluid are injected.

(i.e., $\Delta V/\Delta P$). The compliance of an isolated blood vessel can be determined by measuring the pressure inside the vessel while known volumes of fluid are injected; compliance is derived from the slope of the volume–pressure curve, as shown in **Figure 4**. Using this approach, it has been determined that fish veins are approximately 25 times more compliant than the corresponding arteries. This difference is similar to that observed between mammalian veins and arteries. It is also evident from the venous compliance curve that veins are very compliant at very low pressures because they are partially collapsed and little pressure is needed to substantially increase blood volume. Once the vessels become distended, compliance decreases dramatically. This degree of distention is not physiological.

Venous Compliance *In Vivo*: Vascular Capacitance Curves

It is far more appropriate, but technically more difficult, to measure venous compliance (and function) *in vivo*. Instead, we measure vascular capacitance. Vascular capacitance curves are constructed from the relationship between blood volume and mean circulatory filling pressure. Mean circulatory filling pressure (also known as zero-flow pressure) is the pressure that will exist throughout the cardiovascular system when there is no blood flow and, therefore, blood pressure in the arterial, capillary, and venous vessels is equal. Experimentally, mean circulatory filling pressure is obtained by either stopping the heart electrically, or with drugs, or by transiently clamping the ventral aorta. During this procedure arterial pressure falls and venous pressure increases as blood flows through the capillaries into the veins. Because arterial and venous pressures do not quite achieve equilibrium during the brief interruption of cardiac output, the venous pressure only approximates mean circulatory filling pressure. (Blood flow must be restored within 10 s to prevent cardiovascular reflexes from responding to the drop in arterial pressure.) Even so, the error is generally minimal. After 15–20 min recovery, a known volume of blood is either removed or added to the fish (using blood from a donor fish), another mean circulatory filling pressure measurement is made, and blood volume is once again quickly returned to normal. Repeating these experiments over a range of blood volumes produces the vascular capacitance curve (yellow data points in **Figures 2** and **3**). Vascular compliance is the slope of the capacitance curve. Usually, compliance is determined from the data points near the normal blood volume (100% blood volume, or 35 ml kg^{-1} body weight in **Figure 2**). The intersection of the compliance line with the *y*-axis when mean circulatory filling pressure equals 0 mmHg provides an estimation of the unstressed blood volume. The stressed blood volume is the difference between total blood volume and unstressed volume.

If an experimental protocol increases vascular compliance, the compliance line will be rotated counterclockwise about the unstressed volume (line B, **Figure 2**). The net effect of this is that at normal blood volume mean circulatory filling pressure will be lower, which will reduce venous return, and cardiac output will decrease. If an experimental protocol increases venous tone, the compliance line will be displaced downward indicating that blood has been shifted from the unstressed to the stressed compartment (line C, **Figure 2**). The net effect of this is that at normal blood volume mean circulatory filling pressure will be greater and this will increase venous return and cardiac output. A decrease in vascular compliance or venous tone will have the correspondingly opposite effects. If blood volume changes during the experimental protocol, this will artificially affect the capacitance curve. As an example if blood volume is decreased experimentally or by hemorrhage, the compliance curve is now shifted to lower blood volumes (line D, **Figure 2**), which has the effect of increasing compliance (because the veins are now more collapsed) and decreasing the unstressed volume (which reflects some of the blood that has been removed).

Glossary

Arterial Adjective pertaining to blood that has been oxygenated.

Avascular Adjective pertaining to the lack of blood vessels or capillaries.

Choroid Pertaining to a vascular structure behind the retina, so-called because it resembles the chorion, the membranous structure that surrounds an embryonic mammal and contributes to the development of the placenta.

Countercurrent Flowing in opposite directions. Used for an arrangement of vessels (e.g., blood vessels or kidney tubules) such that fluid flows in one direction in one vessel that lies close to another vessel in which the flow is in the opposite direction. This arrangement allows the transfer of molecules or heat from one vessel to another in such a ways as to maintain a gradient along the countercurrent vessels.

Dorsal aorta The main artery in fishes that delivers oxygenated arterial blood to the body.

Endotherm An animal that uses its own metabolism as the major source of heat to maintain its body temperature greater than that of the surrounding environment.

Equilibrium Pertaining to the situation when all forces acting are balanced by others resulting in a stable unchanging system.

Myotome Blocks of white muscle in fish used for burst swimming. When cooked, they separate as flakes.

Partial pressure The pressure that a component of a gas mixture would have if it alone occupied the same volume at the same temperature as the mixture.

pK_a and K_a K_a is the equilibrium constant for the dissociation of a weak acid that is related to the strength of the acid. pK_a is –log10(K_a).

Post-cardinal vein The main vein that returns venous blood to the heart.

Pyloric ceca Blind, finger-like projections stemming from the proximal intestine that contain pancreatic tissue and secrete digestive enzymes, thus facilitating digestion in some species.

Red muscle Striated skeletal muscle that generates ATP aerobically and is used to perform sustained low-intensity swimming. Red muscle has many mitochondria and a good blood supply to provide oxygen and nutrients.

Rete Structure consisting of densely packed blood vessels, mostly with a countercurrent blood flow scheme, arranged to facilitate the exchange of, e.g., heat or oxygen.

Root effect A property of fish hemoglobin in which protons decrease the maximal oxygen saturation of hemoglobin. For practical purposes, it is defined as a reduction of oxygen saturation at atmospheric oxygen tension.

Venous Adjective pertaining to blood that has passed through tissues and has had some of its oxygen removed for metabolism.

Visceral Pertaining to internal organ structures in the abdominal cavity.

What Is a Rete and How Does It Work?

Rete (plural retia) refers to a structure found in fish and other vertebrates that consists of a collection of tubules arranged in parallel. An example of a nonvascular rete is the rete testis, which is a network of tiny tubules of the testicle that carries sperm. In comparative physiology, a rete usually refers to a vascular rete consisting of both arterial and venous vessels. The diameter of the vessels is small (about the size of an arteriole or capillary), and the blood vessels are arranged so that the arterial blood flows in the direction opposite to that of the venous blood (i.e., countercurrent). The juxtaposition of an arterial vessel(s) to a venous vessel(s) allows for the exchange of heat or

Table 1 Number and diameter of blood vessels in the heat exchange and gas exchange retia of fishes

		Body weight	*Length (cm)*	*Arterial vessels number*	*Venous vessels number*	*Arteria diameter (μm)*	*Venous diameter (μm)*
Heat exchange retia							
Central muscle	Skipjack tuna	1.9 kg	1	134 000	121 000	36	84
Central muscle	Black skipjack	1.7 kg		66 800	64 100	54	110
Central muscle	Yellowfin tuna	8 kg				44	116
On liver	Porbeagle shark	88 kg	9	2000	1 sinus	130	
Gas exchange retia							
Choroid rete	Tuna		0.18	7 940 000	8 140 000	10.5	23.2
Swimbladder	Eel		0.77	670 000	360 000	21.6	33.7
Swimbladder	Eel			116 000	88 000		
Swimbladder	Eel		0.4	34 000	22 000	9–10	12

substances between them; hence, they are often called exchangers. In addition, because the blood flows in opposite directions in the two types of vessels, the structures also are called countercurrent exchangers.

In fish, there are two types of countercurrent exchangers: heat exchangers and gas exchangers. Heat exchangers are found in only a few species of fish and are found at various locations in the body. Gas exchangers are found in a wide variety of fishes and are located near the region where gases are secreted into the swimbladder and on the vessels that serve the eyes. The vessels that constitute a heat exchange rete are larger (typically 40–100 μm in diameter) than those in a gas exchange rete (typically 10–20 μm in diameter) (**Table 1**). This article focuses on the structure and the function of vascular retia.

Rete mirabile (plural retia mirabilia) is the correct term for a vascular rete, and because the retia in fish contain both arterial and venous vessels, the more apt term is rete mirabile geminum (rete is Latin for 'net or network', mirabile for 'wonderful' or 'miracle', geminum for 'paired'; plural retia mirabilia geminia). In most of the fish literature, the term rete mirabile geminum is shortened to just rete.

Factors That Affect the Amount of Exchange

Heat and gas exchange between rete vessels take place through conduction and diffusion, respectively. Therefore, the three factors that affect the amount of exchange between the rete vessels are the distance between the vessels, the flow rate in the vessels, and the area available for exchange. Another factor would be the packing of the vessels, but in essentially all vascular retia each arterial vessel is surrounded by venous vessels and vice versa.

Figure 1 illustrates how an exchanger works and the effect of proximity. **Figure 1**(**a**) shows two blood vessels: one containing warm blood flowing from left to right and the other containing cool blood flowing in the opposite direction. Because the blood vessels are distant from each other, there is so little exchange between the two that the temperature remains essentially the same throughout the length of each blood vessel. In **Figure 1**(**b**), the two blood vessels are in proximity; thus, there is an opportunity for heat (or gas) exchange between the two. Different colors represent different temperatures (but also could represent different oxygen partial pressures). The warm blood is

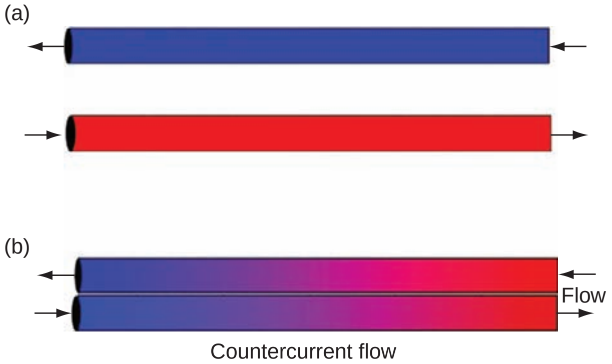

Figure 1 Schematic of a simple exchanger and the effect of proximity of blood vessels. (a) Two blood vessels distant from each other: one containing warm blood (red) flowing from left to right and the other containing cool blood (blue) flowing in the opposite direction. (b) The two blood vessels in proximity.

cooled and the cool blood is warmed as it passes through the exchanger, thus approaching thermal equilibrium. If the exchanger is very efficient, then exchange will be almost complete, and the temperature (or gas partial pressure) at the input side of one vessel will be almost the same as that at the output of the other.

The second factor that affects exchange is the flow rate in the vessels. If the flow in both blood vessels were stopped so that flow rate was zero, then there would be more time for exchange between the vessels and eventually the temperature would reach equilibrium and would be the same in both the vessels throughout their length. At the other extreme, if the flow rate were extremely high, there would be insufficient time for exchange and very little transfer between the vessels would take place. In a living fish, the flow rate lies somewhere between these two extremes. The blood flows in both blood vessels, and heat in the warm vessel warms the blood in the cool vessel and vice versa.

The third factor that affects exchange is the surface area of contact between the vessels. **Figure 1** shows only one artery and one vein. **Figure 2** shows a situation where the total cross-sectional area is the same, but in one case there are two large warm vessels and two large cool vessels (**Figure 2**(**a**)), whereas in the other case there are many small warm vessels and many small cool vessels (**Figure 2**(**b**)).

Although the cross-sectional area is the same in both the cases, there is a larger area available for exchange with the small vessels when compared with the large vessels and thus much more exchange will take place. In actual retia, the blood vessels divide many times so that there are large numbers of arterial vessels, each surrounded by venous vessels, and large numbers of venous vessels, each surrounded by arterial vessels. For example, the large arteries that feed the lateral muscle retia in giant Atlantic bluefin tuna are about 5 mm in diameter, and these divide and subdivide many times so that the vessels in the retia that serve the muscles are only about 0.04 mm in diameter. Even if the subdivision into smaller and smaller blood vessels were such that the total cross-sectional area remained the same, the perimeter of the vessels (i.e., the area available for exchange) would have increased 100 times. In fact, the cross-sectional area of the vessels in the rete is always several times greater than that of the artery that supplies it.

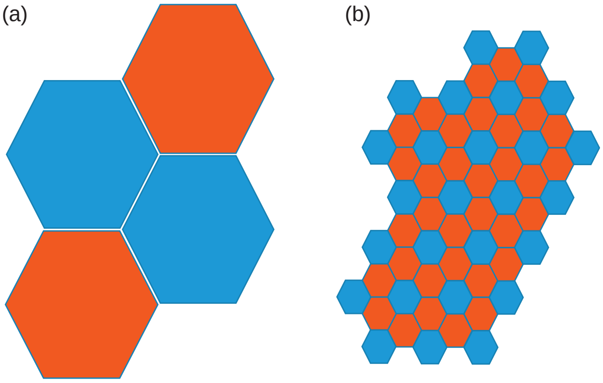

Figure 2 (a) An exchanger consisting of two large warm vessels and two large cool vessels. (b) An exchanger consisting of many small warm and cool vessels, but with the same cross-sectional area as in (a). The contact area for exchange is much greater with many smaller diameter vessels.

The length of the rete vessels also contributes to exchange area: if the vessels are very short, then there is little opportunity for exchange. However, there are some important trade-offs associated with an exchanger with longer vessels of larger diameter as opposed to an exchanger with shorter vessels of smaller diameter. Resistance to blood flow is very sensitive to changes in diameter; it increases with fourth power. Thus, smaller diameter vessels require higher input pressure. On the contrary, long rete vessels require more space for the rete. Moreover, there is no advantage to having vessels longer than that required for exchange to occur. For example, the choroid rete behind the eye in most fishes consists of small-diameter short vessels (there is very little space between the eye and the brain for a rete). In contrast, the visceral rete consists of larger-diameter vessels that are much longer. Thus, all three factors are important for the exchanger to work effectively: proximity of the arterial and venous vessels, flow rate, and subdivision into smaller-diameter vessels to increase the area for exchange. In the example discussed earlier, heat was exchanged between the blood vessels, but in some retia carbon dioxide and oxygen are exchanged – both types of exchangers in fishes are discussed.

Countercurrent Heat Exchangers in Fishes

Although there are about 30 000 species of fish, only about 30 species have well-developed countercurrent heat exchangers; they include tunas, some billfishes, and certain shark species. These fishes have heat exchangers that serve their muscles, their brains and eyes, and their viscera. The exchangers conserve the metabolic heat produced by a particular tissue in that tissue itself; that is, these fishes are warm-bodied, whereas all other fishes have tissue temperatures that are almost identical to that of their environment. The functional significance of endothermy or being warm-bodied is discussed in **Pelagic Fishes**: Endothermy in Tunas, Billfishes, and Sharks. All animals produce metabolic heat, largely because biochemical reactions are not 100% efficient and much of the energy is lost as heat. Most fishes are cold-blooded owing to the pattern of circulation and the fact that all of the blood passes through the gills for gas exchange. As the venous blood passes through a tissue, its temperature equilibrates with that of the tissue (i.e., it picks

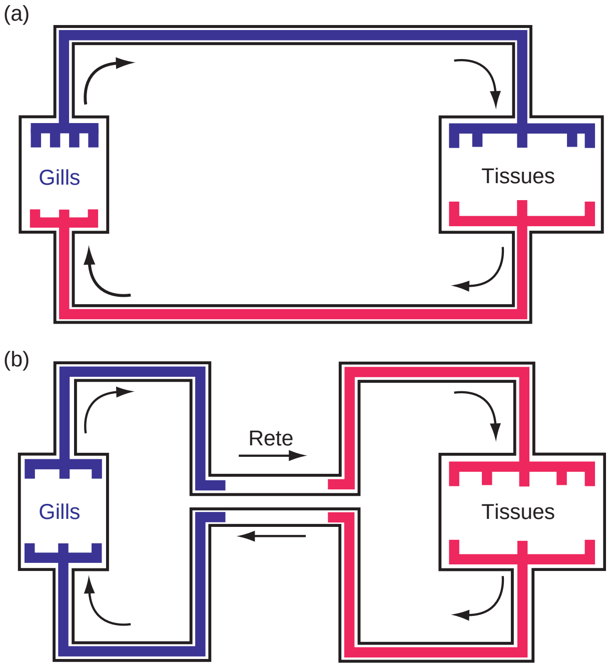

Figure 3 (a) The pattern of circulation in most fishes in which all the metabolic heat produced by the tissues is lost at the gills during gas exchange. (b) The pattern of circulation in fishes with countercurrent heat exchangers – the metabolic heat produced by the tissues is conserved in the tissues that produce it.

up the metabolic heat produced by that tissue and carries it to the gills). The gills have a very large surface area for gas exchange, and the water passing over the gills has a very high heat capacity. Thus, as the blood passes through the gills, the blood temperature equilibrates with ambient water temperature. All the metabolic heat is lost to the ambient water and the arterial blood that delivers the oxygen to the tissues is at the same temperature as the ambient water (**Figure 3**).

Figure 3(**a**) shows the pattern of circulation in most fishes in which all the metabolic heat produced by the tissues is lost at the gills during gas exchange. **Figure 3**(**b**) shows the pattern in tunas in which the metabolic heat produced by the tissues is conserved in the tissues that produce it. Thus, retia on the blood vessels that serve the stomach will conserve heat produced near the stomach and will keep it warm. It is important to appreciate that an individual rete on a tissue conserves the metabolic heat produced by that tissue only.

Heat Exchangers That Serve the Viscera

The first, and still the best, anatomical description of retia in fish is that of Eschricht and Müller published in 1835. They provided an extremely detailed description with exquisite illustrations of the retia that serve the viscera of the giant Atlantic bluefin tuna. These retia are huge, some as large as an orange, and consist of many thousands of arterial and venous blood vessels arranged in parallel. A drawing of a visceral rete from their study is shown in **Figure 4**. Of the 15 species of tunas, only five have visceral retia: *Thunnus thynnus* (Atlantic bluefin), *Thunnus maccoyii* (southern bluefin), *Thunnus alalunga* (albacore), *Thunnus orientalis* (Pacific bluefin), and *Thunnus obesus* (bigeye).

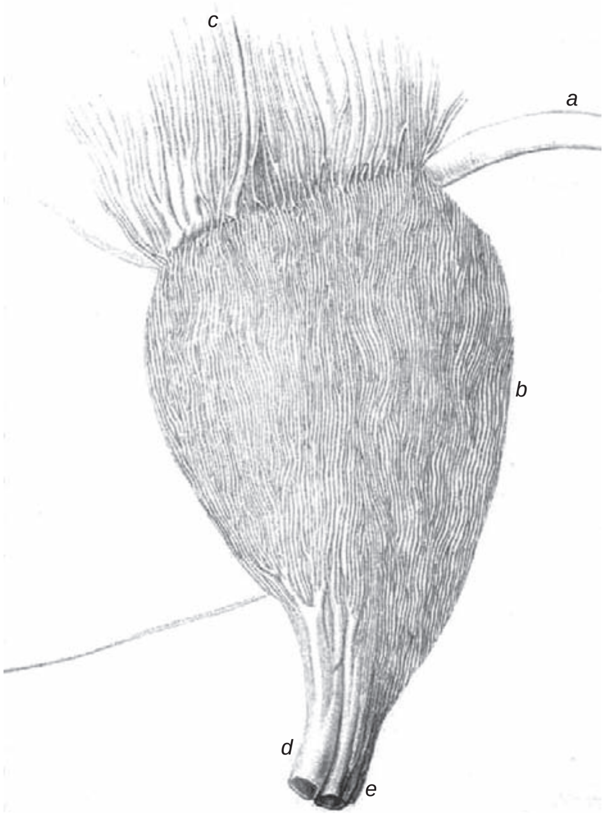

Figure 4 One of the drawings by Eschricht and Müller of a single visceral rete from a giant Atlantic bluefin tuna; the rete vessels are about 7 cm long. (a) Branch of the visceral artery that forms the arterial vessels within the rete. (b) Rete. (c) Branches of the hepatic portal vein that carry the venous blood after passing through the rete. (d) Branch of the visceral portal vein that forms the venous vessels within the rete. (e) Artery formed from arterial rete vessels carrying the arterial blood after passing through the rete.

Figure 5 shows an example of a visceral rete from a 450-kg giant Atlantic bluefin tuna. The rete on the left is still intact and connected to the liver and the pyloric ceca. The rete on the right dissected out of the gut was perfused with saline to remove the blood. The blanched color emphasizes the fact that the vascular tissue making up the rete is translucent white, and it is the blood that gives the intact rete its purplish-red color (in the living animal it would be bright red because the blood in the arterial vessels would be oxygenated).

Although there is only one shark (common thresher) with large retia on their visceral organs similar to those found in bluefin tuna, some other sharks do have retia on

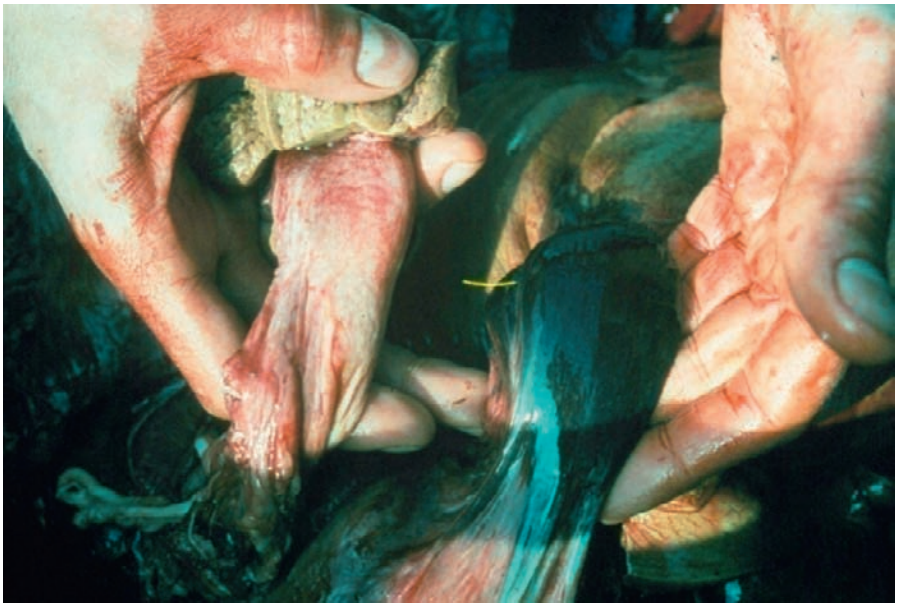

Figure 5 Photograph of visceral retia from a 450-kg giant Atlantic bluefin tuna. (Left) A rete that has been dissected out of the fish and perfused with saline to remove the blood in both the arterial and venous vessels of the rete. (Right) A rete *in situ* and still attached to the viscera.

their livers called suprahepatic retia. The structure of these retia in the lamnid sharks is quite different from that described for the tunas. In these sharks, rather than a grid of arterioles and venules, an array of arterioles pass through a large venous sinus where they are warmed (**Figures 6** and **7**). After being warmed in the venous sinus, the small arterial retial vessels unite to form arteries that supply the stomach and intestines. The main difference between the visceral heat exchangers of the tunas and the lamnid sharks is that in the tunas the liver is not warmed (except by conduction from the viscera), whereas in the lamnid sharks both the liver and the viscera are on the warm side of the visceral rete. The salmon shark also has a separate rete that lies under the kidney and serves to keep it warm.

Heat Exchangers That Serve the Swimming Muscles

The fishes that have retia on their muscles – the tunas, common thresher shark, and lamnid sharks – have their red muscle located centrally rather than in a superficial

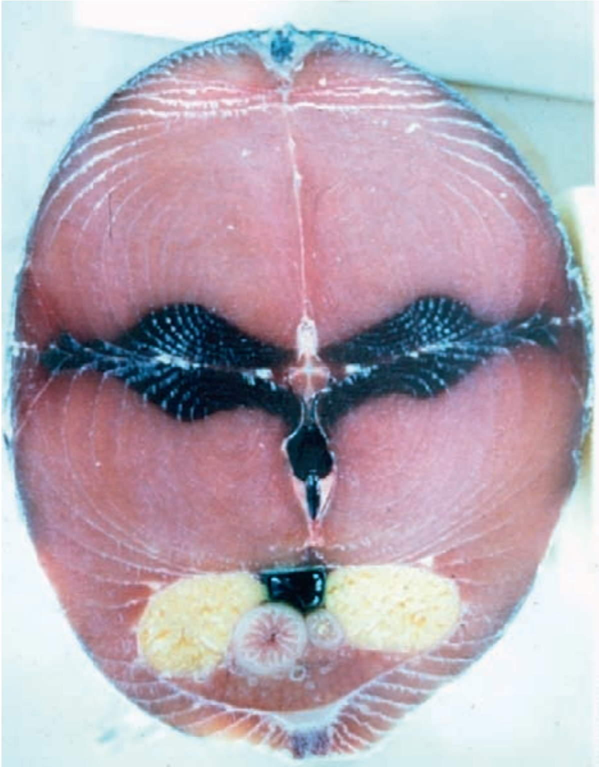

Figure 8 Cross section of a 2-kg skipjack tuna showing the internalized red muscle and the central rete underneath the spinal cord that serves the red muscle. The dorsal aorta and the postcardinal vein are immediately below the rete and are surrounded by kidney tissue.

layer. It is the centrally located red muscle that the retia serve to conserve metabolic heat. Some of these fishes have the retia located centrally, under the spinal cord, and others have the retia located laterally.

Skipjack tuna (*Katsuwonus pelamis*) have the best developed central muscle rete. The location of the rete is shown in **Figure 8**, with a histological slide of the rete region in **Figure 9**(**a**) and a schematic of the slide in **Figure 9**(**b**). After having passed through the gills, the blood in the dorsal aorta is cool and about the same temperature of ambient water. Segmental pre-retial vessels carry blood from the dorsal aorta to the bottom of the rete where they branch many times to form the arterial vessels of the rete. After passing through the rete and picking up the metabolic heat from the venous retial vessels, they unite at the top of the rete at each myotomal segment to form the arteries that supply red muscle. Venous segmental vessels, now warmed in the muscle by its metabolism, return the blood to the top of the rete. There they branch many times to form the venous vessels of the rete. As the blood flows through these venous retial vessels, the heat is transferred to the surrounding arterial vessels. The venous retial vessels, now cooled, unite at the bottom of the rete to form segmental venous vessels that carry the blood to the postcardinal vein. There are about 125 000 arterioles and a similar number of venules in the central rete of a 2-kg skipjack tuna. **Figure 10**(**a**) shows a cross section of the rete vessels to show the large number of parallel rete vessels and **Figure 10**(**b**) shows a higher magnification of the vessels to show how each (small, thick-walled) arteriole tends to be surrounded by (large, thin-walled) venules and vice versa. **Figure 10**(**c**) shows a longitudinal section of five rete vessels to show the diameter relative to the size of the red blood cells. The large number of blood vessels in the rete results in a considerable increase in the total cross-sectional area of the vascular bed; hence, the blood velocity is slower than in the dorsal aorta that supplies it. In fact, the velocity is slowed to about 1/80th of that in the dorsal aorta, and it takes the blood about 1 s to pass through the rete and allow for heat exchange to occur.

Lateral muscle retia are more common and are found in the five species of lamnid sharks, the common thresher shark, and tunas other than *Katsuwonus* (**Table 2**). There is less quantitative information on the number and the size of

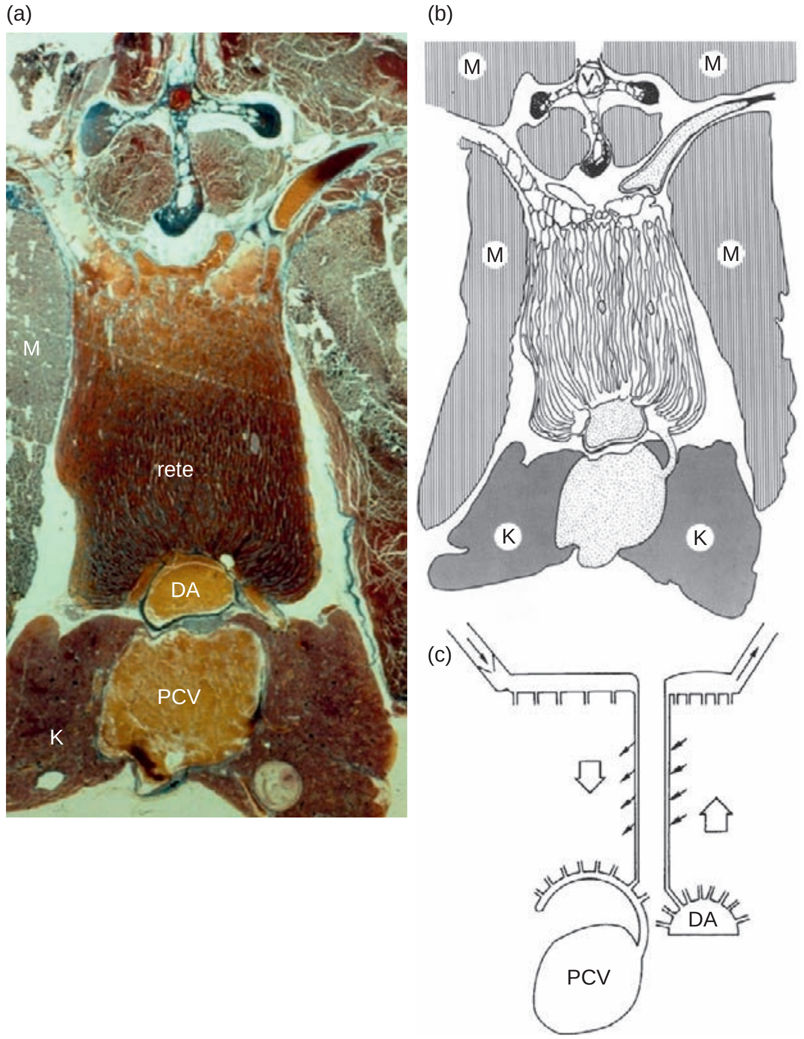

Figure 9 (a) Slide of the central rete of a skipjack tuna. (b) A sketch of the same rete. Compare (a) with diagrammatic sketch in (b) to identify parts of the rete. (c) The pattern of circulation on the right from the DA, through the rete, uniting in segmental arteries at the top of the rete, and on the left from segmental veins, through the rete, uniting in collecting vessel at the bottom of the rete that returns the blood to the postcardinal vein. As the blood passes through the rete, heat is transferred from the blood in warm venous vessels to the blood in the arterial vessels. Thus, heat produced by the muscle is conserved in the muscle. vessels in these retia than for the central retia. In the tunas these retia are supplied by two lateral arteries on each side of the body, whereas in the sharks they are supplied by only one lateral artery on each side of the body.

Heat Exchangers That Serve the Brain and Eyes

The true tunas (*Katsuwonus*, *Euthynnus*, and *Thunnus*) have a rete on each internal carotid artery to conserve heat in the brain and eyes. Lamnid sharks have a separate blood vessel that carries warm blood from the warm red muscle to a venous sinus near the brain and eyes. Cool arterial blood enters arterial rete vessels within the venous sinus where it is warmed before exiting and going to serve the brain and eyes.

Countercurrent Multipliers That Serve the Swimbladder and the Retina in Fishes

The retia that serve the swimbladder and the retina are talked about together because they consist of vessels of similar size and they use the same mechanism to conserve and secrete oxygen (**Figure 11**). In the swimbladder, the oxygen is released in gas form and contributes to buoyancy. In the eyes, the oxygen is used for metabolism by the avascular retina. Although in both cases the result is

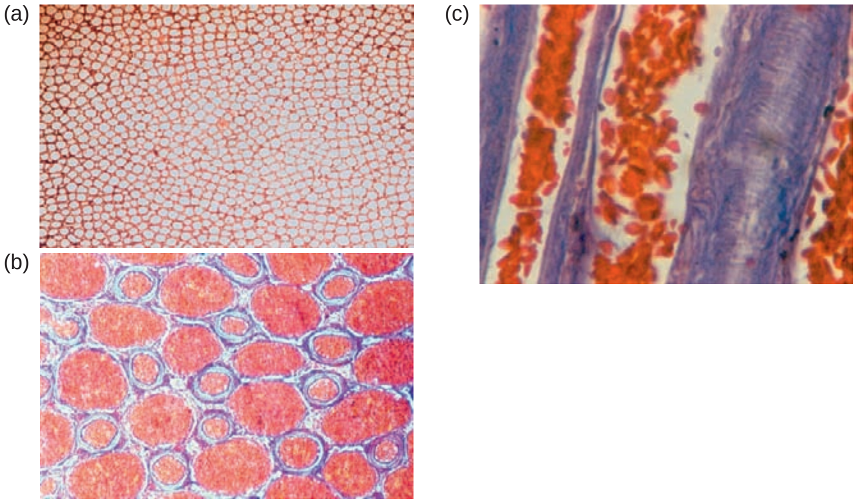

Figure 10 (a) Cross section of the central rete (low-power magnification) of a 2-kg skipjack tuna. The rete has been perfused with saline to remove the blood to show how the vessels are packed together to facilitate exchange. (b) Cross section of the central rete (high-power magnification) of a skipjack tuna. The rete has not been perfused with saline so the red blood cells are still visible. The larger thin-walled vessels are venous and are surrounded by smaller thick-walled arterial vessels. Note that the venous vessels are surrounded by arterial vessels and vice versa. (c) Section of the rete parallel to the vessels in the rete. Individual red blood cells are visible; the diameter of the vessels is almost the same as those of arterioles and venules. EYE refers to the heat exchange retia that warm the brain and eyes (these are not the same as the choroid retia that are involved in gas exchange; RM, red muscle); LAT MUS refers to the retia located on the outside of the body wall that warm the red muscle; CENT MUS refers to the rete located centrally below the vertebral column of some tunas; GUT refers to the visceral heat exchange retia.

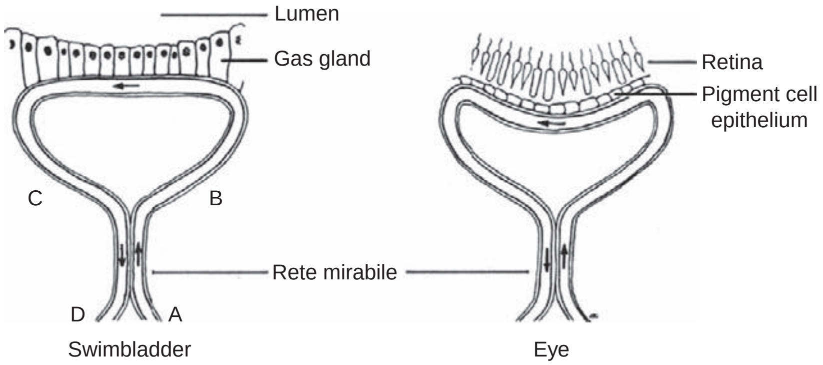

Figure 11 Schematic showing the similarity in the pattern of circulation in the choroid rete that serves the retina and in the rete that serves the swimbladder. Reproduced from Wittenberg JB and Wittenberg BA (1974) The choroid rete mirabile of the fish eye. I. Oxygen secretion and structure: Comparison with the swimbladder rete mirabile. *The Biological Bulletin* 146: 116–136.

an increase in oxygen pressure, the mechanism involves the transport of both oxygen and carbon dioxide across the rete.

The motive for conserving oxygen is best illustrated in the swimbladder. For a fish living at a depth of 1000 m, the hydrostatic pressure is 100 atm and, thus, the pressure inside its swimbladder must also be 100 atm. However, the total gas pressure in ambient water is only 1 atm and of oxygen about 0.2 atm; thus, the maximum in arterial blood is 0.2 atm. If this arterial blood went directly to blood vessels in the wall of the swimbladder, it would equilibrate and essentially all of the oxygen in the swimbladder would be lost to the blood and then lost to the water as the venous blood passed through the gills. Therefore, it is essential to conserve the gas that is at high pressure in the swimbladder; the only way to achieve this is with a rete. The mechanism involved in conserving gas is essentially the same as that described earlier for conserving heat. The blood that leaves the swimbladder contains oxygen dissolved at very high pressure (essentially the same as the pressure in the swimbladder). As the venous blood flows through the venous capillaries in the rete, the oxygen diffuses (sometimes called back-diffusion) into the arterial capillaries. After the oxygen passes through the rete, its partial pressure will be almost the same as that in the incoming arterial vessels. Thus, the rete conserves the high oxygen pressure in the swimbladder.

Because there is a large P_{O_2} gradient between the swimbladder and the ambient water, some oxygen will diffuse out and eventually be lost. This gas must be constantly replaced. In addition, gas must be secreted into the swimbladder when a fish descends in the water column and the increase in hydrostatic pressure squeezes the swimbladder to a smaller volume. (Boyle's law states that volume of a gas in an elastic container is inversely proportional to pressure.) To maintain neutral buoyancy, gas must be secreted into the swimbladder to restore its volume. The mechanisms involved in gas secretion are complex and are discussed in detail in **Buoyancy, Locomotion, and Movement in Fishes**: Swimbladder Function and Buoyancy Control in Fishes. Gas secretion involves more than just exchange, and these retia are called countercurrent multipliers because the P_{O_2} achieved by the structure is greater than the input value. An important aspect of the countercurrent multiplier is that the end of the rete forms a loop (**Figure 11**). The repeated recirculation or back-diffusion of oxygen across the rete leads to further increases in P_{O_2}. There are three other traits that must be present for gas secretion to occur. Fishes that employ this strategy have hemoglobin molecules with special properties, the so-called Root effect (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems and **Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Root Effect Definition, Functional Role in Oxygen Delivery to the Eye and Swimbladder). These molecules have a reduced capacity to bind oxygen in the presence of acid. Also important is the feature that blood must have a low buffering capacity so that the addition of acid results in a decrease in pH. The third feature is specialized cells that produce lactic acid even though oxygen levels are high. Acidification also occurs because the rete conserves CO_2.

The rete multiplies the P_{CO_2} so that it is high at the gas gland end. The addition of lactic acid (pK_a 3.8) to the blood by the gas gland favors the shift of carbonate and bicarbonate ions to form dissolved CO_2 (pK_a 6.1); both the lactic acid and CO_2 result in a decrease in pH. This acidification results in oxygen release from hemoglobin into solution. Because of the low solubility of oxygen in plasma, there is a large increase in P_{O_2}. This oxygen diffuses out of the venous capillary in the rete and into the arterial capillary where the P_{O_2} is lower. The multiplier effect is achieved because oxygen is repeatedly added, with higher and higher P_{O_2} values on the gas gland side of the rete so that the partial pressure on the gas gland side of the rete is 500-fold higher than that on the incoming side. In the same way that oxygen is multiplied by the rete at the gas gland side, carbon dioxide also is multiplied.

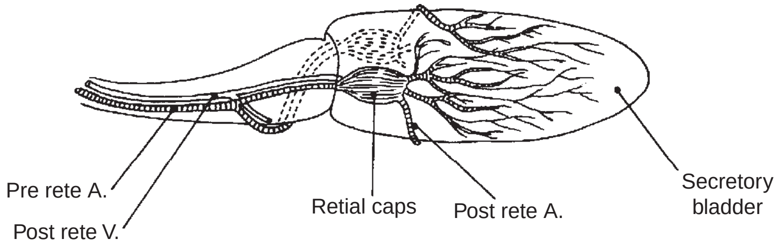
Countercurrent Exchangers That Serve the Swimbladder

In most fishes, the swimbladder is a buoyancy organ; however, in many fishes, the swimbladder is involved in hearing. This is because there is a connection between the hearing organ and the swimbladder, and the bladder amplifies sounds, much like a drum. In some fishes (e.g., the eel), the swimbladder rete is a distinct structure easily visible to the naked eye (**Figure 12**), whereas in most fishes there are many retia that are diffusely located and cover much of the surface of the swimbladder.

Countercurrent Exchangers That Serve the Retina

The rete that serves the retina is called the choroid rete mirabile. The retia serving the eyes and the swimbladder have vessels of similar diameter, but the vessels of the choroid rete are shorter because the P_{O_2} required for diffusion into the retina is not as high as that required for diffusion into the swimbladder when the fish is at depth. The length of the vessels in the choroid rete is almost the same in all fishes, about 0.14 cm; it is independent of the size of the fish (from 2 g to 400 kg). The rete creates a high oxygen partial pressure for diffusion to meet the high metabolic demand of the avascular retina. In most other vertebrates, the retina is well vascularized with an abundant supply of capillaries to deliver oxygen to the metabolically active tissue. In fish, the retina is not vascularized and oxygen demand must be met by diffusion over large distances – hence the need for a high oxygen partial pressure. The distance over which oxygen must diffuse is about 6 times greater than in mammals. Thus, most, but not all, fishes have a rete behind the retina. For example, skate (*Raja ocellata*), sting ray (*Dasyatis centroura*), dogfish (*Mustelus canis*), gar (*Lepisosteus* sp.), and eel (*Anguilla rostrata*) do not have choroid retia, whereas cod (*Gadus morhua*), bluefish (*Pomatomus saltatrix*), menhaden (*Brevoortia tyrannus*), trout (*Oncorhynchus mykiss*), and bowfin (*Amia calva*) have well-developed and large choroid retia. Generally speaking, the fishes that do not have a choroid rete are not visual predators, rather they rely on other senses (chemical and electrosense) to locate their prey.

The choroid rete lies within the eyeball in the choroidal layer retinal cells at the back of the retina. Thus, the schematic diagram in **Figure 13** is slightly misleading because the actual rete lies close to the retina. The ophthalmic artery divides into two branches, one on



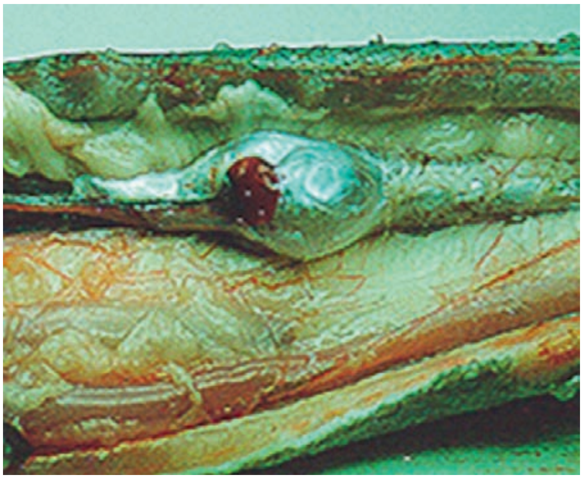


Figure 12 (Top) Schematic showing the large size of the swimbladder retia in the eel (ventral view). Reproduced from Satchell GH (1991) *Physiology and Form of Fish Circulation*. Cambridge: Cambridge University Press. (Bottom) Photograph of the swimbladder rete in the eel. Courtesy of Ben Clemens.

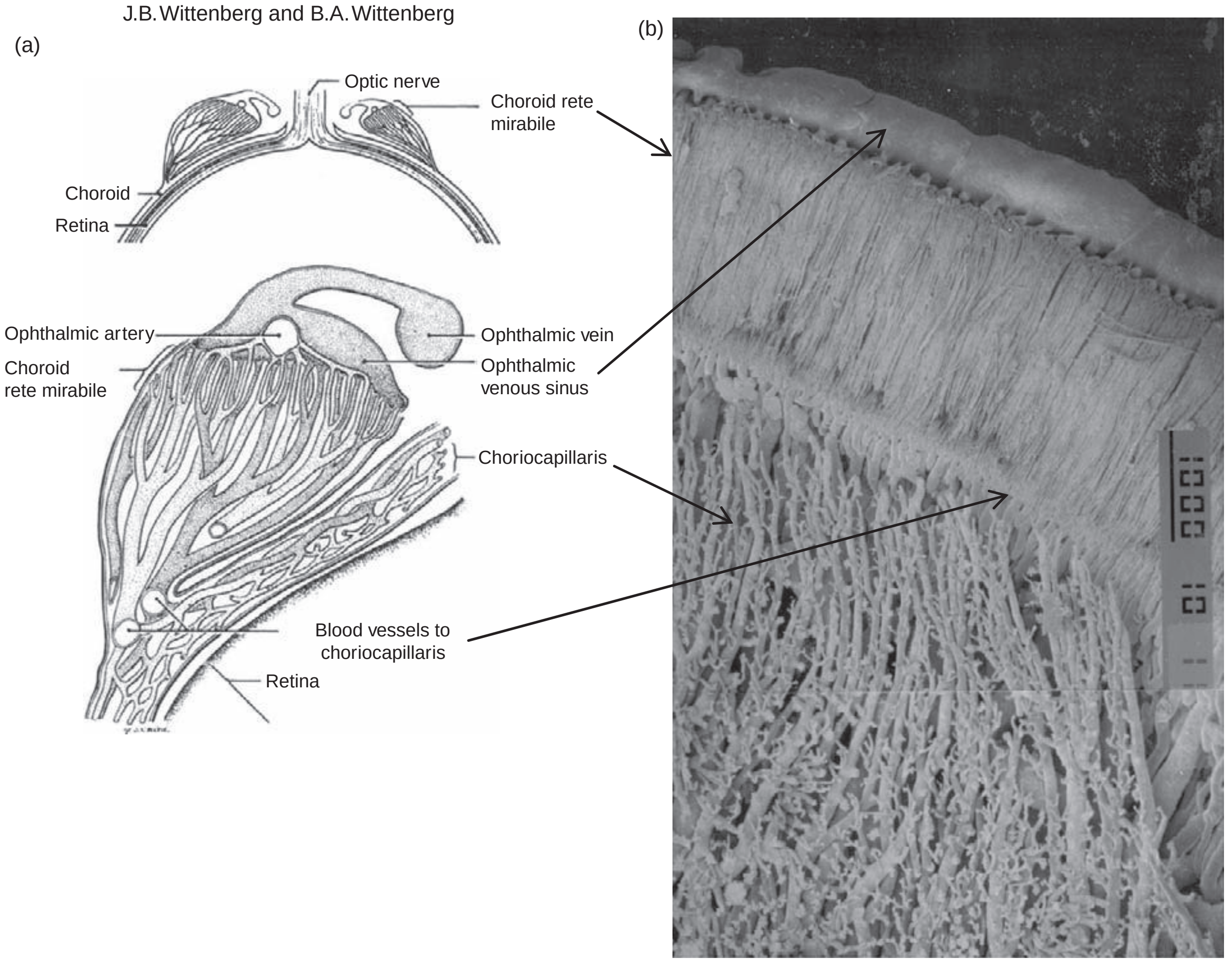

Figure 13 (a) Schematic of the choroid rete. (b) A scanning electron microscopic image of a vascular cast of the choroid rete in a similar orientation showing the same structures as in the drawing. The ophthalmic artery (containing cool arterial blood) divides into thousands of small rete vessels, which then reunite at the bottom of the rete to form the vessels that supply the capillaries of the retina (choriocapillaris). The blood leaving the retina enters the bottom of the rete, passes through it, and then unites at the top to pass blood to the ophthalmic vein. Both oxygen and carbon dioxide are maintained at high partial pressures on the retina side of the rete. Specialized cells on the retinal side of the rete add acid to the blood, resulting in the release of oxygen from hemoglobin and corresponding increase in P_{O_2} (a) Reproduced from Wittenberg JB Wittenberg BA (1974) The charoid rete mirable of the fish eye. 1. Oxygen secretion and structure: Comparison with the swimbladder rete mirable. *The Biological Bulletin* 146: 116–136. (b) Courtesy of Ken Olsen.

each side of the retina. Many smaller arteries branch off from the main ophthalmic artery, and then subdivide many times to form the small vessels of the choroid rete. They then merge to form the larger choriocapillaris vessels that supply oxygen and nutrients to the retina. The location of the choroid rete, the path of blood flow, and a

Table 3 Fishes with well-developed choroid retia tend to have high P_{O_2} values in the eyes

scanning electron microscopic image of a vascular cast are shown in **Figure 13**.

The presence of the choroid rete in a particular species of fish is associated with a high P_{O_2} in the eyes. Fishes with well-developed choroid retia have high P_{O_2} values in the eyes (**Table 3**). Without a choroid rete, it would be impossible to achieve a P_{O_2} value higher than that in the arterial blood, which is higher than about 120 mm Hg. The aggregate length of the vessels in the choroid rete of the tuna eye (**Table 1**) is 2.9 km, which gives some idea of the extremely large surface area available for exchange.

Evolution of Retia in Fishes

There has been some recent work by Berenbrink that sheds light on the evolution of retia in fishes (**see also Transport and Exchange of Respiratory Gases in the Blood**: Root Effect: Molecular Basis, Evolution of the Root Effect and Rete Systems). This work has shown that the structures involved in oxygen secretion evolved very early in the fishes, that the choroid rete evolved first, and that it evolved only once. It first appeared in the ray-finned fishes when the bowfin or a relative (order Amiiformes) diverged from the gars (order Lepisosteiformes) about 250 million years ago. Thus, most teleosts have a choroid rete. However, it has been secondarily lost in a few different groups: for example, elephantnose fishes (Mormyrids), which live in the water with very poor visibility and generate an electric field to 'see' in their murky environment. The evolution of the retia involved in oxygen secretion required a number of associated traits. Most important was a hemoglobin that would release oxygen in the presence of acid. Additionally, specialized cells that produce acid and plasma with low buffering capacity also were essential.

Unlike the choroid rete, the swimbladder rete and other features required for oxygen secretion evolved at least four separate times in the teleost lineage. In every case, the evolution of the swimbladder and its rete was associated with an expansion into a new ecological niche and the accompanying speciation. The evolution of oxygen secretion into the swimbladder is complex because it has two very distinct functions: (1) provides buoyancy and (2) amplifies sound to facilitate hearing. In some groups of fishes, the swimbladder and its rete are important for buoyancy, in some for hearing, and in some for both.

The evolution of the heat exchanger retia occurred much later, about 60 million years ago. It occurred at about the same time in the two very different groups: the lamnid sharks and the tunas. This is an excellent example of convergent evolution. The evolution of these retia is associated with the evolution of a number of other traits that include modification of the structure of the myotomes so that aerobic red muscle used for sustained swimming is internalized; continuous swimming to maintain a vertical position in the water column and to irrigate the gills; high activity of metabolic enzymes, gills with a large exchange area; and regional endothermy. The billfish with retia on the brain and eyes evolved even more recently, about 15 million years ago.

Glossary

Cardiac output (*Q*) Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.

Catecholamines Any of the group of amines derived from a catechol that has important physiological effects as neurotransmitters and hormones. The main catecholamines are dopamine, adrenaline, and noradrenaline.

Gastrointestinal tract In this article defined as the esophagus, stomach (some fish species lack a stomach) intestine, rectum, and anus. Accessory organs is the liver gallbladder and pancreas.

Hyperemia Increase in blood flow through vasodilation.

In vivo From Latin meaning 'within the living' refers to biological processes or experiments occurring or carried out in living organism as opposed to a partial or dead organism.

Sedentary Contrast to active.

Vasoconstriction A decrease in the diameter of a vessel.

Vasodilator A substance that vasodilates a blood vessel, meaning increases its diameter.

Introduction

The Fish Cardiovascular System

The fish cardiovascular system has a serial arrangement (see **Figure 1**). With the exception of the lungfish, the fish heart is built up of four undivided chambers – the sinus venosus, one single atrium, one single ventricle, and a bulbus arteriosus/cordis (b. arteriosus in teleosts and b. cordis in elasmobranchs) (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes, Accessory Hearts in Fishes, and The Outflow Tract from the Heart). The cardiac chambers are serially connected, and the heart pumps venous blood first into the gills where the blood is oxygenated. Thus, all of the cardiac output (*Q*) goes to the gills. After the oxygenation in the gills, most of the blood leaving the gills enters the dorsal aorta (arterio-arterial route), the main arterial distribution vessel in fishes, which distributes the *Q* to the various parts of the body (the systemic circulation) according to the needs of each tissue. One of the first major arterial distribution paths is the gastrointestinal (GI) tract, which is the focus in this article.

The arrangements of the main vascular beds in fish are interesting from a hemodynamic point of view. When calculating the total vascular resistance, the gills and the systemic circulation (R_{GILL} and R_{SYS} in **Figure 2**) are connected serially and therefore can be added. This means that a change in vascular resistance in the branchial circulation directly affects the dorsal aortic blood pressure, which is the driving pressure for all of the vascular beds that collectively make up the systemic circulation, including that of the GI tract. The systemic circulation can then be subdivided into the GI circulation (visceral) and the somatic circulation, which are connected in parallel (represented by R_{GUT} and R_{SOM} in **Figure 2**), in contrast to the serial connection of branchial and systemic circulation. Thus, the total vascular resistance of the systemic circulation is not the addition of the R_{GUT} and R_{SOM} but instead it is calculated as $1/\text{total} = 1/R_{\mathrm{GUT}} + 1/R_{\mathrm{SOM}}$. This point has to be kept in mind for later in the article when we consider changes in R_{GUT} and R_{SOM}, and how they affect each other.

Definition of the GI Tract

In this article, the GI tract will be loosely defined as a tube that runs from the mouth to the anus in which muscle movements and released enzymes process the food. The

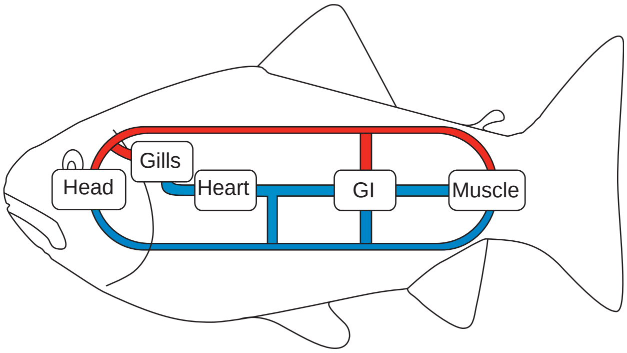

Figure 1 Schematic drawing of the circulatory system in a fish. Note that the heart and gills are placed in series with each other while the GI tract and muscle is connected in parallel. This means that if the blood flow to the GI tract increases, the muscle blood flow will decrease and vice versa unless there is a compensatory increase in overall flow from the heart. Ohm's law states that $V = I \times R$ (V, potential difference in units of volts; R, resistance; I, current). Ohm's law can be applied to the circulatory system as blood pressure = blood flow × vascular resistance, where blood pressure equals V, blood flow equals I, and vascular resistance equals R. This might facilitate the understanding of what happens when blood pressure, blood flow, or vascular resistance changes.

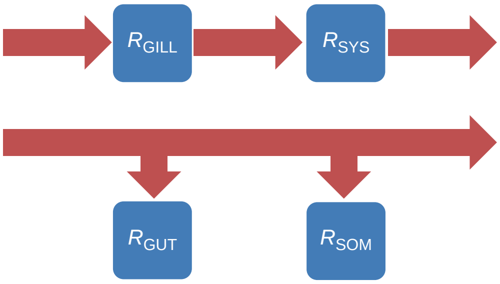

Figure 2 Serially connected resistances. (Top model) The total resistance is additative ($R = R_1 + R_2 + \ldots + R_n$). If the resistances are instead arranged in parallel (bottom model), the total resistance is calculated as $1/TPR = 1/R_1 + 1/R_2 + \ldots + 1/R_n$. In fish the branchial (R_{GILL}) and systemic (R_{SYS}) vascular resistance are serially connected, while the gastrointestinal (R_{GUT}) and somatic vasculature resistance (R_{SOM}) are connected in parallel.

GI tract starts with the mouth followed by the esophagus, stomach, different parts of the intestine, and, finally, the anus. Some fish species (e.g., Cyprinids) lack stomach and the anatomy of the GI tract varies a lot between species and groups (**see also Gut: Anatomy and Morphology**: Development of Fish Gut). The accessory organs associated with the GI tract include the liver, gallbladder, and pancreas, and they are also supplied by the same vascular system that has its origin off the dorsal aorta.

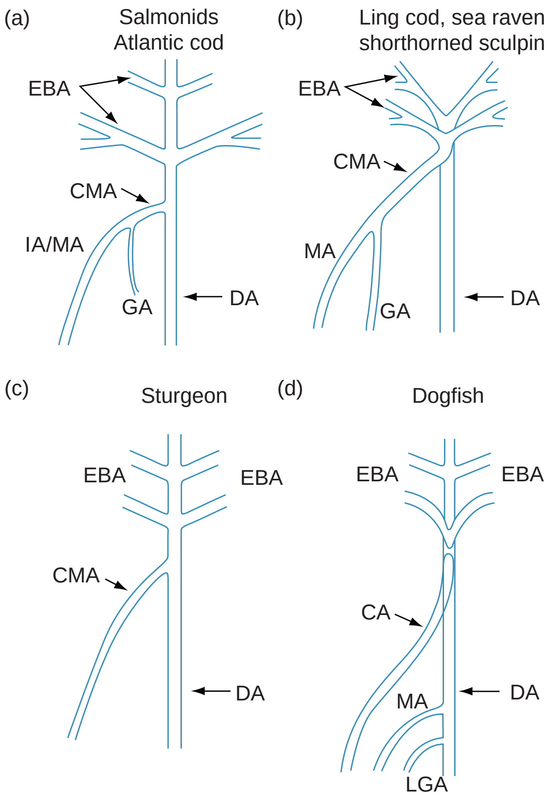

Figure 3 Schematic drawings of the postbranchial vascular tree in different fish species showing where the gastrointestinal blood supply originates. EBA, efferent branchial arteries; CMA, coeliacomesenteric artery; DA, dorsal aorta; GA, gastric artery; IA, intestinal artery; MA, mesenteric artery; LGA, lienogastric artery. Vascularization of the GI Tract

In elasmobranchs (sharks, rays, and skates), the blood supply of the GI tract resembles the distribution pattern found in mammals with at least three distinct blood vessels, arteria coeliaca, arteria mesenterica superior, and arteria mesenterica inferior (see **Figure 3(d)**). In contrast, in most studied teleosts (bony fishes), the GI tract is supplied by one major vessel, arteria coeliacomesenterica or the coeliacomesenteric artery (CMA), which branches off the dorsal aorta. This vessel then divides into several smaller vessels supplying the gonads, stomach, and

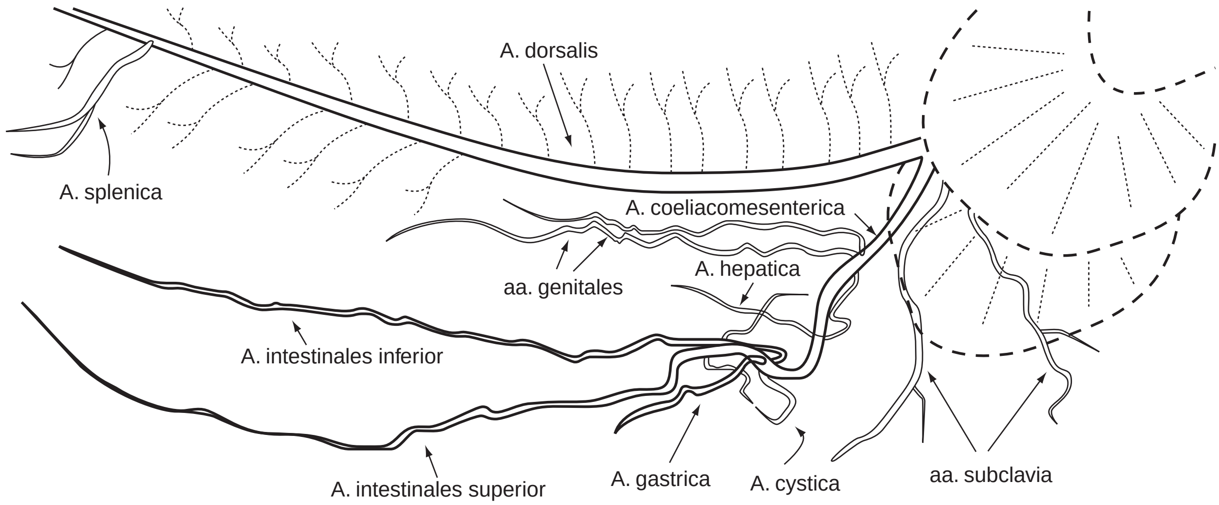

Figure 4 Illustrations of the arterial vascular system in the rainbow trout (*Oncorhynchus mykiss*) with focus on the gastrointestinal blood supply. The figure is based on several corrosion casts. Smaller vessels have been omitted for clarity. A., arteria, aa., arteriae. Redrawn from Seth H, Sandblom E, and Axelsson M (2009) Nutrient-induced gastrointestinal hyperemia and specific dynamic action (SDA) in rainbow trout (*Oncorhynchus mykiss*) – importance of proteins and lipids. *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 296(2): R345–R352.

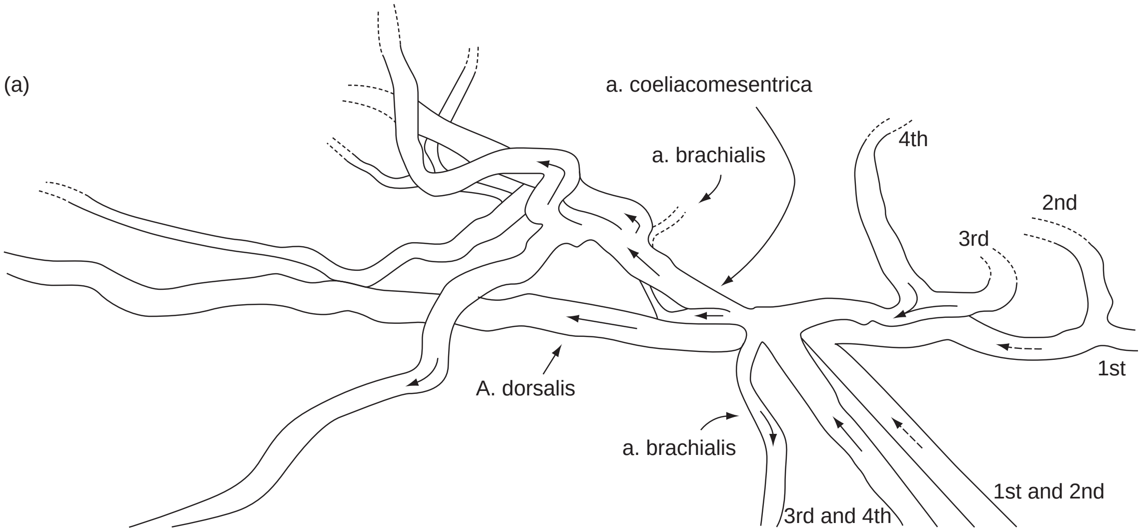
intestine, as well as the liver with blood (**Figures 3**(**a**)–(**c**), **4**, and **5**). Both hagfishes and lampreys have a number of unusual features. Both lack a renal portal system and the kidney is supplied with blood via an arterial connection only. Furthermore, in the lamprey, the intestinal vascular couples have a unique vascular arrangement. Each of these vascular couples consists of an intestinal artery vessel from the dorsal aorta and intestinal vein returning to the posterior cardinal vein. The functional significance of this type of arrangement is unknown. Furthermore, the venous return from the intestine in this group does not enter the hepatic portal system, but returns via a suprarenal venous system to the cardinal vein.

The anatomy of the vasculature of teleost fish, as well as some elasmobranch species, has been investigated using standard *in situ* ocular dissection, with and without color injections of the vascular beds of interest, or the corrosion cast technique (e.g., **Figure 5**). The latter technique normally produces a more detailed picture of the vascular bed and can also be used for electron microscopy imaging looking at the fine details of the vascular casts. In this technique, the vasculature of the euthanized animal is first perfused with saline with an added vasodilator such as sodium nitroprusside. Once the vasculature has been fully rinsed, a two-component epoxi-plastic can be carefully injected and allowed to cure. The organic tissues of the animal are then removed with potassium hydroxide to expose the cast of the vasculature. In some cases, hydrochloric acid is used to remove bony structures that have not been dissolved by the potassium hydroxide treatment (see links in **Figure 5**(**b**)).

This technique has revealed differences between various teleost species, possibly indicating adaptations of the circulation depending on the habitat and feeding regime. In some species the common CMA splits off the dorsal aorta (DA) well behind the junction of the four afferent branchial arteries (see **Figures 3**(**a**), **3**(**c**), and **3**(**d**)), while the CMA vessel branches off very close to this junction in other species (**Figure 3**(**b**)). For example, in the rather sedentary bottom-living shorthorn sculpin (*Myoxocephalus scorpius*), which has a relatively large and very well-vascularized GI tract that receives a large portion of $\dot{Q}$, there seems to be a peculiar anastomose where the branchial arteries unite to form the DA, possibly enabling the animal to direct oxygenated blood from the gills directly to the GI tract (**Figures 3**(**b**) and **5**(**a**)–**5**(**b**)). Whereas in the more active rainbow trout (*Oncorhynchus mykiss*), the CMA branches off the DA well downstream of the branchial arteries (**Figures 3**(**a**) and **4**).

The Liver

All vertebrates have a liver (from the Greek word hepar), which is usually one of the larger organs in the abdominal cavity, accounting for 4–10% of body mass. It is derived from the developing GI tract early in embryonic development. It has a dual blood supply. The arterial supply is derived from branches of the CMA (or one of the mesenteric arteries in elasmobranchs). Some estimates of the arterial blood supply indicate that the liver receives around 2–3% of $\dot{Q}$ via this pathway. The much larger venous supply via the hepatic portal system is constructed of a series of hepatic portal veins (HPVs) draining blood from the GI tract. The arterial blood from the CMA that has first passed through the GI tract drains back to the liver via the HPV and subsequently the



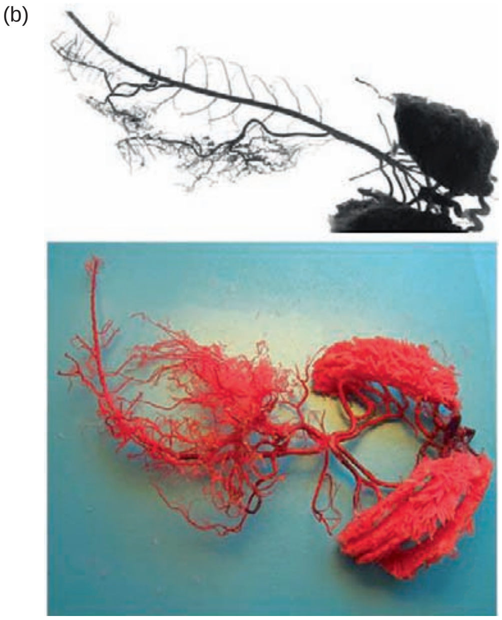


Figure 5 (a) Ventrolateral view of a schematic diagram of the vascular system in the shorthorn sculpin (*Myoxocephalus scorpius*). The figure is based on several corrosion casts. The drawing illustrates the intricate structure of the connection between the efferent branchial arteries (1st, 2nd, 3rd, and 4th) coming from the gills, and the dorsal aorta as well as CMA (supplying the GI tract with oxygenated blood). A., arteria; aa., arteriae. (b) A photo of two corrosion cast made of the vascular bed of the dogfish (*Scualus acanthias*, top) and shorthorn sculpin (lower). The schematic drawing of the major vasculature in **Figures 3**(**d**) and **5**(a) is based on this type of vascular casts. (a) Redrawn from Seth H and Axelsson M (2009) Effects of gastric distension and feeding on cardiovascular variables in the shorthorn sculpin (*Myoxocephalus scorpius*). *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 296(1): R171–R177.

heart via the hepatic veins. The HPV supply has been estimated in a few species to be around 20–30% of $\dot{Q}$. The similarity of this measurement with those for entire GI blood flow (GBF) confirms that the venous output from the GI tract predominantly forms the hepatic portal blood flow into the liver.

The definition of a portal circulation is that the vessels provide a serial connection between two different vascular capillary beds. In the case of the hepatic portal system, the first capillary bed is situated off the GI tract (in the villi), while the second is composed of the wide, fenestrated capillaries of the liver.

In some elasmobranchs, a muscular sphincter is situated on the hepatic veins that return blood from the liver to the heart via the sinus venosus or common cardinal sinuses. These sphincters can constrict with acetylcholine and increase their rate of relaxation with adrenaline. The physiological role of these sphincters is unknown, but clearly they have the potential to affect both the flow of blood leaving the liver and the rate of the venous return to the heart. They could easily work as an external cardiac valve for minimizing the back flow of blood into the liver during the contraction of the sinus venosus. These hepatic sphincters are not unique to elasmobranchs, since inlet and/or outlet hepatic sphincters have been described in mammals, reptiles, amphibians, and other fish species.

The Pancreas

The fish pancreas can be divided into its exocrine and endocrine parts. The exocrine pancreas secretes digestive enzymes into the intestine, while the endocrine pancreas, the Islet of Langerhans, secretes hormones (insulin and glucagons) (**see also Gut Anatomy and Morphology**: Pancreas for more information). The exocrine pancreas is a diffuse organ in teleosts, spread out over the intestinal surface, along the portal vessels and in the overlaying adipose and connective tissue. This means that the pancreas does not have a single distinct blood vessel supplying it. In cyclostomes and most teleosts, the endocrine pancreas is located adjacent to the exocrine pancreas and therefore has a similar diffuse blood supply.

Control of the GBF under Routine Conditions

Under routine conditions, that is, before the ingestion of a meal in a stress-free environment, GBF is regulated to a level sufficient for the housekeeping needs of the GI tract. This routine requirement appears to represent a GBF that is typically 20–40% of routine cardiac output. This percentage is similar to that reported for mammals.

Among fishes, the lowest percentages are reported for sea raven (*Hemitripterus americanus*) and sea bass (*Dicentrarchus labrax*), and the highest for the Atlantic cod (*Gadus morhua*) (see **Table 1** for information on a few selected species and **Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion for more detailed information about effects of feeding).

Since the heart cannot simultaneously perfuse all vascular beds at their full capacity, there must be a tight control of each vascular bed to optimize its blood flow and hence oxygen delivery both to its needs and also relative to the needs of other tissues. An example of this balancing act is discussed below for a fish that is swimming while digesting. Regardless of the balancing act that must take place at the level of the whole animal, each vascular bed is not routinely fully perfused, and instead its vessels are constricted to increase their resistance and reduce blood flow to the minimum requirement of the tissue. If tissue activity and oxygen needs increase, so does its blood flow.

In unfed sea raven and red Irish lord (*Hemilepidotus hemilepidotus*), the routine GBF is maintained by an active vasoconstriction of the vasculature in the entire GI tract that is mediated via an α-adrenergic tonus. This was demonstrated by an injection of a drug that blocks α-adrenergic receptors on vascular smooth muscle (the antagonist phentolamine) lowering the vascular resistance of both the celiac and the mesenteric vascular beds in both species. However, in the Atlantic cod only the mesenteric vascular resistance is affected by phentolamine. Therefore, species differences exist among fish species in terms of the details of the control of routine GBF.

This α-adrenergic tonus on the GI vascular beds is most likely chiefly of nervous origin. This has been difficult to definitively verify, primarily because of the difficulty in separating adrenergic effects due to circulating catecholamines from those due to neural tone. However, one study in rainbow trout confirmed that there is in fact a substantial vasoconstrictor tonus on the GI vasculature via the sympathetic innervation. These results were obained by sectioning the sympathetis nerves (via the splanchic nerve) innervating the GI tract. The plasma levels of circulating catecholamines in the species studied to date are likely also too low to significantly stimulate the systemic vascular smooth muscle or the heart. Even so, these rather low concentrations can alter R_{GILL}. In the rainbow trout, especially at cold temperatures, circulating catecholamines may exert an effect, indicating both inter- and intraspecies differences in sensitivity to circulating plasma catecholamines. More studies are needed to resolve these questions.

Factors Influencing the GBF in the Unfed Animal

As noted above, most animals studied so far cannot fully perfuse the entire cardiovascular system at the same time, and integration of the demands of different tissues must occur, with some tissues being prioritized. Exercise, hypoxia, and general stress are good examples of situations where GBF has a lower priority and so GBF is reduced to allow more blood to be directed for fight or flight responses. Below is a short description of the various external stimuli and the effect on the GBF. For more information on the effects of feeding alone, the reader is referred to **Integrated Response of the Circulatory**

Table 1 Postprandial cardiovascular responses, measured as cardiac output and gut blood flow plus the percentage of cardiac output that passes through the coeliacomesenteric artery, in a selection of several different species. The meal sizes used are also given as percentage of body weight.

System: Integrated Responses of the Circulatory System to Digestion.

Stress

The definition of stress is complicated (**see also Hormonal Responses to Stress**: Hormone Response to Stress, Stress Effect on Growth and Metabolism, and Impact of Stress in Health and Reproduction). It can be claimed that stress is any type of external stimuli that affects an organism (a stressor). This wider definition of a stressor could be applied to exercise, hypoxia, hypercapnia, and temperature, for example. However, this is too simplified a view since fish clearly react differently to each of these external stimuli, and there are even different grades of responses. For example, during voluntary aerobic exercise, the classical stress hormones, adrenaline, noradrenaline, and cortisol, typically are not released. Only with more vigorous and exhaustive exercise is a species-specific threshold reached when these stress hormones are released in order to help the system to cope with the higher demand (**see also Hormonal Responses to Stress**: Hormone Response to Stress, Stress Effect on Growth and Metabolism, and Impact of Stress in Health and Reproduction). Thus, it might be more appropriate to apply one of the first definitions of stress given by the Canadian endocrinologist Hans HB Selye in the late 1930s, who described the stress as “the non-specific response of the body to any demand for change.” He argued that stress could be divided into negative stress (distress) and positive stress (eustress). He also argued that stress always involves the hypothalamic–pituitary–adrenal (HPA) axis system.

The fight or flight response also describes the two options that an organism has, either fight the stressor or avoid it. In both cases the body has to prepare for skeletal muscle (locomotory) activity, and the role of the gut can be temporarily put on hold. A number of studies with fish have either noted that a general stress reduces GBF or studied the specific effect of general stress on the GBF. **Figure 6** shows the effects of general stress on GBF in a green sturgeon (*Acipenser medirostris*) equipped with a dual channel telemetric blood flow system. This is a rather typical response that involves a rapid reduction in GBF. The rapid response is likely too fast to be mediated by changes in plasma levels of catecholamines, and probably involves nervous control. Regardless, the mechanism serves to redistribute blood in support of a fight or flight response.

Exercise

In 1982, Whipp defined exercise as “. . . a process which depends upon the transformation of the biochemical energy of ingested food into mechanical energy of muscle contraction and work.” Other definitions have been proposed, but all acknowledge that exercise is an active process that increases the demand for oxygen and nutrients. This demand is met by an increase in blood flow to the activated locomotory muscles. This increase in blood flow is the result of an increase in *Q* and/or a redirection of blood to these muscles away from nonpriority vascular beds.

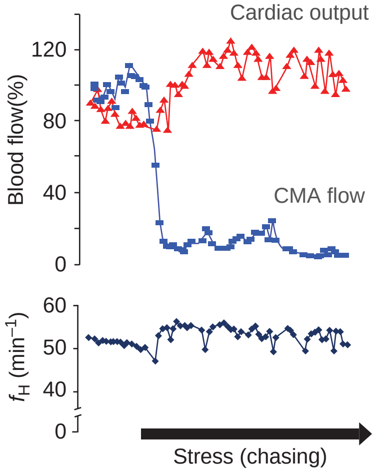

Figure 6 The graph shows the effects of chasing (stress) on *Q* and CMA blood flow (top graph) and f_H (bottom graph) in a green sturgeon (*Acipenser medirostris*) equipped with a dual channel telemetric blood flow system. Note the rapid decrease in CMA blood flow and the increase in *Q* and f_H. Blood flow is directed away from the gastrointestinal tract in order to prepare the animals for fight or flight.

The GI tract is one of the nonpriority vascular beds. Reducing GBF leads to a redistribution of blood toward active locomotory muscles, which could amount to the 30–40% of *Q* it receives in resting, undisturbed fish. Even during moderate exercise, there is a clear reduction in routine GBF (see **Figure 7**). At maximum prolonged swimming speed in a salmonid, the decrease in GBF can be as high as 70–90%, which means that as little as 5% of the routine *Q* would be reaching the GI tract. However, because this reduction in GBF is combined with an increase in *Q*, there is an even larger increase in the total blood flow reaching active muscles. Consequently, GBF is an even smaller fraction of the actual *Q* during exercise.

The reduction in GBF during exercise is via an increase in the vascular resistance of GI tract and mediated by an α-adrenergic mechanism. Obviously, reduced GBF during exercise will reduce the ability for digestion and absorption of nutrients from the gut, dealing meal processing. In seawater fish that drink water to regain water loss across the gills to the hypertonic environment (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction, Mechanisms of Gill Salt Secretion in Marine Teleosts, Mechanisms of Ion Transport in

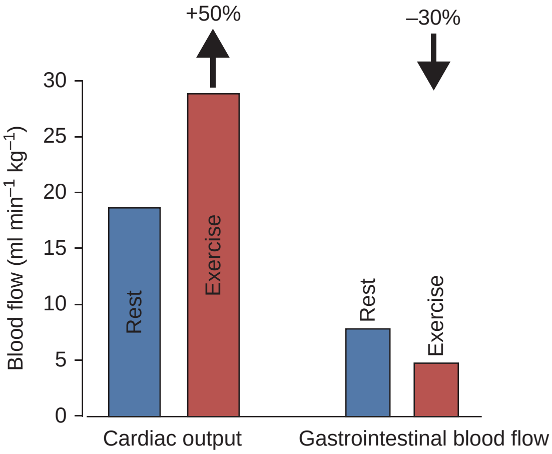

Figure 7 The bar graph shows the redistribution of blood from the GI tract during exercise. The graph is a synthesis of the results from a number of tests in various fish species. During exercise the active muscles have a higher oxygen demand and therefore need more oxygenated blood. This can be achieved by either increasing *Q* or reducing GBF (redistribution), or through a combination of the two as shown in the graph.

Freshwater Fishes, and Water Balance and Aquaporin), there is also a possibility that the osmoregulatory capacity could be compromised during intense exercise.

The effects of exercise after feeding have been tested in a few studies. After feeding, GBF is increased, and this increase is, in most cases, supported by an increase in *Q* (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion). If the fish are then forced to swim, GBF is maintained at a higher level compared to the unfed fish at low swimming speeds but becomes compromised when the fish reaches its maximal swimming capacity. This transition reflects the differences between nonstressful submaximal exercise and anaerobic maximal exercise that mimic the general stress response.

Hypoxia

Hypoxia, which is defined as a lowering of the environmental oxygen availability, may or may not be accompanied by increased carbon dioxide (hypercapnia). In water the amount of physically dissolved oxygen is relatively small, for example, in freshwater at 0 °C and 1 atm, only 10.2 ml oxygen per liter water is available. With increasing temperature and salinity, the available oxygen decreases and at 35 °C and 35 ppt salinity the value is 4.0 ml per liter of water. The levels of both oxygen and carbon dioxide are also highly variable in water compared to air due to the production and consumption with both diurnal and seasonal changes (**see also Hypoxia**: The Expanding Hypoxic Environment). Adding to this low availability of oxygen is the viscosity and density differences between air and water that increase the cost of ventilation dramatically in fish. Responses to hypercapnia *per se* are considered below and here the discussion is restricted to the effects of hypoxia *per se*.

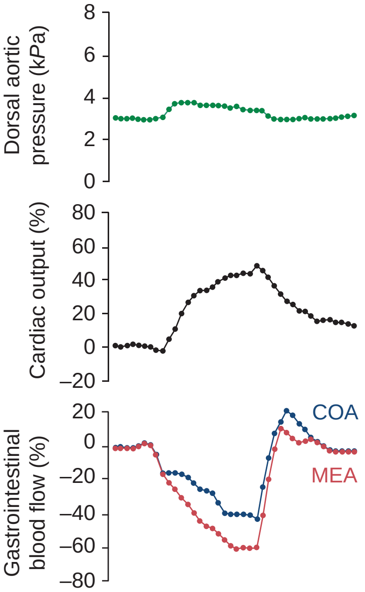

Figure 8 Effects of hypoxia on DA blood pressure (top trace), *Q* (middle trace), and GBF (lower trace) in the Atlantic cod (*Gadus morhua*). Redrawn from Axelsson and Fritsche (1991) Effects of exercise, hypoxia and feeding on the gastrointestinal blood flow in the Atlantic cod, *Gadus morhua*. *Journal of Experimental Biology* 158: 181–198.

When fish are exposed to an hypoxic environment, several adjustments to the cardiorespiratory system occur (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia). Fish characteristically undergo a hypoxic bradycardia that may or may not be compensated by an increase in cardiac stroke volume to leave *Q* unchanged (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia). Even so, GBF decreases (see **Figure 8**), as it is not a priority circulation, again due to the increased vascular resistance in the GI tract that is mediated by adrenergic nerves. This vasoconstriction is especially important because dorsal aortic pressure normally increases, which increases the perfusion pressure for both the GI and the systemic circulations. Splenic contraction in some species leads to an increase in circulating red blood cells (**see also Blood**: Cellular Composition of the Blood). The rerouting of blood from the GI tract toward vascular beds that are more dependent on oxygen, together with the increase in total oxygen-carrying capacity due to the spleen contraction and the increase in ventilation, are all aimed at maintaining homeostasis in critical tissues.

Hypercapnia

Carbon dioxide is the end product of the aerobic respiration in both animals and plants. Atmospheric carbon

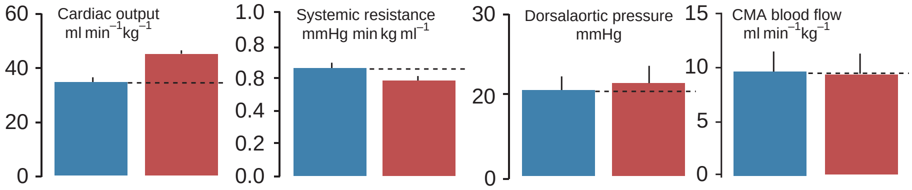

Figure 9 Cardiovascular variables in the white sturgeon (*Acipenser transmontanus*) under control normocapnic conditions (blue bars) and during a 2-h exposure to severe hypercapnia (red bars) P_{CO2} 20 torr at 18 °C. *Q* is increased during the hypercapnic exposure but there is no change in CMA blood flow. Redrawn from Crocker CE, Farrell AP, Gamperl AK, and Cech JJ Jr. (2000) Cardiorespiratory responses of white sturgeon to environmental hypercapnia. *American Journal of Physiology* 279: R617–628.

dioxide levels are increasing from preindustrial levels of around 280 to 370 ppm today. This increase may not in itself be sufficient to affect adult fish, but in combination with other factors such as increased temperature, it could be critical additive stressor. Perhaps more immediately relevant in the fish world is the advent of closed, intense fish aquaculture, which injects oxygen (not air) into the water. Under these situations, carbon dioxide levels in water can easily exceed 10 times normal. Information about the effects of hypercapnia on GBF is scarce. In white sturgeon (*Acipenser transmontanus*) exposed to severe hypercapnia, representative of that seen in an aquaculture setting, CMA blood flow was maintained while overall systemic vascular resistance was lowered and *Q* increased (see **Figure 9**). However, the fish were easily agitated and the decreases in GBF associated with erratic active were deeper and much longer lasting.

Temperature

Little is known about the effects of temperature on the GBF in fish (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature). Studies have indicated that some fish species change their temperature preference after feeding, possibly as a means to increase the efficacy of the GI tract in digesting and absorbing the meal and perhaps also to directly affect GBF. For example, under certain conditions the Bear lake sculpin (*Cottus extensus*), a daytime benthic feeder, migrated into shallower, 10 °C warmer water at night. The consquence of this was a tripled growth rate. In contrast to this, sockeye salmon (*Oncorhynchus nerka*) surface at dusk and dawn to feed, and in between migrate to colder deeper water to minimize routine metabolic rate while digesting their meal and thereby maximizing growth rate.

An interesting observation using free swimming sturgeon equipped with a dual channel blood flow telemetric system showed that GBF did not vary with temperature in fasted animals, while in fed animals there was a strong positive correlation between GBF and temperature. If the temperature increased too much, a typical stress response was triggered, with GBF decreasing presumably to maintain oxygen delivery to other more oxygen-sensitive, priority organs (see **Figure 10**).

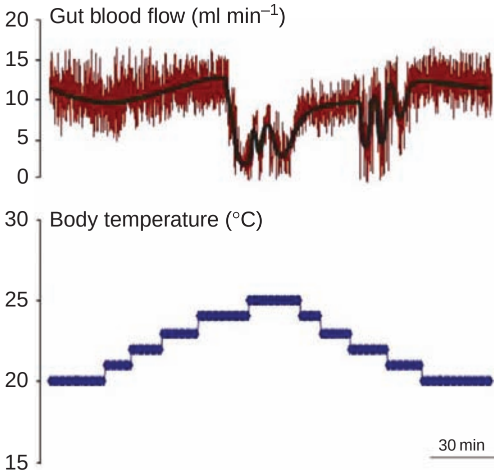

Figure 10 GBF (upper trace, phasic signal in red and average in black) and body temperature (lower panel) in a green sturgeon (*Acipenser medirostris*). The animal was equipped with a dual channel blood flow telemetric system that also records temperature. Temperature was stepwise increased from 20 °C. GBF slowly increases as the temperature increases but is then abruptly decreased, presumably when the temperature passes a critical level and prioritizations have to be made in order to supply the body with enough oxygen.

How preferred temperature changes during infections (exogenous fever) and environmental hypoxia might affect GBF is unknown. A change in preferred temperature during an infection could affect GBF indirectly through a change in temperature, as well as directly through the immune system and the inflammatory processes that follow. The changes in preferred temperature during hypoxia could also affect GBF directly via a stress response or indirectly via a temperature effect, but again this is unknown.

Concluding Remarks

While the above discussion of external stimuli is very interesting, few studies have addressed the question of how the combination of one or more external stimuli will affect GBF. Without GBF, or with a reduced GBF, digestion will cease or slow down, leading to a suboptimal growth and potentially a reduced fitness. In reality, many effects occur simultaneously in the environment, although they were considered separately above. For example, ocean acidification, resulting from elevated atmospheric carbon dioxide levels, is tightly linked to a simultaneous increase in atmospheric and water temperature. Separately, a change in one may not be of sufficient magnitude to be detrimental to fish, but together they can reduce a fish's fitness. Another example is feeding where many species actively search for food and might explore both hypoxic water and different temperatures in combination with the increased demands on the system due to the foraging (exercise) as part of this natural search for food. How these combinations affect the GBF and the capacity of processing food remain largely unknown.

Glossary

Angiogenesis The process by which an existing microvascular bed expands by growth of new capillaries (the smallest blood vessels) from preexisting vessels.

Anisotropic A capillary bed that is orientated along the axis of the muscle fibers it supplies, without significant meandering.

Arteriogenesis The growth of resistance vessels, vessels that are capable of dynamic adjustments in diameter by way of their contractile smooth muscle layer and innervation. Arteriogenesis usually involves remodeling of the smaller arterioles.

Capillary-to-fiber ratio (*C*:*F*) A commonly used index of the extent of capillarization. It is calculated by dividing the number of capillaries in a field by the number of fibers in the same field. It is not to be confused with either CAF or SF.

Capillaries around a fiber (CAF) The mean number of capillaries surrounding individual fibers.

Capillary density (CD) An index of the functional capacity of the exchange vessels, usually expressed as the number of capillaries per unit area of muscle fibers. It is also often expressed as capillaries per unit area of tissue section, which would also include interstitial tissue, in this case making the meaning of CD less clear.

Capillary length density, J_V(c,f) The length of capillaries per unit volume of muscle. This is calculated by multiplying CD by an estimate of capillary tortuosity.

Capillary surface density, S_V(c,f) An index of the surface area available for respiratory gas, substrate, and metabolite exchange within muscle. It is calculated by multiplying the perimeter of the capillary, *b*(c), by J_V(c,f).

Capillary volume density, V_V(c,f) The instantaneous blood volume within the microcirculation calculated by multiplying capillary cross-sectional area, *a*(c), by $J_V(c,f)$.

Isotropic A capillary bed that runs over the muscle fibers it supplies at varying angles, showing a meandering pattern when viewed in longitudinal sections.

Krogh's radius (*R*) The maximum distance from a capillary that may be adequately supplied by oxygen diffusion, based on hypothetical tissue cylinders. *R* is calculated from the capillary length density as $1/[\pi \cdot J_V(\mathrm{c,f})]^{1/2}$.

Maximum hypothetical diffusion distance (*D*) The maximum distance from a capillary that can be adequately supplied by oxygen diffusion, but without the restrictive and unrepresentative uniform geometry of Krogh's model. Calculated as $\sqrt{[1/\{N(f)a(f)\}/\{\pi N(c)\}]}$, where *N*(f) and *N*(c) are number of fibers or capillaries in the sample area, and *a*(f) is the mean fiber cross-sectional area.

Microvascular unit (MVU) The anatomically connected supply arteriole, exchange capillaries, and drainage venule. These are often longitudinally staggered and/or adjacent MVUs interdigitate in order to even out oxygen tension across a tissue.

Sharing factor (SF) The number of fibers each individual capillary is in contact with.

Stereology An application of geometrical probability theory that permits extrapolation of structural information from *n* to *n*+1 dimensions (e.g., length to surface and area to volume). For example, a systematic random sampling regime is used to quantify muscle fine structure from electron micrographs as volume density (V_V, $\mu m^3 \cdot \mu m^{-3}$), surface density (S_V, $\mu m^2 \cdot \mu m^{-3}$), or numerical density (N_A, μm^{-2}).

Symmorphosis The hypothesis that, in biological organisms, structural design is matched to functional demand.

Vasculogenesis The *de novo* generation of blood vessels from mesenchymal stem cells during embryogenesis.

Introduction

This article is about the anatomical design and plasticity of the microvascular (capillary) supply of tissues, whose primary task is to deliver sufficient oxygen and substrates, and remove waste products. The cardiovascular system has been described in detail elsewhere (**see also Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns; **Circulation**: Circulatory System Design: Roles and Principles). Briefly, in fish, it consists of a single-pass circulation that is powered by the heart, a muscular pump of varying complexity. In some cases, the heart requires its own microvascular supply, the coronary microvasculature, to generate adequate power to sequentially perfuse the branchial gas-exchange system followed by the systemic circulation (**see also Design and Physiology of the Heart**: The Coronary Circulation and Cardiac Anatomy in Fishes). The branchial microvasculature is explained in detail in other articles (**see also Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns and **Design and Physiology of Arteries and Veins**: Branchial Anatomy). Therefore, the focus here is on the microvasculature of the skeletal muscle, which comprises up to 80% of the body mass of a fish.

When compared with other vertebrates, oxygenated blood is delivered into the systemic circulation of fishes at relatively low blood pressure, thereby limiting the potential for convective oxygen delivery to peripheral organs. Thus, metabolic error signals, brought about by insufficient substrate delivery or excessive cellular demand, require both anatomical adaptations and physiological responses that improve substrate delivery. The usual vertebrate methods of controlling peripheral arterial resistance and hence tissue-perfusion patterns exist in fishes (sympathetic innervation to constrict pre-capillary vessels, and nitric oxide (NO) and prostaglandin (PG) release to dilate resistance vessels; (**see also Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System and **Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). Some peculiar vascular arrangements exist, such as a primitive hypobranchial system that provides a dual arterial supply to the locomotory pectoral muscles in some Antarctic teleosts, and is particularly evident in the hemoglobinless icefish (*Chaenichthyidae*). A double supply presumably maximizes delivery of oxygen by perfusion. Overall, vascular adaptations are consistent with improving delivery of blood-borne substances (**Figure 1**).

Capillary Structure

Capillaries are thin tubes that are 4–10 μm in diameter and 500–100 μm in length. They consist of a monolayer of endothelial cells and represent the blood/tissue interface of the circulatory system. Capillary fine structure is closely related to its primary function, diffusive exchange of gases and metabolites, which demands a minimal barrier thickness and a large surface area to facilitate the process of passive diffusion. At the same time, adequate integrity is needed to accommodate the transmural stress of blood perfusion pressure.

At the start of the microvascular unit (MVU), where supply arteries divide into many pre-capillary arterioles, there is a massive increase in total cross-sectional area of blood vessels. As cross-sectional area increases, the velocity of blood flow within the MVU is reduced. This increases the time taken for an erythrocyte to pass through a capillary. The resultant increase in erythrocyte contact time with the capillary endothelial barrier therefore aids oxygen diffusion.

In general, fish have similar capillary dimensions as those of mammals but they have larger blood cells (**see also Blood**: Cellular Composition of the Blood) and a lower body temperature. Even so, the lower deformability of the colder fish erythrocytes does not appear to limit capillary perfusion. Probably more is known about fish capillaries from retia (choroidal, swimbladder, and internalized red muscle), but these are unusual: 4 mm long with endothelial cells up to 4 μm thick, compared with those in skeletal muscle of

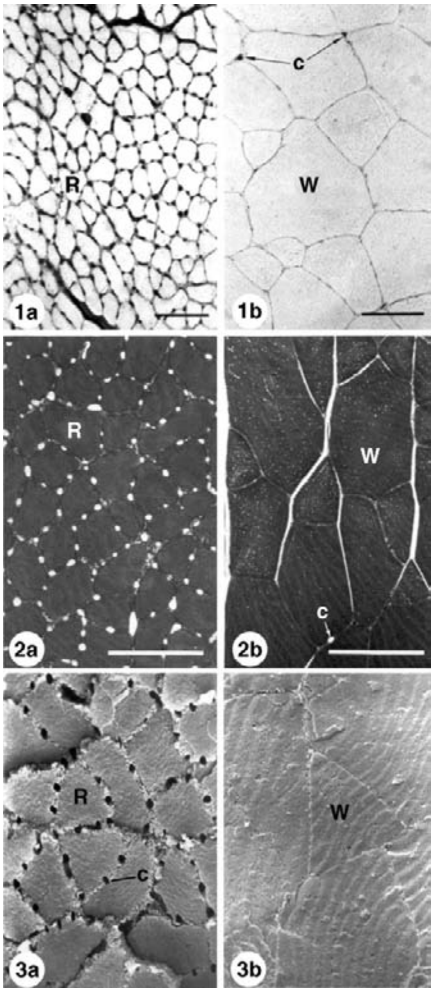

Figure 1 Differences in density of red (R) and white (W) muscle capillary supply in flathead, *Platycepgalus bassensis.* (1) Indian ink-gelatin perfusion followed by cryostat sectioning of frozen tissue (10–12 μm sections, scale bar 100 μm). (2) Fixed muscle, resin embedded (1μm sections, scale bar 100 μm). (3) Scanning electron micrographs of freeze-fractured myotomal muscle (×1400–1500). Note the higher capillary density (c) in red compared to white muscle, and reasonable agreement between estimates of capillary supply derived from the different preparation methods in terms of number per fiber, but not number per fiber area due to tissue shrinkage. Composite of images from Mosse PRL (1978) The distribution of capillaries in the somatic musculature of two vertebrate types with particular reference to teleost fish. *Cell and Tissue Research* 187: 281–303.

0.5–1 mm and 0.2–1 μm, respectively (**see also Design and Physiology of Arteries and Veins**: The Retia).

There are only minor differences apparent between fishes and mammals with regard to their basic capillary structure in the skeletal muscle, with the exception of icefish (**Figure 2**). An obvious difference given the higher blood pressure is a thicker endothelium in mammals. However, owing to the low systemic blood pressure, inter-endothelial junctions are likely to be less tight than in the skeletal muscle of other vertebrates, perhaps contributing to the reported higher capillary permeability in fish (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange).

Unlike mammalian muscle, where intermittent perfusion as a result of periodic vasomotion leads to the appearance of collapsed vessels on fixing by immersion, fish muscle capillaries always appear open. This suggests two potential anatomical differences: fish blood vessels may not recoil significantly in the absence of perfusion pressure, which would mean that adventitial filaments join with connective tissue to prevent collapse (as seen with mammalian lymphatic vessels and in the elasmobranch intestine, kidney, and pancreas, as radial strands from the basal lamina surrounding capillaries). Alternatively, there may be continuous blood perfusion of fish capillaries. Observations by intravital microscopy of superficial red muscle in anesthetized fish suggest that the latter is more likely.

Skeletal muscle capillaries are composed of continuous endothelium, but other organ systems have fenestrated capillaries, with or without diaphragms, as befit their function, be it cellular or macromolecular traffic. A tight endothelial blood–brain barrier (BBB) in teleosts appears to be analogous to that in other vertebrates, although elasmobranchs have a glial BBB.

Capillary Function

In mammals, the capillary hydrostatic pressure (developed by the heart and regulated by resistance arterioles) that drives filtration of small molecular weight solutes is opposed by the oncotic pressure of the blood, favoring reabsorption (Starling's forces). It is this balance that regulates fluid exchange. In fishes, the functional consequences of a low blood pressure across the capillary wall would be to reduce any such regulation. However, the capillary wall in fish is unusually permeable to macromolecules and proteins, and 5 times more than mammalian capillaries (filtration coefficient of 5 ml mmHg^{-1}), which therefore allows solute exchange, but at the cost of a reduced oncotic pressure difference (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange). For example, plasma hydrostatic pressure decreasing from ~13 to 3 mmHg along a capillary, with a capillary oncotic pressure of ~8 mmHg, would result in no net fluid movement without a degree of selective permeability and/or effective lymph-like drainage. The consequence is that interstitial fluid has a high protein concentration, but the ease of fluid exchange allows large changes in plasma volume to be tolerated, for example, the half-time of transcapillary fluid exchange is

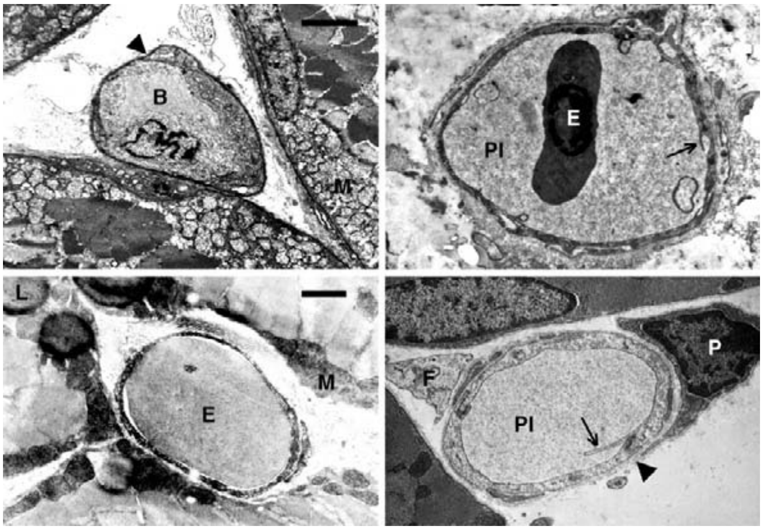

Figure 2 Electronmicrographs of skeletal muscle capillaries from blackfin icefish *Chaenocephalus aceratus* (top left, scale bar = 10 μm), rainbow trout *Oncorhynchus mykiss* (bottom left, scale bar = 5 μm), striped bass *Morone saxatilis* (top right), and rat hindlimb (bottom right) illustrating the similar fine structure, but contrasting endothelial cell thickness and cross-sectional area. From Egginton S (1990) Morphometric analysis of tissue capillary supply. In: Boutilier RG (ed.) *Vertebrate Gas Exchange from Environment to Cell*, Advances in Comparative and Environmental Physiology, vol. 6, pp. 73–141. Berlin: Springer; Egginton S and Rankin JC (1998) Vascular adaptations for a low pressure/high flow blood supply to locomotory muscles of icefish. In: Di Prisco G, Clarke A, and Pisano E (eds.) *Fishes of Antarctica: A Biological Overview*, pp. 185–195. Berlin: Springer; and Egginton S, Cardirer S, Skilbeck C (2000) Thermal compensation of peripheral oxygen transport in skeletal muscle of seasonally acclimatized front. *American Journal of Physiology* 279: 375–388.

approximately 15 min, allowing rapid replacement of plasma volume following hemorrhage.

In contrast, branchial-exchange capillaries, which are exposed to relatively greater pressure, and the BBB, which is within a rigid container, correspondingly have reduced permeability (reflection coefficient for proteins is close to 1), thus avoiding the deleterious consequences of edema in these tissues.

Oxygen flux is influenced by different capacities of the compartments that regulate the oxygen cascade between the environment and mitochondria – where oxygen is utilized. Tissue capillary density (CD) will largely determine the rate at which oxygen will diffuse from erythrocytes to mitochondria, and the clearance rate of metabolites, by setting the anatomical diffusion distance in red muscle. This is because the rate of diffusion is inversely proportional to the square of the distance traveled, and CD is a primary determinant of diffusion distance.

In red muscle, the maximal hypothetical diffusion distance (*D*) varies between 7.1 μm in Crucian carp (*Carassius carassius*), 15.5 μm in yellow eels (*Anguilla rostrata*), and 25.7 μm, 47.5 μm, and 52.0 μm for sharks (*Galeus*, *Etmopterus*, and *Chimaera*, respectively; **Table 1**). Krogh's radius (*R*) is 13.3 μm for rainbow trout and 12.9 μm for striped bass under cold conditions. The large variability in values of *D* and *R* among species may in part reflect differences in tissue preparation prior to measurements, true interspecific differences in fiber radii, the lifestyle of the fish, and/or oxidative capacity of the muscle. Note that the *in vivo* (physiological) diffusion distances may differ from the measured anatomical diffusion distance with variation in perfusion pressure or intramuscular convection, but *D* or *R* permit reasonable and practicable estimations of diffusive capacity (**Figure 3**).

The efficacy of diffusive exchange may be improved in the more tortuous red muscle capillaries (**Figure 4**) compared to the largely straight vessels in white muscle. Increased capillary tortuosity (reduced anisotropy) within the same muscle length allows for a greater capillary length per muscle. This increases the capillary surface area for diffusion and the capillary transit time for an erythrocyte. Sluggish fish have the most anisotropic capillary bed recorded in aerobic muscle (**Table 2**). The extent of tortuosity may be further developed where there is increased potential for a metabolic error signal – either with reduced blood-oxygen-carrying capacity (e.g., icefish, **Figure 5**) or with increased oxygen consumption, MO_2 (e.g., tuna; **see Pelagic Fishes**: Physiology of Tuna). Other principles are exemplified by studies of skeletal muscle, cardiac muscle, and skin.

Cardiac hypertrophy in male rainbow trout is accompanied by angiogenesis: from a $\mathcal{J}_v$(c,f) of 1620 mm^{-2} in immature fish, an increase in myocyte girth initially reduces this to 1103 mm^{-2}, but then eventually recovers to 1457 mm^{-2}, thus ensuring that the intramuscular

Table 1 Symbols along with their definitions used in the text

Symbol	*Definition*
a	Mean area of object
a(c)	Capillary cross-sectional area
a(f)	Mean fiber cross-sectional area
A	Reference or total area
b(c)	Perimeter of the capillary
c	Capillary
C:F	Numerical capillary to fiber ratio: in stereological notation, N_N(c,f)
CAF	Numerical of capillaries around a fiber: in stereological notation, *N*(c,f)
CD	Numerical capillary density: in stereological notation, N_A(c,f)
D	Maximum hypothetical diffusion distance
f	Muscle fiber
J_v(c,f)	Capillary length density
MO_2	Oxygen consumption
N	Number of object
N_A	Numerical density – number of objects per unit area of reference
N(c)	Number of capillaries in the sample area
N(f)	Number of fibres in the sample area
PO_2	Partial pressure of oxygen (oxygen tension)
R	Radius of krogh's tissue cylinder
S_v	Surface density – surface area of object per unit volume reference
S_v(c,f)	Capillary surface density

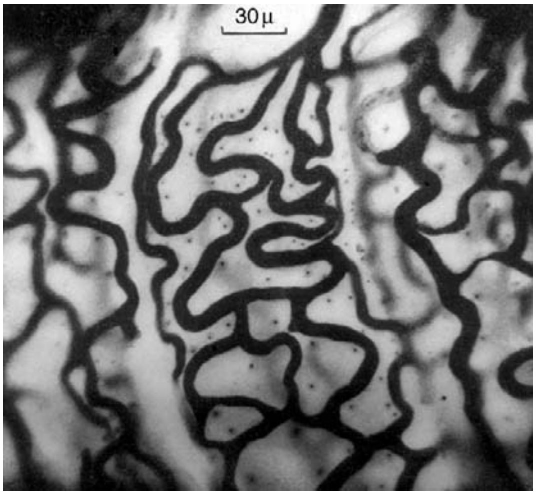

Figure 3 Indian-ink-filled capillary bed in fish red muscle. Note the highly tortuous path for erythrocytes during perfusion, which would increase the transit time compared to straight vessels, and hence maximize diffusive exchange. Scale bar = 30 µm. From Barets A (1961) Contribution a l'étude des systèmes moteurs "lent" et "rapide" du muscle lateral des Teléosténs. *Archives d'Anatomie Microscopique et de Morphologie Expérimentale* 50: 91–187.

diffusion distance remains low enough to maintain adequate oxygenation. Within the compact myocardium of trout sampled at different seasonal temperatures, CD = 1371, 1194, and 2178 mm^{-2} at 4, 11, and 18 °C, respectively. As there is no seasonal variation in myocyte diameter, ventricular CD parallels heart rate and hence is highest at 18 °C, suggesting that angiogenesis in fish cardiac muscles is probably stimulated by different mechanical factors when compared with skeletal muscle.

Fish skin microcirculation is extensive, similar to that of amphibians (e.g., 6 m of capillaries per gram per body mass in common carp *Cyprinus carpio*). The skin may function as an additional respiration site, as with amphibians, which is certainly the case in larval fishes before the gill secondary lamellae are fully developed (**see also Ventilation and Animal Respiration**: Respiratory Gas Exchange During Development: Models and Mechanisms). Capillaries are found at varying depths within the dermis of different species, but those between the scales and the epidermis may account for up to 30% of oxygen uptake in adults of some fishes. This may have been important in the evolution of air breathing – indeed, aerial exposure of eels leads to hyperaemia (accumulation of blood) of the dorsal fin, although a large proportion of the uptake capacity may be required to support skin metabolism itself.

Vascular Origins

Vasculogenesis occurs in the developing embryo independent of the heart and aorta. The macro- and microvasculature join to form a functional circuit around the time when cutaneous oxygen exchange becomes limiting. The timing of capillary appearance follows the rostral–caudal developmental axis, and, in myotomes, occurs after segmental artery perfusion is evident. It is likely that the intersegmental vessels arise as sprouts from the dorsal aorta, and the arteriogenesis and angiogenesis that originates from these larger vessels is initiated to

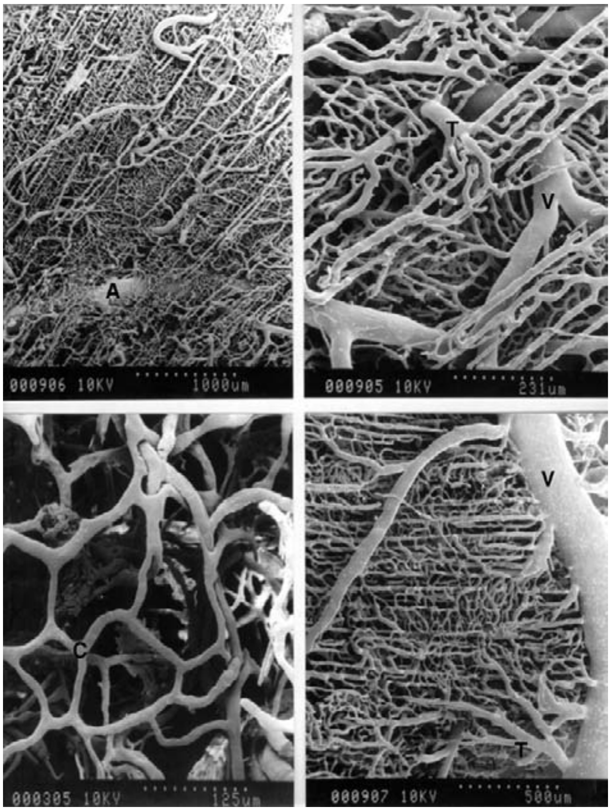

Figure 4 Scanning electronmicrographs of vascular casts from icefish (*Chionodraco hamatus*) pectoral muscle. (Top-left) Feed arteriole (A) lying under a mat of capillaries, some of which branch direct from the parent vessel. (Top-right) The capillary bed covers muscle fibers in an evenly spaced network, orientated with the long axis. (Bottom-left) Loops formed by convergence and divergence of capillaries (C) provide maximal coverage of the fiber surface for diffusive exchange. (Bottom-right) Large drainage venules (V) have joining capillaries as well as terminal venules (T). Muscle fiber axis lies in the horizontal direction. T, terminal arteriole; C, capillary; V, collecting venule. From Egginton S and Rankin JC (1998) Vascular adaptations for a low pressure/high flow blood supply to locomotory muscles of icefish. In: di Prisco G, Clarke A, and Pisano E (eds.) *Fishes of Antarctica: A Biological Overview*, pp. 185–195. Berlin: Springer.

supply muscle with increasing oxygen demand and distance from large vessels or the skin during development. The molecular basis of arteriogenesis becomes clearer from the study of zebrafish embryos, but most of the signals controlling other vascular growth processes tend to be inferred from the dominant mammalian literature. There are few reliable cytochemical markers of capillary endothelium in fishes; so, many studies have utilized resin sections of glutaraldehyde-fixed material (which introduces an unavoidable ~30% shrinkage of tissue). This is a time-consuming method, in part explaining the sparse literature, but it does allow unambiguous identification compared with expression of markers that may vary with developmental age or physiological condition. Morphometric data quantify the structural capillary supply, which correlates with functional capacities, such as potential maximum rates of oxygen delivery and metabolite removal, but says little about the efficiency of exchange at sub-maximal rates. These issues are discussed in detail elsewhere.

Angiogenesis

The signals leading to capillary growth may vary in time and space, may be systemic or local, and may be species specific. Seasonal changes in hormonal status, for example thyroid or growth hormones, likely help match changes in activity with organ function, the responses being moderated or limited by local receptor density. An obvious feedback loop is to induce angiogenesis in response to either increased metabolic demand or reduced oxygen delivery. Both of these triggers likely signal via either local metabolites, for example, adenosine, or transcriptional responses, for example, mediated by hypoxia inducible factor (HIF). Given the generally low $\dot{M}_{O_2}$ for all but tropical species and higher solubility of oxygen in cold water and body fluids, angiogenesis in response to reduced oxygen delivery may be less important in fishes than in endotherms.

The angiogenic response to hypoxia (inadequate oxygen supply to tissues) varies among species, inducing a dramatic angiogenesis in the tench *Tinca tinca* (C:F = 0.9 vs.1.5), a modest response in channel catfish *Ictalurus punctatus* (1.4 vs.1.9), but a slight reduction in microvascular supply in Crucian carp *Carassius carassius* (1.9 vs.1.5).

The angiogenic response may also be initiated either directly or indirectly by local mechanical forces on the endothelium. This is most clearly seen in the skeletal muscle, in response to seasonal cold acclimation. The first prize goes to the Crucian carp, which doubles C:F from 2.2 to an exceptional 4.8 on acclimation from 28 to 2 °C. This growth in capillaries may be a result of the increased frictional forces on the endothelium due to the higher blood viscosity at low temperatures (resulting in elevated shear stress on the luminal face of the endothelium, a known trigger for angiogenesis), and increased rigidity of the nucleated (and therefore large) erythrocytes. In addition, the growth and therefore stretch of muscle fibers (hypertrophy) seen in cold-acclimated fishes imposes a mechanical strain on the abluminal side of the endothelium. Similarly, stretch-induced angiogenesis may govern expansion of the capillary bed during ontogenetic growth (**Figure 5**).

In mammalian skeletal muscle, ontogenetic growth primarily involves fiber hypertrophy, where the increased girth of muscle cells pushes existing capillaries apart, disturbing the normally quiescent endothelium. This stimulates angiogenesis, possibly via mechanotransduction of the lateral strain at vessel

Table 2 Stereological analysis of capillary tortuosity in fish red muscle[a]

Conger eel (*Conger conger*)	–	1.02 (10 °C)	
Rainbow trout (*Oncorhynchus mykiss*)	1.06@4 °C	1.04@11 °C	1.07@18 °C
Skipjack tuna (*Katsuwonus pelamis*)		1.44 (25 °C)	
Nototheniids (*N. coriiceps, G. gibberifrons*)	1.11 (<0 °C)		–
Channichthyids (*C. aceratus, C. rastropinosus*)	1.44 (<0 °C)		–

[a] Random (isotropic distribution) capillary orientation would have a value of 2, orientation along the muscle fiber axis (anisotropic distribution) would have a value of 1

Note that tortuosity is independent of temperature, but increases with the potential metabolic error signal due to either high demand (tuna > trout > eel) or low supply (Channichthyids < Nototheniids).

From Egginton S and Johnson IS (1983) An estimate of capillary anisotropy and determination of surface and volume densities of capillaries in skeletal muscles of the conger eel (*Conger conger* L.). *Quarterly Journal of Experimental Physiology* 68: 603–617; Egginton S, Cardiner S, and Skilbeck C (2000) Thermal compensation of peripheral oxygen transport in skeletal muscle of seasonally acclimatized front. *American Journal of Physiology* 279: 375–388; Mathieu-Costello O (1993) Comparative aspects of muscle capillary supply. *Annual Review of Physiology* 55: 503–525; and O'Brien KM, Skilbeck C, Sidell BD, and Egginton S (2003) Muscle fine structure may maintain the function of oxidative fibres in haemoglobinless Antartic fishes. *Journal of Experimental Biology* 206: 411–421.

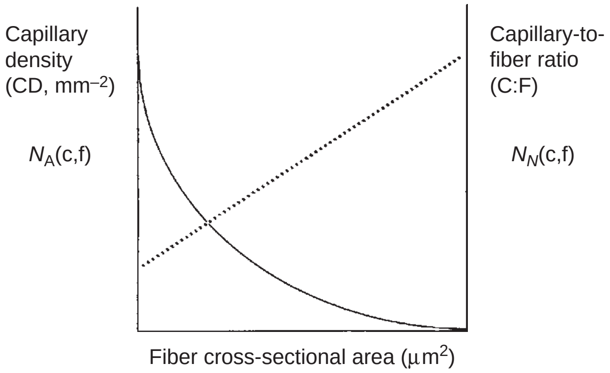

Figure 5 Scaling of capillary supply to skeletal or cardiac muscle during ontogenetic growth, or adaptive remodeling. An angiogenic signal is generated as muscle fibers undergo hypertrophy, leading to an increase in C:F. However, the rate of fiber growth exceeds that of capillary growth, hence CD falls. This may eventually limit muscle activity if other adaptive mechanisms (e.g., altered blood flow or remodeling of the intracellular compartment) become ineffective, leading either to enhanced angiogenesis or impaired physiological performance. From Egginton S (2002) Temperature and angiogenesis: The possible role of mechanical factors in capillary growth. *Comparative Biochemistry and Physiology – Part A* 132: 773–787.

bifurcations. CD decreases exponentially during normal development as capillary growth occurs more slowly than fiber growth, while C:F increases in an approximately linear manner. Consequently, the major determinant of capillary oxygen supply during mammalian development appears to be the mean fiber cross-sectional area, although this relationship may be modified by other angiogenic stimuli.

In contrast, postnatal muscle growth in fishes involves both hyperplasia (growth of new fibers) and hypertrophy (increase in size of existing fibers). Fast-growing, small species rely more on hyperplasia and hypertrophy than slow-growing larger species, which largely rely on hypertrophy. Among fish species, a decrease in CD and an increase in C:F with increasing fiber size is only seen in red muscle, and then only over a relatively small size range (**Figure 6**). Above a mean fiber area of around 1000 μm^2, capillarization appears to be independent of the fiber size. This indicates that mechanisms other than angiogenesis become important at this point, possibly involving reorganization of pathways for intracellular diffusion (e.g., intracellular lipid increases and mitochondrial ribbons are seen). As fiber size varies with body mass, increasing C:F and decreasing CD are seen during ontogenetic growth, irrespective of activity levels.

Matching Angiogenesis and Microvascular Function

It is normally assumed that the role of the microcirculation is primarily one of oxygen delivery, as formalized in the concept of symmorphosis. While this underestimates other roles such as metabolite redistribution, including heat in the case of tunas (**see also Pelagic Fishes**: Physiology of Tuna), it has led to the widely held belief that oxygen supply corresponds with demand, for example, by matching muscle capillarity and mitochondrial content. In mammals, there is indeed a positive correlation between CD (supply) and mitochondrial density (demand). While selective reading of the literature on fishes would support this view, there are sufficient exceptions to demand a reappraisal (**Figure 7**). In addition to scaling of intramuscular diffusion distances, intracellular diffusion distance also exhibits plasticity, revealing a sensitive feedback control that may adjust different parts of the oxygen cascade according to specific demands (**Figure 8**).

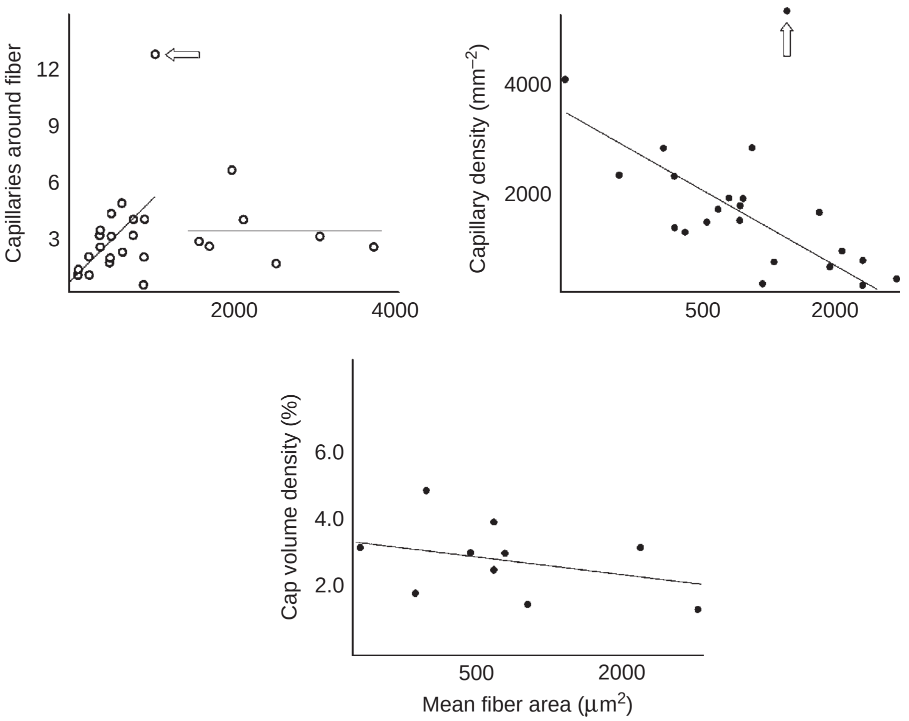

Figure 6 Apparent scaling of capillary supply in red muscle among different fish species (data from various studies using a variety of methods). The number of capillaries adjacent to a fiber increases until a maximum around 1000 μm^2, after which it plateaus and may even decline in species with extremely large fibers (regressions shown with exclusion of data from anchovy, arrow, which is clearly an outlier due to unusual fiber anatomy). By contrast, capillary density decreases with fiber size (top right). Scaling of vessel size, however, results in a relatively invariant capillary volume density (bottom panel). This suggests a tight feedback control of the microcirculation to regulated perfusion capacity while other changes, for example, changes in capillary tortuosity, may regulate diffusion capacity.

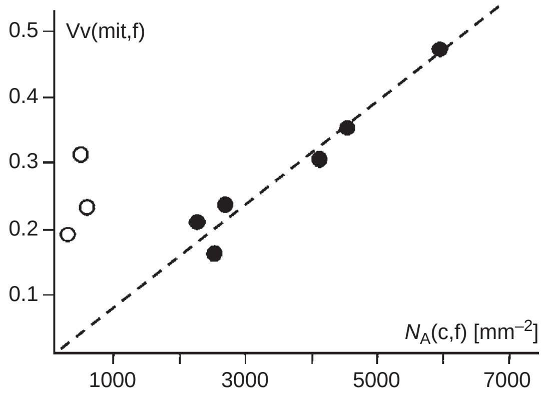

Figure 7 The assumption that oxygen supply and demand must covary, a relationship influential in developing the concept of symmorphosis appears to hold across a range of temperate teleost species (closed circles). However, this may be affected by other considerations, for example, large fiber size and low temperatures associated with sluggish and Antarctic species (open circles).

Skeletal Muscle Capillarity

By far the greatest information exists about the capillarity of skeletal muscle, with a few examples of myocardial capillary supply. These data help to identify the adaptive capacity of muscle and the potential signals involved. Skeletal muscle in the fish trunk is divided into anatomically discrete (red and white), functionally separate (slow and fast), and metabolically distinct (oxidative and glycolytic) regions. The superficial aerobic muscle is highly vascular to sustain low-speed swimming, while the deep anaerobic muscle is reversed for burst activity that requires only a sparse capillary bed. The composition of the fiber types reflects their functions, where red muscle can have a 30-fold greater mitochondrial content and a much higher microvascular supply than white muscle. For example, the capillaries around a fiber (CAF) in the red, pink, and white muscle of the starry sturgeon (*Acipenser stellatus*) are 2.3, 0.9, and 0.2, respectively. The European anchovy *Engraulis encrasicolus* is an outlier with very high values of CAF and CD; the unusually shaped (laterally compressed) muscle fibers allow greater packing of vessels.

An MVU in skeletal muscle spans the myotome of fishes, although there is some doubt whether the arterioles/venules access via the myosepta, as originally suggested from ink-filled preparations. This may vary among species, but if it were the case, then it would prevent staggering of MVUs and the resultant O_2 exchange between vessels. To avoid the decrease in O_2 gradient along a capillary bed impairing aerobic activity

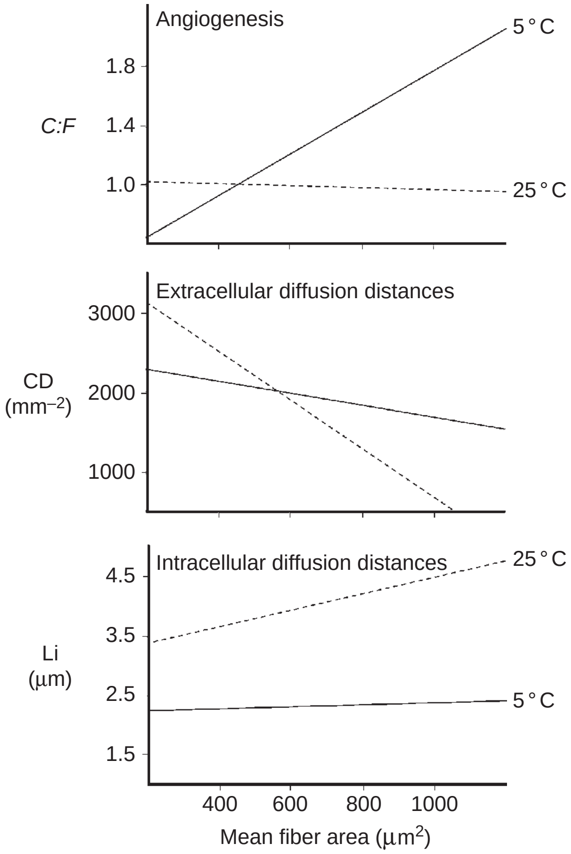

Figure 8 Scaling of intramuscular response (C:F, CD) and intracellular (mitochondrial separation, Li) diffusion distances in red muscle of striped bass acclimated to seasonal extremes of 5 °C and 25 °C. Note that the increase in C:F compensates for decreased O_2 diffusion rate and increased diffusion distance (due to fiber hypertrophy) in the cold to maintain CD, while reduced O_2 flux due to low temperature is compensated by the decrease in Li. The processes identified by the different parameters are indicated for each panel. From Egginton S (1998) Anatomical adaptations for peripheral oxygen transport at high and low temperatures. *South African Journal of Zoology* 33: 119–128.

(contractile activity fueled by oxidative phosphorylation), either fiber mitochondrial content must decrease or muscle CD must increase. The former would seem unlikely along a cell of homogeneous phenotype and, indeed, seems to increase at the myoseptal ends, but there is no quantitative evidence for the latter.

The literature on plasticity of vascular supply to fish muscle is less comprehensive than that for mammals, in part due to the greater diversity of fish species. Skeletal-muscle capillarity changes during ontogenetic growth (as described earlier), during exercise training, and in response to environmental temperature. The similarity with some of these changes described for mammals has generated current interest in identifying whether analogous or homologous angiogenic stimuli are responsible. Although the absolute capillarity is considerably lower in white muscle than in red muscle, the angiogenic potential (i.e., the possibility of increasing capillary supply before reaching the maximum number of capillaries a muscle can accommodate) is relatively greater. For example, striped bass acclimated to 5 °C show an increase of 41% in RM C:F when compared with that at 25 °C, whereas WM increase is 62%; similarly, exercise training of trout produced a 27% increase in CAF for RM but a 95% increase in WM.

However, cross-specific comparisons may have limited value in determining adaptability of the microcirculation because of widely different aerobic capacities and modes of locomotion. For example, the range of RM capillary supply varies from a low in the primitive, deep-water holocephalan ratfish *Hydrolagus colliei* (C:F = 0.3, CD = 118 mm^{-2}) to a high in the fast-swimming European anchovy (CAF = 12.9, CD = 600 mm^{-2}). This means that, in the latter, no myofibril is >8 µm from a capillary, thus permitting a much higher $\dot{M}_{O_2}$ compared with 27.4 µm in dogfish and 47.5 µm in ratfish. Similar caution must be exercised when comparing data using different indices as these may give quite a different interpretation, for example, goldfish RM $N(c,f) = 3.3$ but $N_N(c,f) = 1.1$ at 5 °C.

Due to their myotomal arrangement, the fast muscle (WM) contractions in fish are more isometric than isotonic, which in mammals is not generally seen as a pro-angiogenic stimulus. This may explain the apparently poor training response in this tissue, although the proportional increase may be greater due to much lower initial values. Capillary growth in RM, therefore, may be stimulated by a combination of functional hyperaemia (exercise-induced increase in muscle blood flow), with the more isotonic duty cycle, and the metabolic character of the host tissue. In larval fish, training effects only become evident after the motor program has become fully activated, showing a differential effect between cardiac and skeletal muscle, though whether the usual vertebrate pattern of decreased responsiveness with age also applies to fish has not been investigated. However, the most studied plasticity has been the response to altered temperature.

Thermal Environment

Despite profound effects of temperature on biochemical reaction rates (acute Q_{10} *c.* 2–3) different fish species have successfully colonized niches ranging from <−1.8 °C in Polar seas to >40 °C in East African hot springs. Thus, over evolutionary time, speciation has resulted in fishes with widely different thermal tolerances, within the biological temperature range (freezing point of water to the temperature for protein denaturation), that do not overlap. Cardiac output increases upon maximal sustainable exercise at all temperatures for most fish, with the greatest increase in cardiac performance occurring at the temperature that coincides with the maximum sustainable swimming speed. These, and other data involving, for example, postprandial redistribution of blood flow (**see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation), suggest that central cardiovascular scope may be a major limiting factor in performance (**see also Circulation**: Circulatory System Design: Roles and Principles). However, diffusion of metabolites and respiratory gases within tissue and cells, which has received little attention since the studies of August Krogh, is also a potentially limiting factor for muscle performance. This would involve adaptive remodeling of muscle fine structure, or the microvascular supply.

Cold Acclimation

In general, fiber size varies inversely with environmental temperature in fishes. This is true both within individuals in response to short-term or seasonal cold-temperature acclimatization (**Figure 9**) and among species inhabiting different latitudes. However, the species ecotype and/or oxidative capacity may modulate this basic relationship, for example, oxidative fibers of the hemoglobinless icefishes are larger than those of congeneric red-blooded nototheniids. Fiber diameter affects the distance oxygen must diffuse to the fiber center and, as mitochondria are found in that location, we must assume that oxygen diffusion is adequate. There are various competing influences on the oxygen-transport cascade, including diffusion distance (influenced by fiber size), diffusivity of oxygen (influenced by cellular composition and temperature), oxygen demand (set by mitochondrial content), and PO_2 gradient (determined by the capillarity). The integrative response may be explored by means of mathematical modeling, which has so far only been done for low temperature, suggesting that angiogenesis is the most effective way of avoiding peripheral limitations in oxygen transport to tissue. The influence of different transit times and capillary tortuosity is unexplored.

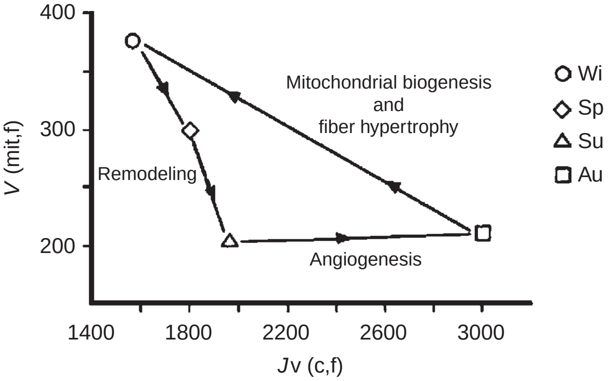

Figure 9 The changing relationship between muscle oxygen delivery (capillary length density) and fiber oxygen consumption (mitochondrial volume) in red muscle of rainbow trout during acclimatization to seasonal differences in environmental temperature. The interspecific relationship obtained from other published values is shown as the linear regression line, suggesting that in winter, trout may be under-supplied and in summer/autumn over-supplied with capillaries. *V*(mit,f), fiber mitochondrial volume; J_V(c,f), capillary length density; Wi, winter; Sp, spring; Su, summer; Au, autumn. Modified from Egginton S, Cardiner S, and Skilbeck C (2000) Thermal compensation of peripheral oxygen transport in skeletal muscle to seasonally acclimatized front. *American Journal of Physiology* 279: 375–388.

Cold Adaptation

Capillary length density, J_V(c,f), is probably the best numerical descriptor of the exchange capacity for oxygen and metabolites between capillaries and muscle. There is an apparent mismatch in supply and demand among Antarctic fishes, lower J_V(c,f) but higher V_V(mit,f) are found in the oxidative pectoral (locomotory) muscles of hemoglobinless icefishes compared to congeneric red-blooded nototheniids, although $\dot{M}_{O_2}$ may be similar. The microcirculation plays a major role in maintaining aerobic-based activity. In addition to changes in surface area due to higher tortuosity, capillary diameter is also adaptive. In red-blooded Antarctic species the total peripheral resistance (TPR) is similar to those of temperate species, but in the icefishes it is only $\sim$20% of the norm. Although much control over tissue perfusion exists at the arteriolar level, and altered blood viscosity influences TPR, given that vessel resistance is proportional to $1/(\text{radius})^4$, capillary diameter also plays a role. It can be calculated that in order to maintain intracellular PO_2, species lacking facilitated diffusion require a 50% greater capillary diameter, or proportionally higher CD.

Changes in muscle fine structure may help compensate for low capillarity and help maintain adequate oxygen diffusion to mitochondria. Striped bass acclimated to low temperatures (5 °C) have a lower capillary:cristae surface area ratio compared to species at 25 °C, while oxygen flux may be maintained in the cold by an increase in intracellular lipid droplets where oxygen is more soluble than it is in aqueous cytoplasm. Although of limited value in most Antarctic species, intracellular lipid may be an important storage site for oxygen and/or act as a low-resistance pathway for oxygen diffusion, for example, the diffusion coefficient for oxygen increases in cold-acclimated striped bass in line with increased lipid content. Given the various possibilities, it is of no surprise that different species adopt differing strategies to overcome the potential limitations of life in the cold (**Figure 10**). The challenge remains to undertake a cost–benefit analysis to identify the relative efficiency of these strategies.

Concluding Remarks

Although specific information and mechanistic explanations in fish lag behind that in other groups, it is clear that there are many similarities but also some distinctive differences between the anatomy and physiology of the microcirculation in fishes and mammals. In part due to

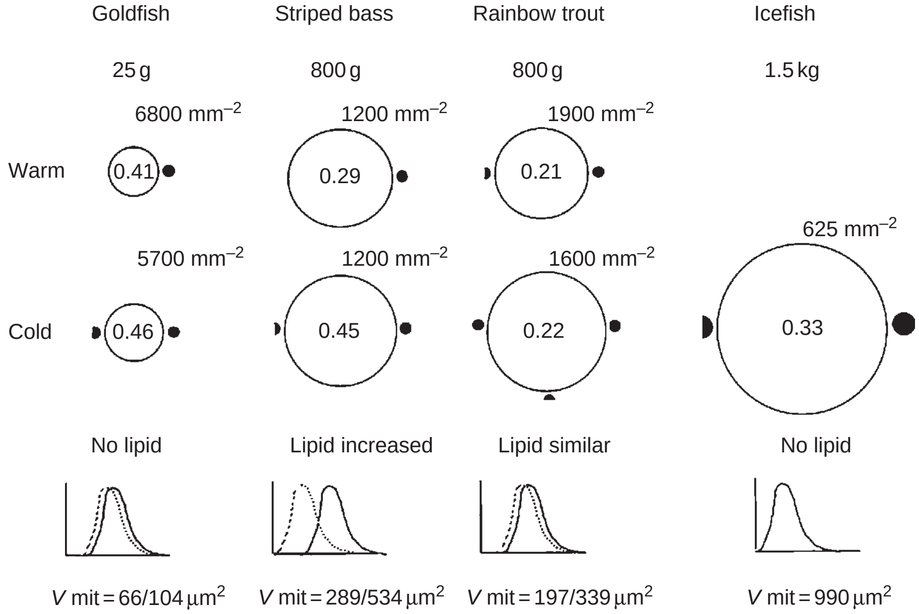

Figure 10 Schematic representation of the varied anatomical adaptations among species (body mass, given under species name) to maintain adequate peripheral oxygen transport at high and low environmental temperatures. Differences in tissue geometry that may be exploited include CD (mm^{-2}), mitochondrial volume density (inside fibers), fiber size (open circles), as well as C:F and capillary size (closed circles). Complementary changes in the intracellular compartment are shown by the involvement of lipid, and the distribution of mitochondrial separation (histograms), with the total mitochondrial content per fiber (μm^2). their aquatic existence, aerobic capacity is largely limited by the structure and functional capacity of the cardiovascular system, which has two major components: systemic cardiac output and local-tissue capillarity. The latter has been quite neglected, and our understanding of fish physiology would be greatly enhanced by more research effort in this area.

Glossary

Colloid osmotic pressure Unique form of osmotic pressure created by unequal protein concentrations across a membrane or capillary, also called 'oncotic pressure'.

Extracellular fluid The fluid outside of cells. Typically, this includes the plasma and interstitial fluid.

Hematocrit The percentage of packed red blood cells contained in a volume of blood after centrifugation.

Hydraulic pressure Pressure imparted on a solution by a piston or pump. Blood pressure is a form of hydraulic pressure.

Interstitial fluid The fluid that bathes the outside of cells but is not a part of the blood. Interstitial fluid volume is the sum of the volumes of the extracellular fluid and plasma.

Intravascular fluid The noncellular component of blood, that is, the plasma.

Lean-body mass The mass of the body without fat.

Oncotic pressure Unique form of osmotic pressure created by unequal protein concentrations across a membrane or capillary, also called 'colloid osmotic pressure'.

Osmotic pressure The hydrostatic pressure produced by the different concentrations of two solutions on opposite sides of a semi-permeable membrane.

Reflection coefficient A measure of the capillary permeability to protein. Protein-impermeable capillaries have a reflection coefficient of 1, whereas the reflection coefficient of protein-permeable capillaries is 0. Also known as the Staverman coefficient and usually represented by the Greek letter σ.

Starling's forces The vascular and interstitial hydraulic and oncotic pressures that affect fluid movement across the capillary.

Transcellular fluid Fluid in the body that is surrounded by epithelium. This includes the fluid in the lumen of the gastrointestinal tract and secretory glands such as the pancreas and liver, renal tubules, urinary bladder, gallbladder, cerebral spinal fluid, and the fluid in the vitreous and aqueous humor of the eye.

Introduction

The convective delivery of materials to and from the cells, and cardiovascular function in general, relies on sufficient venous return and this, in turn, is dependent on adequate blood volume and vascular tone (**see also Circulation**: Circulatory System Design: Roles and Principles and **Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System). Control of fluid volume through drinking, gill and skin exchange of water and salt, and kidney function are discussed in other articles of this enyclopedia (**see also Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels, **Role of the Kidneys**: The Kidney, **Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation, **Role of the Gills**: The Osmorespiratory Compromise, and **Osmotic, Ionic and Nitrogenous-Waste Balance**: Water Balance and Aquaporin). This article discusses the unique relationship between the intravascular and interstitial compartments and the forces that affect movement of fluid between them.

The Basic Fluid Compartments

As described in **Circulation**: Circulatory System Design: Roles and Principles, movement of biologically important molecules occurs by diffusion, convection or, in the case of biomembranes, via selective carriers. The body fluids serve as the highway for molecular trafficking between and within cells, and with the environment. These fluids are divided into four compartments based on their location – intracellular, interstitial, intravascular, and transcellular. Intracellular fluid is the water contained within cell membranes, interstitial fluid bathes the cells, and intravascular fluid is the blood plasma. Transcellular fluid is fluid bounded by an epithelium such as the fluid in the lumen of the intestine, kidney, urinary bladder, gallbladder, salivary glands, pancreatic ducts, cerebral spinal fluid, and intraocular fluid. Collectively, all four compartments are referred to as total body water and interstitial and intravascular water are collectively referred to as extracellular water.

In adult mammals, intracellular water is approximately 60% (by weight) of the lean-body mass (LBM), interstitial water is 16% of LBM, plasma 4% of LBM, and transcellular water varies from 1% to 4% of LBM. Fat only contains 10% water by weight. Therefore, the total body water varies with the amount of body fat and is less than 60%. In newborn mammals, total body water may be as high as 75% of LBM, and much of this is due to an increase in the extracellular fluid volume.

There is more variability (and less certainty) regarding many of these parameters in fish. Most studies have shown that intracellular body water is larger in fish than in mammals. Total body water is approximately 70–75% of a fish's body weight, a value surprisingly similar to that of newborn mammals. In addition, the extracellular fluid volume is larger, approximately 25–30% of body weight, which is also similar to the mammalian neonate. There is considerable species variation in plasma volumes; they tend to be high in cyclostomes (15% of body weight), lower in elasmobranchs (4–5% of body weight), and still lower in teleosts (2–3% of body weight). Some of this variability is due to the uncertainty in the ratio of red blood cells to plasma (hematocrit), which is lower in the small vessels and secondary circulation than in the large vessels, and methodological difficulties associated with escape of markers from the vasculature (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy and **Blood**: Cellular Composition of the Blood). It should also be noted that fluid volume measurements in fish are seldom corrected for body fat and it is likely that lean-body water is perhaps slightly greater than most reported values.

The Important Relationship between Interstitial and Intravascular Compartments

Vascular endothelial cells form a physical barrier between the intravascular and interstitial compartments. This barrier prevents red blood cells from leaving the vascular compartment, but allows free diffusion of most molecules. Mammalian capillaries also restrict diffusion of large proteins such as albumin, fish capillaries may be less restrictive (see below). The volume of fluid in each compartment is dependent upon the net driving pressure across the endothelium (between the plasma and the interstitium) and the relative compliance of each compartment. For instance, the volume in the vascular compartment (V_{vas}) is dependent upon the blood pressure and vascular compliance (**see also Circulation**: Circulatory System Design: Roles and Principles). This is described by the equation: $V_{\mathrm{vas}} = P_{\mathrm{vas}} C_{\mathrm{vas}}$, where P_{vas} is the intravascular pressure and C_{vas} the vascular compliance. Similarly, the volume in the interstitial compartment (V_{ist}) is: $V_{\mathrm{ist}} = P_{\mathrm{ist}} C_{\mathrm{ist}}$, where P_{ist} is interstitial pressure and C_{ist} is interstitial compliance. It is also obvious that compliance is defined as the change in volume for a given change in pressure, that is, $C = \Delta V / \Delta P$. If compliance in both compartments remains constant, then the movement of fluid between the two compartments will depend upon the net pressure difference between them. A change in this driving pressure will affect the movement of fluid across the endothelial cells and the amount of fluid transfer between the intravascular and interstitial spaces will depend upon their respective compliances. Shifting fluid from one compartment to the other can impact the blood volume and ultimately blood pressure on the vascular side and produce edema on the interstitial side.

The net driving pressure across the capillary is the sum of the hydraulic and oncotic pressures acting on each side of the endothelium. Collectively, these pressures are known as Starling's forces, named after their discoverer Ernst Starling. The hydraulic pressure in the plasma is generated by the heart and sustained by the mechanical recoil of the vessels (i.e., compliance; **see also Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels and **Design and Physiology of the Heart**: Physiology of Cardiac Pumping). The interstitial hydraulic pressure is derived from the relationship between interstitial fluid volume and interstitial compliance. Fluid moves away from a high hydraulic pressure toward a low hydraulic pressure. Oncotic pressure, also called colloid osmotic pressure, is a form of osmotic pressure that is due to plasma proteins. Fluid moves toward the highest oncotic pressure. The influence of gravitational pressure acting on a column of blood, that is, hydrostatic pressure, which is so important in terrestrial animals, especially tall ones, is negligible in fish that are surrounded by water, which has an opposing force (**see also Circulation**: Circulatory System Design: Roles and Principles).

The net driving pressure across the capillary (the sum of the so-called Starling's forces) is described by the general equation: $P_{\mathrm{net}} = (P_{\mathrm{c}} - P_{\mathrm{t}}) - \sigma(\pi_{\mathrm{c}} - \pi_{\mathrm{t}})$, where P_{net} is the net pressure favoring filtration out of a capillary (if positive) or reabsorption of fluid back into it (if negative), P_{c} is the capillary hydraulic pressure (capillary blood pressure), P_{t} is the hydraulic pressure in the interstitial (tissue) space, π_{c} and π_{t} are oncotic pressures in the capillary and interstitial (tissue) fluids, respectively. σ stands for the reflection coefficient (also known as Staverman coefficient), which is an index of the capillary permeability (leakiness) to proteins. In mammals, σ is obtained from the equation: $\sigma = [1 - (L_{\mathrm{prot}}/C_{\mathrm{prot}})]$, where $L_{\mathrm{prot}}/C_{\mathrm{prot}}$ is the ratio of protein concentration in the lymph and plasma. The assumption is made that L_{prot} is equivalent to the protein concentration in interstitial fluid. If $\sigma = 1$, the capillary is impermeable to protein and, therefore, π_{t} will be 0. If $\sigma = 0$, the capillary is freely permeable to protein and there will be no difference in oncotic pressure between plasma and interstitial fluid. When $\sigma = 0$, P_{net} is due only to the difference in hydraulic pressures across the capillary. Values for σ have been determined for many mammalian tissues and range from ~1 in cerebral and renal capillaries to ~0 in the liver where the endothelial cells do not form a continuous barrier.

Figure 1 shows two potential scenarios for fluid movement between vascular and interstitial compartments. In **Figure 1**(**a**) the capillaries are freely permeable to protein ($\sigma = 0$) and the net driving pressure for transcapillary fluid balance is reduced to the difference between hydraulic pressures in the intravascular and interstitial compartments, that is, $P_{\mathrm{net}} = (P_{\mathrm{c}} - P_{\mathrm{t}})$. In **Figure 1**(**b**) the capillaries are relatively protein impermeable ($\sigma \sim 1$) and the net pressure for capillary fluid filtration must take into account the difference in hydraulic and oncotic pressures in the two compartments, that is, $P_{\mathrm{net}} = (P_{\mathrm{c}} - P_{\mathrm{t}}) - \sigma(\pi_{\mathrm{c}} - \pi_{\mathrm{t}})$. **Figure 1**(**b**) reflects the situation in many mammalian vascular beds. In most mammalian systemic tissues P_{c} at the arterial end of the capillary is 35 mmHg and at the venous end of the capillary it is 15 mmHg. P_{t} is close to zero or even slightly subambient. π_{c} is 25 mmHg, π_{t} 1–2 mmHg and σ is close but not equal to 1. Thus, P_{net} favors filtration at the arterial end of the capillary (~+10 mmHg) and reabsorption at the venous end (~–10 mmHg). In mammals, the lymphatic vessels continuously remove what little protein has leaked into the interstitial fluid and keep π_{t} low (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy). Without a functioning lymphatic system the accumulation of protein in the interstitium will upset this balance and P_{net} will now favor fluid moving from the intravascular into the interstitial compartment. In fact, this is the most important function of the lymphatic circulation in mammals.

Starling's Forces and Transcapillary Fluid Balance in Fish

Most research to date suggests that fish do not have a lymphatic system (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary

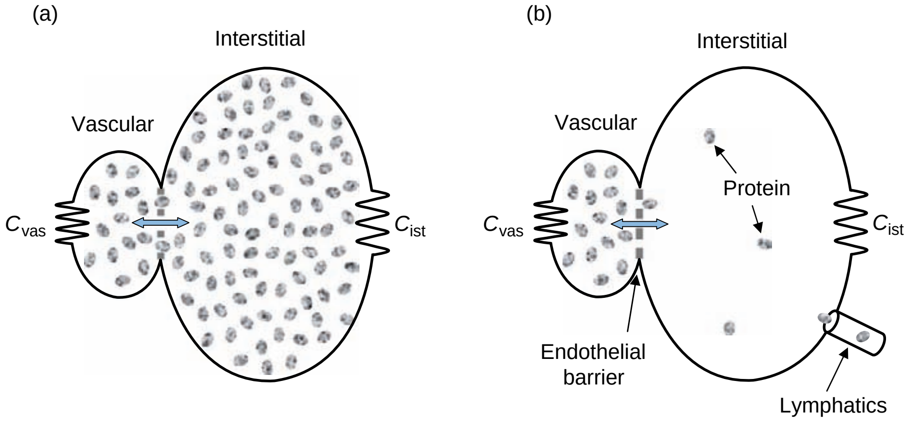

Figure 1 Examples of the forces that affect transcapillary fluid movement between the vascular and interstitial compartments. (a) In vascular beds with a protein permeable endothelium (reflection coefficient ~0), proteins equilibrate throughout both compartments and movement of fluid across the endothelium is governed solely by hydraulic pressures. (b) In vascular beds with a protein impermeable endothelium (reflection coefficient ~1) the net driving pressure is the balance between hydraulic and oncotic pressures in both compartments, that is, Starling's forces. A lymphatic system in (b) is necessary to continuously remove the small amount of protein that leaks into the interstitial fluid and thereby maintain the oncotic pressure gradient. In both examples, a decrease in compliance in one compartment will increase hydraulic pressure in that compartment and favor fluid movement into the other.

Circulation and Lymphatic Anatomy). There is also no compelling evidence that the secondary circulation, which may be the progenitor of the lymphatic system, is integral in removing proteins from the interstitial compartment. Furthermore, the number of studies that have traced the distribution of radioactive protein injected into the vascular system have suggested that protein relatively freely traverses the capillaries in many tissues, that is, they are leaky. Therefore, although there are a few tissues with relatively impermeable endothelial cells, gill and brain, in particular, the whole body σ in fish appears to be fairly close to zero, unlike in mammals. Thus in most fish the factors that determine transcapillary fluid balance are reduced to the difference between intravascular and interstitial hydraulic pressures. Several possible exceptions to this are discussed below.

Fluid Movement between Intravascular and Interstitial Compartments

It is evident from **Figure 1** that a number of factors can affect fluid movement between the vascular and interstitial compartments. In vascular systems with protein-permeable (leaky) capillaries (**Figure 1**(**a**)) an increase in hydraulic pressure in one compartment relative to the other will move fluid out of that compartment, as will a decrease in compliance. In systems where the capillaries are relatively protein impermeable (**Figure 1**(**b**)), transvascular oncotic pressure becomes a factor along with hydraulic pressure and compliance. In these systems, when fluid moves out of one compartment and into the other, the proteins are concentrated in the first compartment and diluted in the second. This decreases the net filtration pressure and retards further fluid movement. There are a number of physiological situations in which the net filtration pressure becomes disturbed and fluid moves from one compartment to the other.

Fluid Reabsorption from the Interstitial Space into the Vasculature

Figure 2 illustrates the mechanism whereby fluid can be reabsorbed from the interstitium into the vasculature. It has been demonstrated in fish and mammals that the

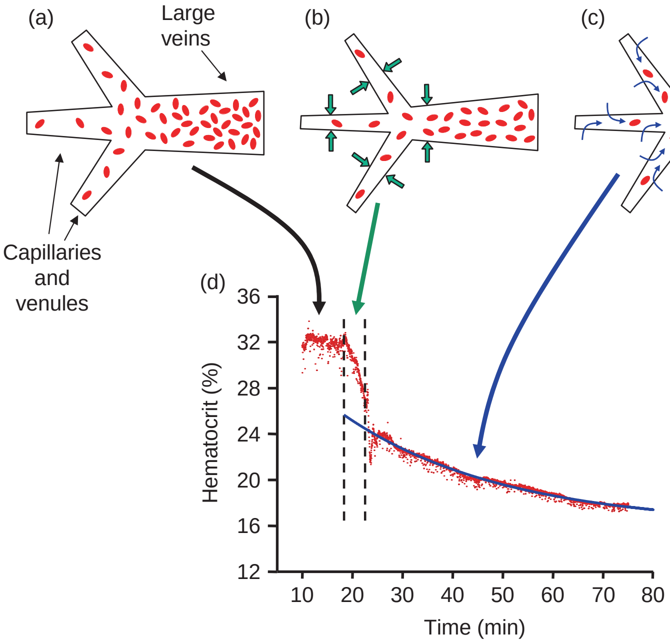

Figure 2 The mechanism of fluid mobilization from the intravascular and interstitial compartments. (a) In the normal situation, the hematocrit in capillaries and small venules is less than that in the larger veins due to the Fahraeus effect. (b) When central venous pressure falls, such as in hemorrhage, the small venules immediately collapse (green arrows) sending plasma-rich blood into the general circulation. (c) A sustained drop in venous pressure shifts the transcapillary fluid equilibrium toward fluid reabsorption and now interstitial fluid is reabsorbed into the capillaries (blue arrows). (d) Actual recording of continuous measurement of hematocrit (red dots) from the aorta of an unanesthetized rainbow trout showing the nearly instantaneous shift of plasma-rich blood from small venules into the larger vessels during a 4 min hemorrage of 35% of the blood volume (dashed vertical lines) and the subsequent reabsorption of interstitial fluid into the vasculature. The blue line illustrates an exponential curve fit to match the decline in hematocrit during interstitial fluid reabsorption. This curve can be used to calculate the rate of fluid flux from the interstitial compartment into the vasculature. (d) Modified from Olson KR, Kinney DW, Dombkowski RA, and Duff DW (2003) Transvascular and intravascular fluid transport in the rainbow trout: Revisiting Starlings forces, the secondary circulation and interstitial compliance. *Journal of Experimental Biology* 206: 457–467.

hematocrit (**see also Blood**: Cellular Composition of the Blood) in capillaries and other small vessels such as venules is considerably lower than that in large vessels, a phenomenon known as the Fahraeus effect (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis). The small venules are also quite compliant and may contain 20–30% of the total blood volume. When blood pressure decreases (**Figure 2**(**b**)), these small vessels immediately collapse, thereby returning the plasma-rich blood into the general circulation. A sustained decrease in blood pressure (**Figure 2**(**c**)) will reduce and subsequently favor fluid reabsorption from the interstitium into the vasculature. This will continue to return fluid to the general circulation. This latter process is more efficient in vascular beds that are protein permeable because it allows the protein to move out of the interstitium with the fluid. In protein-impermeable vascular beds, as fluid is pulled out of the interstitial compartment, the concentration of protein in interstitial fluid increases and in the plasma it decreases. The resulting net change in transvascular oncotic pressure somewhat offsets the change in hydraulic pressure and decreases the amount of fluid that can be absorbed.

Instantaneous hematocrit measurements from an actual experiment on an unanesthetized rainbow trout (*Oncorhynchus mykiss*) subjected to hemorrhage of 35% of its blood volume are shown in **Figure 2**(**d**). The rapid drop in hematocrit (between the two dashed vertical lines) is produced by mobilization of plasma-rich blood that results from the collapse of small venules, as shown in **Figure 2**(**b**). Following this, the continued decrease in hematocrit is produced by reabsorption of interstitial fluid into the capillaries, as shown in **Figure 2**(**c**). This fish was able to recover nearly all of the lost volume within an hour.

Fluid Loss from the Vasculature into the Interstitium

Fluid can be lost from the vasculature into the interstitial compartment through mechanisms, essentially the reverse of those described above. This process is also more efficient in vascular beds with leaky endothelial cells because plasma protein moves with the fluid lost from the vascular compartment and is not concentrated in the plasma. **Figure 3** shows the recovery in plasma, respectively. volume following volume expansion with either isotonic saline or trout plasma. Plasma volume was calculated from the change in hematocrit following volume expansion by addition of either saline or plasma equal to 40% of the initial plasma volume. Fluid movement out of the vasculature was approximately twice as fast as following volume expansion with saline than following volume expansion with plasma. However, at equilibrium the total amount of fluid leaving the vasculature (70% of the injected volume) was identical in both experiments. These results show that proteins slow down the movement of fluid across the vasculature, but they do not affect the total volume exchanged. This would not occur if proteins did not cross the endothelial cells because plasma protein concentration would steadily increase as fluid left the vasculature and the resulting increase in plasma onconic pressure would retain fluid in the plasma.

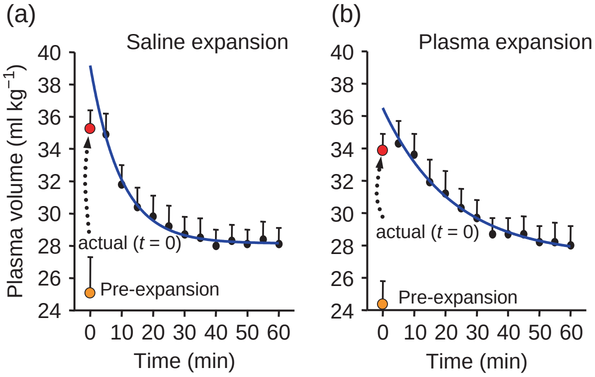

Figure 3 Recovery of plasma volume in unanesthetized trout after volume expansion. (a, b) Restoration of plasma volume following 40% volume expansion with either isotonic saline or trout plasma, respectively. The pre-expansion value (orange circles) indicates the plasma volume prior to volume expansion, actual volume (red circles) is the calculated increase in plasma volume (pre-expansion volume + 40% of pre-expansion volume). The change in plasma volume is calculated based on the change of hematocrit (see also **Figure 2**(**d**)). Fluid moves out of the plasma faster following saline infusion than plasma infusion, however, the total volume of fluid that moves out of the vasculature into the interstitium is identical. This shows that plasma proteins move across the endothelium slower than saline but nevertheless equilibrate between the two compartments. Modified from Olson KR, Kinney DW, Dombkowski RA, and Duff DW (2003) Transvascular and intravascular fluid transport in the rainbow trout: Revisiting Starlings forces, the secondary circulation and interstitial compliance. *Journal of Experimental Biology* 206: 457–467.

Physiological Significance of Transcapillary Fluid Movement

The ability to reabsorb fluid from the interstitial compartment into the vascular compartment provides a significant and rapid safety factor to protect against hemorrhage and it may well be the single most important function of the relatively permeable fish capillaries. This probably explains why fish can replace nearly 100% of their blood volume over the course of 1 h, whereas a blood loss greater than 25% of the total blood volume is fatal to most mammals. Conversely, fish rarely experience a rapid volume overload.

However, the ability to rapidly move plasma out of the vascular space may be advantageous during exercise. Here an increase in blood pressure associated with exercise would shift the plasma out of the vascular compartment and increase hematocrit. This, along with the addition of red blood cells from the spleen (**see also Blood**: Cellular Composition of the Blood), can significantly increase the oxygen-carrying capacity of blood and enhance exercise performance (**see also Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming).

Comparisons of Transcapillary Fluid Flux, Vascular Permeability, and Interstitial and Intravascular Compliance in Fish and Mammals

Although detailed studies on transcapillary fluid balance in fish are limited to rainbow trout, a number of interesting comparisons can be made to the mammalian circulation. Fish capillaries appear quite permeable to plasma protein, which allows for substantial shifts in fluid between intravascular and interstitial compartments. This can explain the high filtration rates across fish capillaries (5 ml mmHg^{-1} kg^{-1} min^{-1}), which are more than 10 times greater than those reported for mammals (0.3 ml mmHg^{-1} kg^{-1} min^{-1}). However, interstitial compliance in fish ($\sim$10 ml mmHg^{-1} kg^{-1}) is similar to that of mammals, as is vascular compliance (3 ml mmHg^{-1} kg^{-1}).

Where Are the Leaky and Tight Capillaries?

A number of studies have examined capillary protein permeability by measuring the distribution of radioactive albumin and red blood cells in tissues following injection of these tracers into the blood vessels. These studies have shown that, relative to red blood cells, high amounts of albumin accumulate in many fish tissues, especially skeletal muscle, gastrointestinal tract, liver, swimbladder, spleen, and skin. The most probable location for the albumin is the interstitial fluid, which is consistent with a leaky endothelium, that is, σ close to zero. Conversely, there appears to be little albumin loss from blood vessels in the gills and brain and this is important physiologically. As described in **Design and Physiology of Arteries and Veins**: Anatomical Pathways and Patterns, blood pumped from the heart must first pass through the gill capillaries before it is distributed to the rest of the body. With this in-series circulation, gill capillary hydraulic pressures are typically 10–20 mmHg higher than capillary hydraulic pressure of any other tissue. If gill capillaries were leaky, this would cause rapid loss of plasma into the environment. The brain is also unique because it is enclosed in a rigid vault. Leaky capillaries would allow plasma to escape into the braincase and the resultant high pressure could directly damage neurons or push against blood vessels and close them off.

There are also some species where the capillaries throughout the body might be relatively impermeable. Perhaps the most notable are tunas and lungfish. Arterial blood pressure in tunas is 2–3 times greater than blood pressures of other bony fish (**see also Pelagic Fishes**: Physiology of Tuna) and protein-permeable capillaries would be disadvantageous. Lungfish appear to possess a functional lymphatic system (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy) and may be able to efficiently remove proteins when they are filtered into the interstitium.

Do Factors other than Starling's Forces Play a Role in Transcapillary Fluid Exchange?

If fish skeletal muscle capillaries are permeable to protein, why does not plasma continue to leak into the interstitial compartment? The answer to this is unclear, but may reside in the skin. As every angler knows, fish skin tightly adheres to the body and cannot be easily pulled away, unlike skin of many mammals. In fact, fish skin is designed to be flexible along the longitudinal axis of the body to permit swimming, but it resists outward stretching. Thus, when blood pressure increases, fluid will initially move into the interstitium but, because the skin does not stretch, interstitial hydraulic pressure will increase and prevent further fluid from entering.

Glossary

Arterioarterial anastomosis An anastomosis is the joining of one blood vessel to another. In an arterio-arterial anastomosis, two arteries or arterioles are connected without an intervening capillary.

Edema An accumulation of fluid in the interstitial space. This results when filtration of fluid across the capillary wall exceeds the capacity of lymph drainage.

Hydraulic pressure Pressure imparted on a solution by a piston or pump. Blood pressure is a form of hydraulic pressure.

Immunohistochemistry Cellular or subcellular localization of specific molecules by staining them with antibodies labeled with a fluorescent or pigmented material.

Indicator dilution method A method to determine the volume of a compartment or space by injecting a known amount of a molecule (indicator) and measuring its final concentration after equilibrium throughout the compartment.

Interstitial fluid The fluid that bathes the outside of cells and is separated from the blood or lymph by an endothelium. Interstitial fluid volume is the sum of the volumes of the extracellular fluid and plasma.

Interstitial space The area surrounding cells and containing interstitial fluid.

Lymph Interstitial fluid that has entered the lymphatic circulation.

Lymphatic circulation A system of blind-end capillaries that collects excess interstitial fluid and proteins filtered from the capillaries and, through a series of progressively larger vessels, returns it to the venous circulation.

Oncotic pressure Unique form of osmotic pressure created by unequal protein concentrations across a membrane or capillary, also called colloid osmotic pressure.

Osmotic pressure The hydrostatic pressure produced by the different concentrations of two solutions on opposite sides of a semipermeable membrane.

Lymph Vessels and the Lymphatic System

The structure and function of the mammalian lymphatic system is well known. The primary function of the lymphatic system is to return protein back to the general circulation after it has leaked from the vascular capillaries into the interstitial spaces. If this protein was not continually removed from the interstitial fluid, its concentration would progressively increase and the osmotic pressure exerted by this protein (colloid osmotic pressure, also known as oncotic pressure) would continue to draw more fluid from the vascular capillaries into the interstitial space and ultimately produce edema. Thus, the presence of lymphatic capillaries maintains a normal balance between hydraulic and oncotic pressures across the vascular capillary wall (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange).

Lymph vessels provide a one-way conduit for return of fluid from the peripheral interstitial spaces back to the circulatory system. Lymph capillaries are blind-end vessels made up of endothelial cells that collect the interstitial fluid. The endothelium has specialized cell junctions that allow the cell margins to act as one-way valves, permitting the entry of interstitial fluid into the lymphatic vessel while blocking its escape (**Figure 1**). Lymph vessels also possess one-way valves in their lumen and periodic compression of smaller lymph vessels or contraction of the larger lymph vessels ensures continuous pumping of lymph from the periphery into progressively larger lymphatic vessels and ultimately into the central systemic veins.

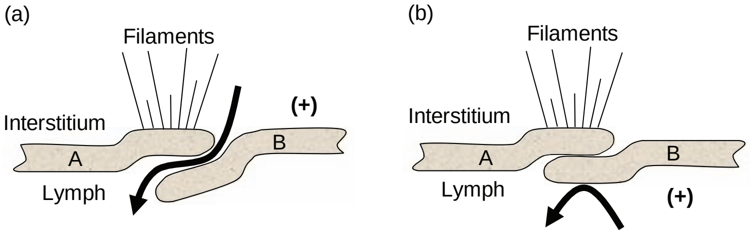

Figure 1 Diagram showing the one-way valve action of endothelial cell junctions in mammalian lymphatic capillaries depending on which direction the net transmural pressure exists (+). (a) An increase in interstitial fluid pressure pushes the endothelial flap B open (down in figure) and permits interstitial fluid to flow into the lymph capillary. Endothelial flap A is connected to the interstitial matrix by thin filaments and cannot move. (b) Compression of the lymph vessel or a decrease in interstitial fluid pressure pushes the endothelial flap B against flap A and prevents back flow of lymph into the interstitium.

This role of the lymphatic system is well known in mammals, birds, reptiles, and amphibians. It was only natural to assume that a lymphatic system was also present in fish, but this question still remains unresolved.

History of the Secondary Circulation

The organization and structure of the fish circulatory system has been the subject of interest and meticulous investigation by anatomists for nearly 200 years. Initially, as often the case for a newly developing field, anatomists viewed the fish circulation from the perspective of the more extensively studied vascular networks in amphibians and mammals, as described above. It is not surprising that these investigators would assume that vessels with a relatively thin wall and few, if any, red blood cells would be part of the lymphatic system and such a set of vessels was frequently observed. Accordingly, the lymphatic system of fish was mapped in great detail (cf. **Figure 2**) culminating in the seminal paper by Kampmeier in 1969 'Evolution and comparative morphology of the lymphatic system'. In the early 1980s, studies by Vogel's group, following up on a brief report from 50 years prior, provided evidence of a direct vascular connection between the arterial system and the so-called lymphatic system. These vascular connections appeared not to anastomose with the lymphatic system but they appeared to be arterio-arterial anastomoses, creating an additional circulatory system. As this second circulation also consisted of arteries, capillaries, and veins, it was called the 'secondary circulation', or in the case of the gills, the 'veno-lymphatic circulation'. These studies and the ones that followed began to question whether or not a true lymphatic system existed in fish, and a hypothesis was developed that the secondary circulation was unique to fish and it was likely the progenitor of a true lymphatic system. Not much evidence has accumulated since then to refute this hypothesis.

Anatomy of the Secondary Circulation

By definition, the secondary circulation is a vascular network consisting of arteries, capillaries, and veins that originate from a major artery in the form of small-bore vessels (arterio-arterial anastomoses) and then re-anastomose to form progressively larger arteries. Like the primary circulation, these larger vessels then feed a second system of arterioles, capillaries, and veins that may even run parallel to the primary circulation. Larger secondary arteries often travel some distance before dividing into a capillary network.

Location of Secondary Vessels

In bony fish, the secondary circulation has been observed in or near external tissues or those that line the body cavity. These include the skin, scales, fins, gills, buccal (mouth) cavity, and peritoneum. The secondary vessels can form complex as well as dense systems, and this is especially true of the gills. Secondary vessels have also been observed in the heat exchangers in tuna (**see also Design and Physiology of Arteries and Veins**: The Retia), but they have not been identified in skeletal muscle, the gastrointestinal tract, liver, kidney, swimbladder, brain, or eye. Secondary circulation has also been observed in gills of non-teleostean species, such as cyclostomes and elasmobranchs, where it is similar to that of bony fish. However, less is known of the secondary system in nongill tissues of these fish.

Arterio-arterial Anastomoses

Secondary vessels usually originate from the dorsal aorta and segmental arteries. Tunas are notable exceptions as the secondary vessels originate from rete arterioles in the

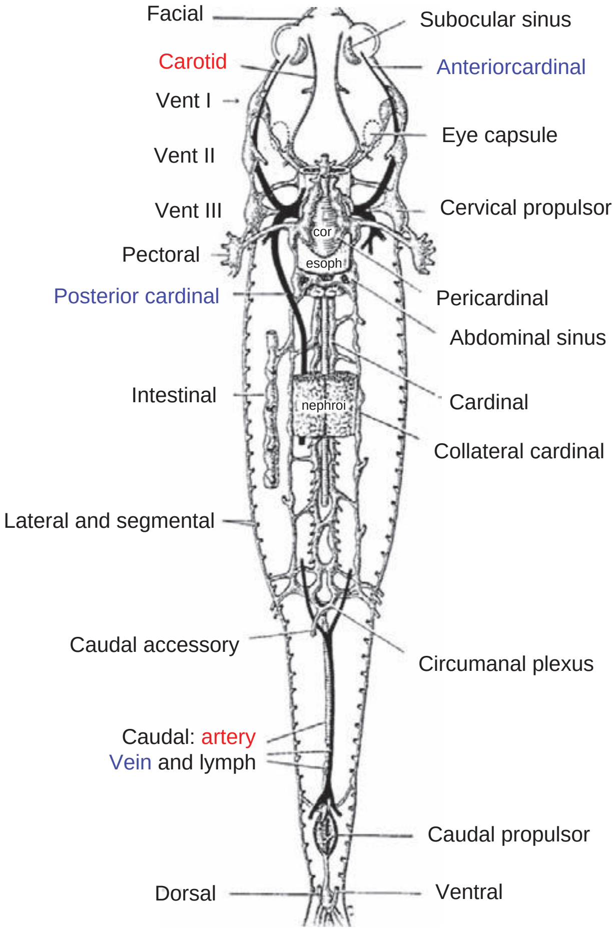

Figure 2 Early interpretation of the so-called lymph circulation in bony fish. The diagram shows the position of lymph vessels (stippled, black lettering) relative to several veins (black, blue lettering) and arteries (cross-lined, red lettering). Vents I, II, and III indicate three levels of communication between the lymphatics and veins in different fish. cor, heart; espoh, esophagus; nephroi, kidney. Modified from Kampmeier OF (1969) *Evolution and Comparative Morphology of the Lymphatic System*. Springfield, IL: Charles C. Thomas.

heat exchanger. Secondary arterio-arterial anastomoses typically emerge perpendicularly from a relatively large primary artery and they follow a long (200–300 μm) and surprisingly tortuous, twisting path before joining with numerous other secondary vessels to form progressively larger arterioles and arteries. Another unique feature of secondary arterioles is the dilated lumen at their origin, forming a funnel-like entrance (**Figure 3(a)**). Microvilli have been reported on the surface of endothelial cells on the parent artery near the origin of the arterio-arterial anastomoses in some fish. These form long microvillous ribbons parallel to the axis of the parent vessel and appear to be guarding the entrance to the secondary arteriole (**Figure 3(c)**). This may physically restrict access of red blood cells into the secondary vessels and contribute to the low hematocrit in the secondary circulation. Leukocytes may also adhere to the microvilli. It has also been suggested that the microvilli provide chemo- or mechanosensory information, but this is yet to be demonstrated experimentally. The tortuous part of the secondary circulation can be embedded within the muscle wall of the primary artery. Thus, it is possible that constriction or dilation of the primary vessel may exert a direct mechanical effect on the arterio-arterial anastomoses as well, perhaps controlling the flow of blood entering the secondary circulation from the primary circulation.

Secondary Vessels in the Systemic Circulation

The translucent body of the glass catfish, *Kryptopterus bicirrhis*, is ideally suited for examining the relationship between primary and secondary circulations in a whole fish. As shown in **Figure 4**, secondary vessels arise from the primary segmental arteries as narrow-bore, tortuous arterioles. These arterioles subsequently re-anastomose to form secondary arteries that enter the ventral fin where they form an extensive secondary capillary network that is restricted to the fins. The capillaries are then drained by secondary veins that ultimately join either with a lateral subcutaneous secondary vein, or less frequently, with the

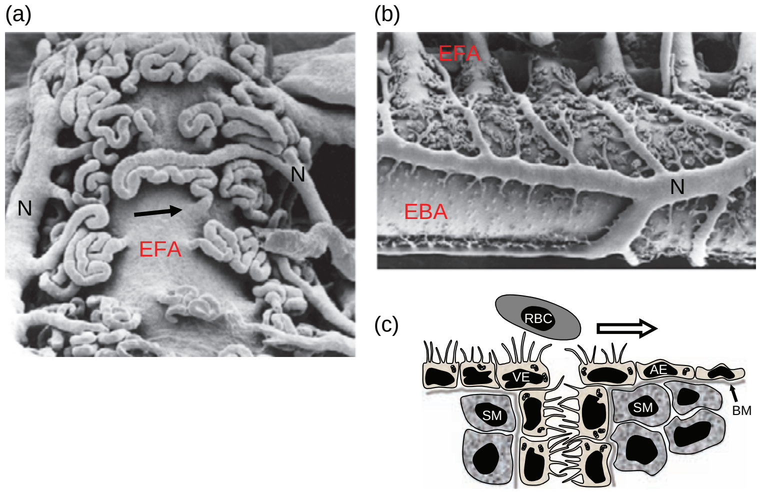

Figure 3 Vascular corrosion replicas from the gill of the climbing perch, *Anabas testudineus*, showing the origin of the secondary arterio-arterial anastomoses. These micrographs of anastomoses are from the gill, but the general anatomy is also typical of systemic secondary arterio-arterial anastomoses. (a) Numerous tortuous vessels arise from the wall of the primary (efferent filamental) artery (arrow) and rejoin to form progressively larger nutrient arteries (N). (b) A large nutrient artery (N) in the gill arch is formed from the anastomosis of numerous tortuous arterioles that arise from both the efferent branchial artery (EBA) and efferent filamental arteries (EFA). (c) Drawing showing the microvillous endothelial cells (VE) lining the efferent filamental artery and preventing a red blood cell (RBC) from entering the narrow-bore vessels that supply the interlamellar system. SM, smooth muscle cells; AE, normal arterial endothelium of the efferent filamental artery; BM, basement membrane. Figure 4 Secondary circulation to the anal fin of the glass catfish. Arterio-arterial anastomoses originate from segmental arteries and form the secondary circulation supplying capillaries in the fin. Secondary capillaries typically drain into large secondary collecting vein or, less commonly, into the secondary subvertebral vein. Reproduced from Steffensen JF, Lomholt JP, and Vogel WOP (1986) *In vivo* observations on a specialized microvasculature, the primary and secondary vessels in fishes. *Acta Zoologica (Stockholm)* 67: 193–200, with permission.

secondary subvertebral vein in the hemal arch. A similar capillary network has been identified in the epithelium that overlies the scales. In the rainbow trout (*Oncorhynchus mykiss*), fluid drains from the secondary circulation of the tail into the caudal heart from where it is then pumped into the caudal vein (**see also Design and Physiology of the Heart**: Accessory Hearts in Fishes). With so much blood reaching the surface of the fish fins and scales, the fish would likely take on a red hue were it not for the fact that there are relatively few red blood cells (1/10th) compared with the primary circulation.

Other investigators have provided slightly different descriptions of the secondary system. In *Blennius pavo* and *Zosterisessor ophiocephalus*, the tortuous arterioles originate from the dorsal, lateral, and ventral segmental arteries as well as from the caudal dorsal aorta. However, these vessels appear to connect directly to secondary veins without an intervening capillary. Thus, this system appears to be an arteriovenous, rather than arterio-arterial circulation.

Lungfish

Lungfish do not have typical secondary vessels and in their place is a well-developed lymphatic system similar to that found in tetrapods. Therefore, lungfishes including the African lungfish (*Protopterus annectens* and *Protopterus dolloi*) and South American lungfish (*Lepidosiren paradoxa*) may represent the transition from a secondary circulation to a true lymphatic circulation. Numerous thin-walled endothelial-lined vessels similar to mammalian blind-end lymphatics are found throughout systemic tissues (except brain) and in the gills of lungfish. These vessels drain into a unique pumping apparatus, the lymphatic micropump. Micropumps are spherical, contractile organs 35–55 μm in diameter. They consist of a single layer of endothelial cells, surrounded by a single muscle cell. The endothelial cells at both the inlet and outlet ends of the pump serve as one-way inlet and outlet valves. The micropumps appear to be suspended within a cell-free interstitium and they contain microfibers that radiate outward from the endothelial cells through perforations in the muscle and extend into the surrounding connective tissue. This gives the appearance of the micropumps being suspended in the interstitial space. Presumably, these microfibers allow the pump to expand by recoil following muscular contraction. Unlike the mammalian lymphatic system, large lymph vessels are absent from lungfish and the red-blood-cell-free lymph is pumped directly from the micropumps into small veins. As many as 105 micropumps per cubic millimeter have been observed in the fin of the South American lungfish.

Zebrafish: A secondary circulation or lymphatic system?

Recent techniques, such as confocal time-lapse imaging of developing vessels and identification of a variety of growth factors important in the development of the mammalian lymphatic system, have been applied to examine vascular development in zebrafish embryos. The time-lapse studies suggest that a true lymphatic system develops in zebrafish and this is supported by immunohistochemical localization of a variety of antibodies to markers of mammalian lymphatic endothelial cells. This raises an interesting question of whether earlier high-resolution anatomical studies mistakenly identified lymphatic vessels as secondary vessels, or whether secondary vessels exist and are indeed progenitors of lymphatic vessels complete with their primordial growth factors.

Non-teleostean fish

The presence of large vascular sinuses filled with low hematocrit blood in the systemic circulation, caudal lymph hearts, and a secondary-like circulation in the gills (see below) all suggest that a systemic secondary circulation is also present in cyclostomes and elasmobranchs. However, arterio-arterial anastomoses similar to those described in teleosts have not yet been observed in these species.

Secondary Vessels in the Gill

There are two vascular networks in the gill, the nutrient and interlamellar pathways, which exhibit some attributes of the secondary circulation. The relationship between these vascular pathways and other the gill vessels is described in detail in **Design and Physiology of Arteries and Veins**: Branchial Anatomy.

The nutrient system arises either from the efferent branchial artery or from the efferent filamental artery near its junction with the efferent branchial artery. Here, numerous narrow-bore, tortuous arterioles arise from the wall of the larger primary vessels and re-anastomose to form progressively larger nutrient arteries that subsequently divide into arterioles and capillaries. These vessels then supply the nonrespiratory tissues of the gill arch and filament (**Figures 3(a)** and **3(b)**), that is, tissues other than the secondary lamellae. While the origin of these nutrient vessels exhibits features of secondary circulation, that is, they originate from small vessels that re-anastomose to form a larger arterial network, they originate directly from the post-gill respiratory circulation, not major systemic arteries and they do not supply a capillary network in parallel with another primary network. Thus, the gill nutrient circulation most closely resembles a primary circulation.

The interlamellar system in the gill filament is considerably different from the nutrient system and has a number of attributes that suggest that it is lymphatic like or at least a progenitor of the lymphatic system, but it too may not be a true secondary system. The interlamellar system in the gill filament was previously called the central sinus, central

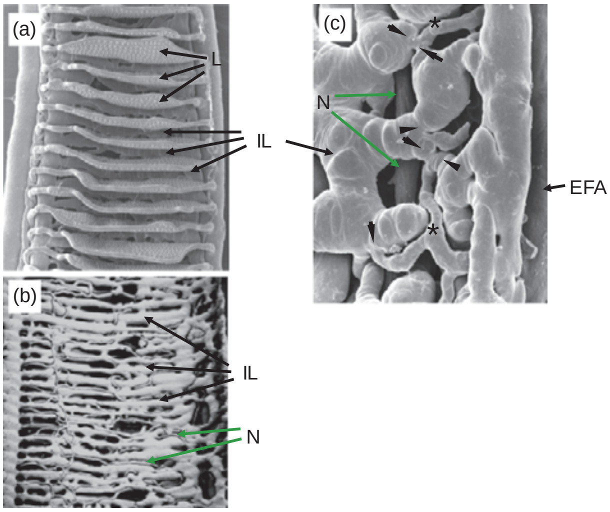

Figure 5 Vascular corrosion replicas showing the relationship between the interlamellar vessels (IL), lamellae (L), and nutrient arterioles (N) in the gill filament. (a) With the lamellae intact, it is clear that the interlamellar system lies between and runs parallel to the inner lamellar margins. (b) With the lamellae removed, the relationship between the larger interlamellar vessels (black arrows) and smaller nutrient arterioles and capillaries (green arrows) is evident. (c) Higher magnification showing the narrow-bore vessels (*) that originate from the efferent filamental artery (EFA) and supply the interlamellar system (arrowheads). The interlamellar system also appears distended in this micrograph. (a, c) Walking catfish, *Clarias batrachus* and (b) rainbow trout. (a, c) Reproduced from Olson KR, Ghosh TK, Roy PK, *et al*. (1995) Microcirculation of the gills and accessory respiratory organs of the walking catfish, *Clarias batrachus*. *Anatomical Record* 242: 383–399, with permission from John Wiley and Sons. (b) From K.R. Olson (unpublished).

venous sinus, or the veno-lymphatic system. The latter is perhaps the most appropriate. The interlamellar system originates primarily from narrow-bore vessels on the medial wall of the efferent filamental artery (**Figure 5**) or efferent lamellar arterioles. These vessels travel partway across the filament and anastomose with the dilated interlamellar system that traverses the filament body (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy). Unlike nutrient capillaries, interlamellar vessels consist of very thin walled endothelial cells and these vessels appear to be quite distensible. Interlamellar vessels contain very few red blood cells and in electron micrographs even the plasma appears to contain less protein (**Figure 6(a)**). The junctions between two endothelial cells are also lymphatic like in that one cell appears to overlap the other (**Figures 6(b)** and **6(c)**). The interlamellar system is drained from the filament into systemic veins that also drain the nutrient capillaries.

Non-teleosts

The detailed accounts of the nonrespiratory gill circulation in cyclostomes are incomplete. In the lamprey, a nutrient system has been described similar to that found in bony fish. In sharks and skates, both interlamellar and nutrient vessels are well developed.

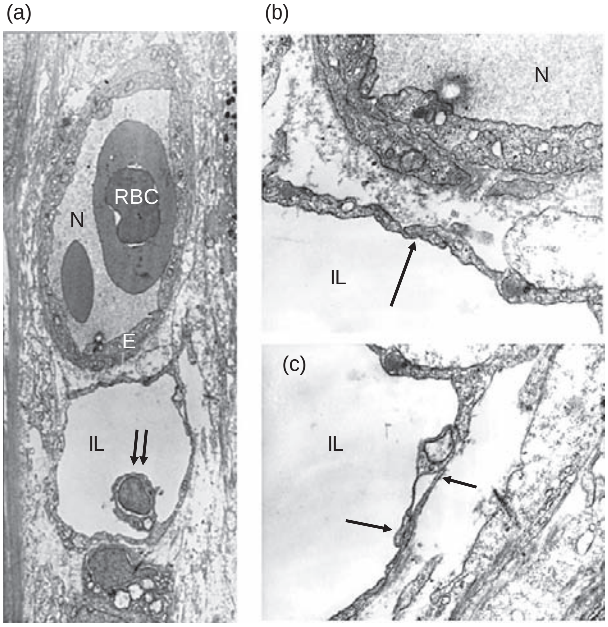

Figure 6 Transmission electron micrographs of the nutrient (N) and interlamellar (IL) vessels in the gill filament of the rainbow trout. (a) Nutrient capillaries contain red blood cells (RBCs), a thick-walled endothelium (E), and the plasma is more electron dense suggesting a high concentration of plasma protein. RBCs are absent from interlamellar vessels, the endothelium is thin-walled, and the nucleus of the endothelial cell (double arrows) bulges into the lumen of the vessel when the vessel is relatively collapsed under low pressure. (b) Higher magnification showing the thick endothelial cells in nutrient capillaries and thin endothelial cells in interlamellar capillaries. The overlapping valve-like arrangement of the interlamellar endothelial cells can be seen. (c) Valve-like interlamellar endothelial cell flaps (arrows) are evident. Reproduced from Olson KR (1996) Secondary circulation in fish: Anatomical organization and physiological significance. *Journal of Experimental Zoology* 275: 172–185, with permission from John Wiley and Sons.

Other Features of the Secondary Circulation

Volume

The volume of the secondary circulation has most often been derived from studies in which dilution of an injected indicator substance is used to estimate volume (indicator dilution method). Typically, these employ radiolabeled red blood cells (assumed to be restricted to the primary circulation) and radiolabeled albumin, or plasma protein tagged with a dye (Evans blue dye) that is assumed to be evenly distributed through both the primary and secondary circulations. In a typical experiment, the indicators are injected into the primary circulation and the volume of the secondary circulation is inferred from the difference between the dilutions of the two indicators. These studies have indicated that the volume of the secondary circulation ranges from 50% to 150% that of the primary circulation.

These values seem excessive given that a secondary circulation has not been identified in skeletal muscle, gastrointestinal tract (including liver and spleen), or brain and these tissues account for the bulk of the fish's mass. Furthermore, other studies have shown that the commonly used indicators of the secondary-circulation volume readily accumulate in skeletal muscle and the gastrointestinal tract. It seems more likely that these indicators have leaked from primary capillaries into the interstitial space. Other studies have confirmed that the primary capillaries of fish are very permeable to protein (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange) and they have suggested that the volume of the secondary circulation may be no more than 20% that of the primary circulation. Clearly, additional work needs to be done in this area.

Pressure

Blood pressure has only been measured in the larger veins of the secondary circulation and, as would be expected from a lymphatic-like system, it is quite low (–3 to +3 mmHg). It is likely that this low pressure is a result of the high resistance in the narrow-bore arterio-arterial anastomoses. Flow into the secondary circulation may be regulated by smooth muscle surrounding these arterio-arterial anastomoses or by direct constriction of the primary artery from which the secondary circulation is derived.

Flow rates have not been measured in the secondary circulation. It is assumed to be lower than that of the primary since flow in the primary circulation is largely determined by the need for oxygen transport (**see also Circulation**: Circulatory System Design: Roles and Principles) and the secondary circulation lacks this role since red blood cells are largely absent. It takes about 20 min for an indicator substance to reach equilibrium between the primary and secondary systems, which suggests that flow in the secondary system may be at least 1/10th of that in the primary circulation given that the primary circulation time is 0.4–2 min (**see also Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System).

Physiological Function

The apparent absence of secondary vessels in skeletal muscle and the gastrointestinal tract argues against the importance of this system in returning protein and interstitial fluid back to the primary circulation as done by classical lymphatics. However, not all mammalian tissues have lymphatics (i.e., brain). It is possible that the secondary system is a prototype lymphatic system that has developed to maintain interstitial environment in the most susceptible tissues, that is, those exposed to an osmotically hostile environment. In other tissues, where intravascular pressures are low, a specialized reabsorptive vasculature may not be necessary (**see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation). The secondary system does not appear to be involved in gas exchange as it is nearly devoid of red blood cells. Despite the inaccessibility to red blood cells, the ability of the endothelial microvilli in the region of the arterio-arterial anastomoses to trap leukocytes may provide immunological protection to the epithelium. Interestingly, fish that have been anesthetized for a long period adopt red coloration to their skin. This may be due to red blood cells entering the secondary circulation that services the skin, scales, and fins.

In summary, fishes are unique among vertebrates in that they possess primary and secondary circulations, with flow reaching the secondary circulation via the primary circulation. While the roles of the primary circulation are well established, those of the secondary system are not. Nutritive and reabsorptive functions are likely, but remain to be confirmed.

Glossary

Dampening The degree to which a controlled variable is allowed to oscillate. Systems that are tightly controlled are highly damped; a poorly damped system allows the controlled variable to deviate considerably.

Effector A variety of mechanisms that can act upon a controlled system. The heart, blood vessels, and kidney are all effectors of arterial blood pressure.

Feedback transducer A reporting mechanism that monitors a physiological variable and converts this into an output signal, usually an action potential or hormone that can be transmitted back to the controller. Stretch receptors in blood vessel walls detect blood pressure and convert mechanical stretch into action potentials to be sent to the central nervous system.

Feedforward Feedforward systems detect an external disturbance and bring about a change in a controlled variable without monitoring their success.

Feedforward systems Prevent rapid deviations away from the setpoint and typically work in conjunction with negative feedback systems.

Gain The amount of effector response exerted on a system. A system with high gain rapidly restores conditions. Gain is calculated as compensation/error.

Homeostasis The equilibrium or stability of the internal environment of organisms in a changing external environment, maintained by many physiological adjustment mechanisms.

Negative feedback A controlled system response that restores critical values back to their starting or optimal condition.

Neutral zone The range around the setpoint in which the controlled variable can oscillate without initiating an effector response.

Programmed rheostasis A change in the setpoint at some predetermined time or life stage. Parr–smolt transformation accompanying the migration of salmon from freshwater to seawater is an example of programmed rheostasis.

Reactive rheostasis A change in the setpoint that achieves a compromise between opposing factions. For example, during hypoxia blood pressure is regulated downward. While this decreases tissue blood flow, it also decreases the work of the heart and therefore conserves the limited energy.

Rheostasis A change in the setpoint, typically one of two types, reactive and programmed.

Setpoint The ideal value for a controlled variable.

Introduction

Physiology is the study of how an organism regulates its internal environment. A variety of simple to complex control systems are employed to achieve this regulation, and physiological experiments are designed with the ultimate goal of understanding these control systems. The following sections provide an overview of the basic principles of control systems and a few illustrations of how these systems act and interact in the control of the fish cardiovascular system.

Control Systems

The importance of regulating the immediate cellular environment (the *milieu interieur*) for the well-being of all cells in an organism was first realized by Claude Bernard, and the significance of being able to maintain this internal environment within the acceptable limits was delineated by Walter Cannon as the concept of homeostasis. The study of physiological control systems is based on general principles of 'system analysis', commonly employed in engineering. As shown in **Figure 1**, there are three general components to any system: input, laws, and output. The factors acting upon the system are the input, the laws are the properties of the system that will produce a particular output (when unknown these laws are often called the 'black box'), and the output is the ultimate result. If any two of these are known, the third is readily obtainable. For instance, in physiological experiments the input is carefully controlled and the output is analyzed to characterize the laws that govern the response. The key to a well-operating control system is to monitor the output in such a way that it can readily be restored back to some optimal value when external factors cause it to deviate. Control systems operate through feedback loops.

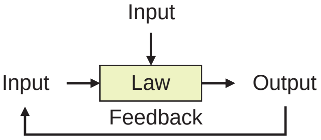

Figure 1 The three components of a controlled system: input, the factors acting upon a system (often external); laws, the intrinsic properties of the system that will produce a particular output (called the 'black box' when unknown); output, the ultimate result. If the result is monitored and can again be readjusted, this becomes a feedback loop. One of the primary goals of science is to identify the laws governing control systems.

Negative Feedback

The basic components of a control system are shown in **Figure 2**. Central to this is the negative feedback loop (yellow in **Figure 2**), which consists of five components. The controlled process is the physiological variable that must be regulated, that is, blood pressure. The feedback transducer is a reporting mechanism that monitors the controlled process (blood pressure) and converts (transduces) the message into another form, usually action potentials or hormones, that can be transmitted to the controller. In the example of blood pressure regulation, this would be stretch receptors in vessel walls that detect the mechanical stretch imposed by blood pressure and convert this into another type of signal, usually nerve action potentials or hormones. The controller receives information from the feedback transducers and compares this to some ideal value, the reference input, also known as the setpoint, and then decides if the controlled process is within an acceptable range. If not, the controller then sends signals to the effectors, which have the ability to make the necessary changes. In the case of blood pressure regulation this may be the heart, blood vessels, kidney, or any other organ that can ultimately affect blood pressure. This feedback loop is a negative feedback system because when the controlled process deviates away from the setpoint the system returns it. Positive feedback loops tend to further drive the system away from the starting point; these are rare in physiology and usually only transient (i.e., blood clotting, action potentials, urination, and defecation reflexes).

Most control systems operate around the desired setpoint, but how tightly the system is controlled may vary. The neutral zone, also known as the dead zone, is the area around the setpoint at which the controlled parameter may change but not initiate a feedback response. The

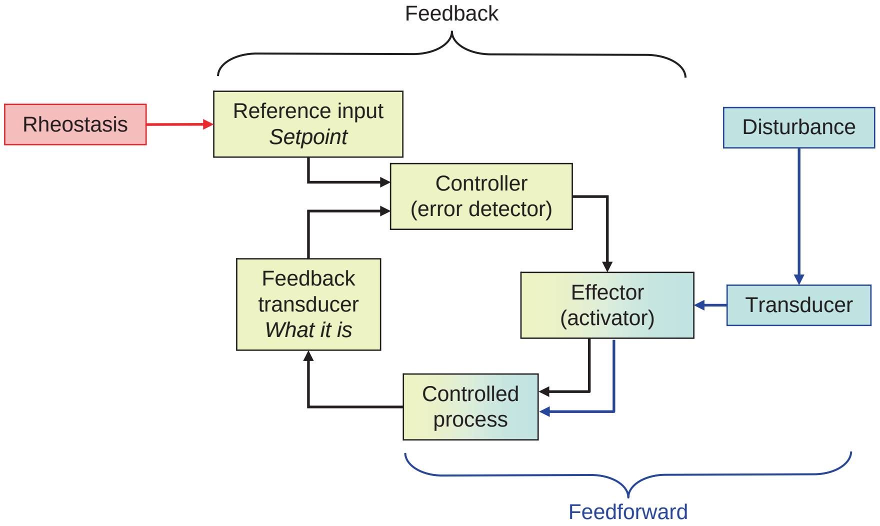

Figure 2 Components of physiological control systems. The basic system relies on a negative feedback loop (in yellow) where the physiological parameter controlled process is monitored by feedback transducers and the signal is sent to the controller and compared to the ideal value, the reference input. If the controlled process has deviated sufficiently away from the ideal, the controller activates mechanisms, effectors, to restore the system. A feedforward system (in blue) detects an outside disturbance and immediately activates the effector to bring about changes in the controlled process. Feedforward systems are anticipatory in that they predict the need for response and initiate the response without directly monitoring their success; thus, they are open-loop systems. Rheostasis (in red) provides a mechanism to change the reference input and thereby adjust the controlled process.

width of the neutral zone determines the dampening, which is defined as the degree of oscillation permitted around the setpoint. The gain of the system refers to how tightly the system is controlled or dampened. Gain can be calculated as the ratio between the amount of correction of an abnormality relative to the amount of abnormality remaining, that is, compensation divided by error. As an example, if after 30% of the blood volume is removed from the fish and its blood pressure falls from 25 to 24 mmHg (net = 1 mmHg) with all control systems intact, but falls from 25 to 15 mmHg (net = 10 mmHg) with all control systems blocked, the compensation is $10 - 1 = 9$ and the error is 1. The gain of this control system is $9/1 = 9$, which is fairly typical. The gain for many physiological systems is between 2 and 10.

Feedforward

Feedforward systems (blue in **Figure 2**) detect an outside disturbance that is a potential threat to the controlled process. However, the transducer sends its signal to the effector, usually without any input from the controller (although these signals often pass through the central nervous system). Activation of the effector changes the controlled process. Feedforward systems are anticipatory in that they predict the need for response and then initiate the response without directly monitoring their success. Thus, feedforward systems are not closed loop because they do not restore the controlled process to the preset value. Rather, they prevent rapid deviations away from optimal. Feedforward systems typically work in conjunction with negative feedback loops.

Rheostasis

Rheostasis (red in **Figure 2**) provides a mechanism to change the setpoint and thereby adjust the value of the controlled process. There are two types of rheostasis: reactive and programmed. Reactive rheostasis is a change in setpoint that is based upon a judgment decision where conditions are such that maintaining the status quo is not in the best interest of the organism. Typically, the new setpoint is some compromise between opposing factions, each of which tends to pull the regulated parameter in the opposite direction. In programmed rheostasis the setpoint changes at some predetermined time or life stage of the animal.

Integration of Control Systems

Most control systems do not operate independently, but are integrated with other control systems. This allows sophisticated regulation of the control processes (while at times makes studying these processes extremely difficult). Even a single controlled process can vary in complexity. Regulation of arterial blood pressure relies upon a highly integrated and extremely complex interaction of numerous effectors that are controlled by multiple areas within the central nervous system (**see also Integrated Control and Response of the Circulatory**

System: Central Control of Cardiorespiratory Interactions in Fish). Conversely, local regulation of blood flow in response to metabolic need is a relatively simple process where an increase in oxygen consumption by tissues reduces the oxygen tension in nearby blood vessels and leads to a direct vasodilation (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels).

Integrative Analysis of the Fish Cardiovascular System

There is considerable detail regarding mammalian cardiovascular control systems and these have been subjected to detailed engineering analysis for over 40 years. Similar analyses have not been performed on fish and this remains as one of the greatest challenges for future research. The following sections provide some examples of control system analysis of the fish cardiovascular system. It is evident that each of these components can be broken down into subcomponents and these can often be further subdivided numerous times.

Regulation of Arterial Blood Pressure

As described in **Circulation**: Circulatory System Design: Roles and Principles, perhaps the most fundamentally regulated parameter by remote control in the cardiovascular system is arterial blood pressure. The primary determinants of arterial blood pressure are cardiac output and total peripheral resistance. Each of these can be further divided into their respective components, resulting in the flow diagram shown in **Figure 3**. The following sections provide a brief overview of these components and references to further details that can be found elsewhere in this encyclopedia.

Cardiac output

The primary determinants of heart rate are parasympathetic inhibition, sympathetic stimulation, mechanical

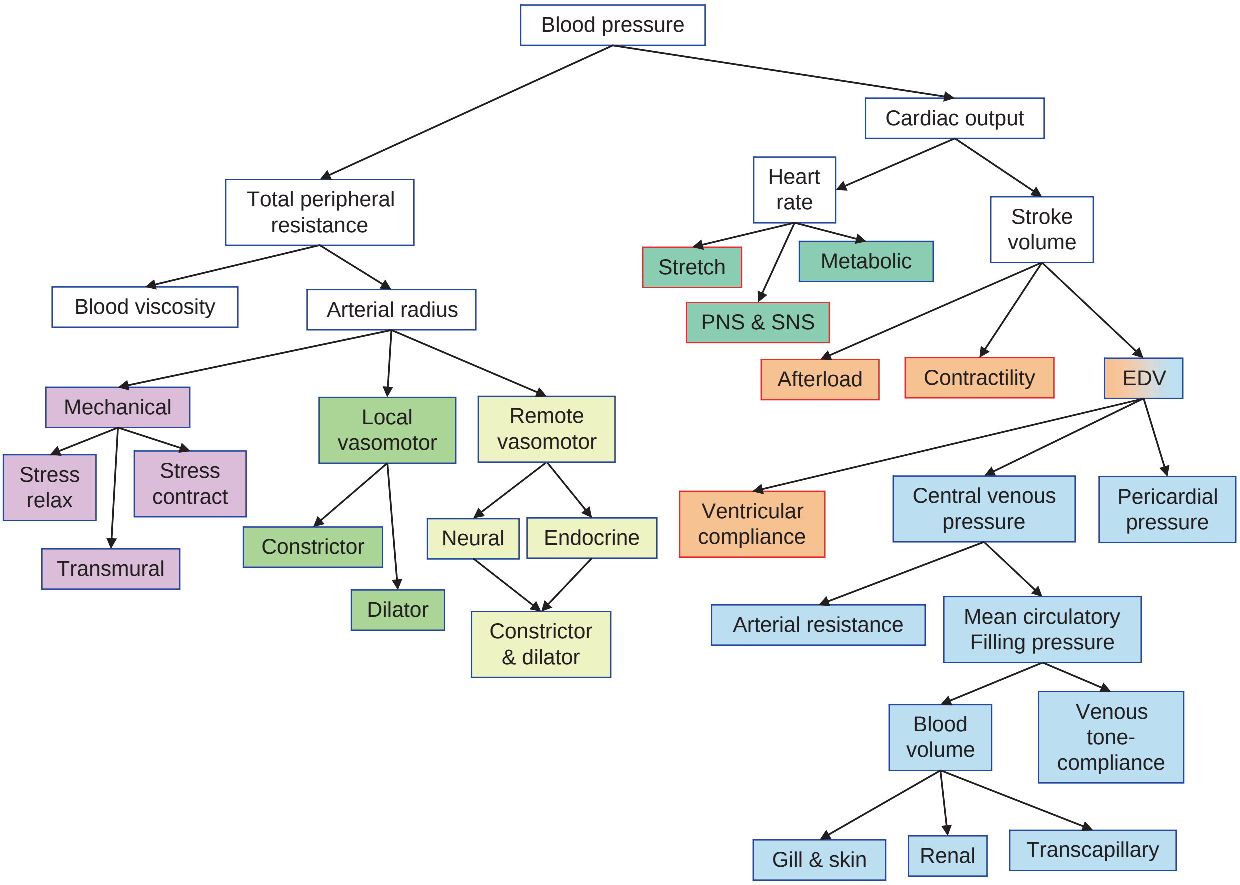

Figure 3 Flow diagram of the factors that affect arterial blood pressure. The cardiac factors that affect stroke volume are shaded in red, extracardiac factors that affect stroke volume are shaded in blue, and factors that affect heart rate are shaded in green. Mechanical factors that affect arterial radius are shaded in lavender, local vasomotor factors in lime green, and remote vasomotor factors in yellow. EDV, end-diastolic volume; PNS, parasympathetic nervous system; SNS, sympathetic nervous system. See text for details.

stretch, and the local chemical environment in the area of the pacemaker cells (**see also Design and Physiology of the Heart**: Cardiac Anatomy in Fishes, Physiology of Cardiac Pumping, **Brain and Nervous System**: Autonomic Nervous System of Fishes, and **Hormonal Responses to Stress**: Catecholamines). Heart rate is slowed by parasympathetic stimulation, increased by sympathetic stimulation, increased by local stretch, and may be decreased by hypoxia, acidosis, or elevated carbon dioxide. Heart rate of many fish is under tonic parasympathetic inhibition and sectioning these nerves alone will produce a modest increase in heart rate due to the faster intrinsic rate of the cardiac pacemaker.

Stroke volume depends upon factors that affect cardiac emptying (e.g., contractility, end-diastolic volume (EDV), and afterload (arterial blood pressure)), cardiac factors that affect filling, including cardiac suction and ventricular compliance, and extracardiac factors that affect filling, namely the mean circulatory filling pressure. Contractility is the strength of contraction independent of the length of the cardiocyte; it is increased by factors such as sympathetic nerve stimulation and elevated intracellular calcium and decreased by factors such as fatigue hypoxia and acidosis (and sometimes parasympathetic nerve stimulation). Afterload (ventral aortic blood pressure) does not affect stroke volume until it becomes approximately 2½ times that of normal ventral aortic pressure, at which point stroke volume will progressively decrease as blood pressure increases. An increase in EDV, within physiological limits, will increase stroke volume due to the increase in strength of contraction when the cardiocytes are stretched. This length–tension relationship is also known as the Frank Starling law of the heart. EDV is directly related to ventricular compliance (an increase in compliance increases EDV, and vice versa). In fish with a rigid pericardium, ventricular contraction decreases pericardial pressure which helps suction blood from the veins into the atrium, a phenomenon known as 'vis a fronte' filling. However, the most important determinant of EDV is central venous pressure and the most important determinant of central venous pressure is the mean circulatory filling pressure. The mean circulatory filling pressure is the 'fullness of the circulation' and is regulated over the short term by changing venous tone (an increase in venous constriction will increase mean circulatory filling pressure), or through rapid adjustments in blood volume by transferring fluid from the interstitial into the intravascular compartment, or vice versa. The mean circulatory filling pressure is also regulated over the long term by changing blood volume through regulation of water and salt balance across the gill, skin, and kidney. In mammals, the ultimate long-term regulator of blood pressure is blood volume, and this appears to be the case in fish as well. Other factors can also transiently increase central venous pressure. For instance, the decrease in arterial resistance accompanying exercise will cause more blood to flow from the arteries into the veins, thereby increasing venous pressure and ultimately cardiac output. For further details on the factors that affect cardiac output, **see Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange, **Circulation**: Circulatory System Design: Roles and Principles, **Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels, Physiology of Resistance Vessels, **Design and Physiology of the Heart**: Physiology of Cardiac Pumping, **Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts, Mechanisms of Ion Transport in Freshwater Fishes, **Role of the Kidneys**: The Kidney, **Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation, and **Role of the Gills**: The Osmorespiratory Compromise.

Total peripheral resistance

The main determinants of total peripheral resistance are blood viscosity and the diameter of small arteries and arterioles. Hematocrit (the relative volume occupied by red blood cells) has the greatest effect on blood viscosity. As hematocrit increases the oxygen-carrying capacity of blood increases but so does blood viscosity. Hematocrit in most fish is around 35, which is a trade-off between the oxygen-carrying capacity and viscosity. High-energy-demand fish such as tuna increase hematocrit to as high as 50 in order to increase oxygen-carrying capacity, but in doing so they also have to increase arterial blood pressure to overcome the elevated viscosity. On the other end of the spectrum, some Antarctic icefish eliminate red blood cells from the circulation altogether in order to reduce viscosity at these very cold temperatures. The loss in oxygen-carrying capacity is compensated for by an increase in oxygen solubility in the plasma due to the cold, and an increase in cardiac output.

The radius of small arteries and arterioles is the primary determinant of total peripheral resistance. Arterial resistance is largely under the influence of both local and remote controlling mechanisms.

Local control

Local control matches blood flow (perfusion) with metabolic demand of the tissue. This is the ultimate purpose of the cardiovascular system. Local control is achieved primarily through vasodilator substances that are consumed by or released from cells as a consequence of tissue metabolism. These typically act upon the smallest resistance vessels and include low oxygen (low P_{O_2}; although low P_{O_2} constricts gill vessels), elevated carbon dioxide, acidosis, elevated potassium, and other metabolites (e.g., ATP, adenosine).

Remote control

The primary function of remote control is to maintain a constant or nearly constant arterial blood pressure to perfuse all tissues, but in crisis situations, such as blood loss due to hemorrhage, the remote system decreases blood flow to less critical tissues (e.g., gastrointestinal tract) in order to maintain sufficient oxygen delivery to oxygen-sensitive critical tissues (e.g., brain and heart). Remote control has both a neural and endocrine component. Neural control is predominantly through a vasoconstriction regulated by the sympathetic nervous system and mediated by catecholamines. However, a variety of other neurotransmitters have also been described, such as nitric oxide (NO), serotonin (5-hydroxytryptamine), purines, and peptides, such as vasoactive intestinal peptide, substance P, tachykinins, and others. Numerous hormonal signals also affect peripheral vascular resistance. The primary vasoconstrictor hormones are angiotensin II, arginine vasotocin, catecholamines, and urotensin II. Vasodilator hormones include the natriuretic peptides and adrenomedullin.

Mechanical factors can also affect arterial radius both passively and actively. Passive compression of blood vessels, which commonly occurs when the skeletal or gastrointestinal muscles surrounding them contract, will increase vascular resistance. Compensatory mechanisms such as an increase arterial blood pressure may be invoked partially to compensate for the increased resistance under these circumstances. Vascular smooth muscle can also respond actively to mechanical stress. An increase in blood pressure will passively dilate blood vessels and decrease their resistance. To overcome this, some vessels such as those of the mammalian kidney constrict in response to mechanical distention in order to prevent excessive decreases in resistance. This constriction may result from an intrinsic response on the smooth muscle cell itself, or may be mediated by stretch of the surrounding underlying endothelial cells and subsequent release of the vasoconstrictor endothelin-1. Whether or not this occurs in fish renal arteries has not been confirmed. Many vessels respond to stretch by stretch relaxation, which is a gradual loss of tone after the vessel has been stretched. This, however, does not appear to have a beneficial effect on regulation of arterial blood pressure. For further information, **see Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels, **Brain and Nervous System**: Autonomic Nervous System of Fishes, and **Hormonal Responses to Stress**: Catecholamines.

Regulation of Tissue Perfusion, a Different Perspective

The example above describes the factors that affect blood pressure which is under the purview of the remote control system. However, one could place any one of these parameters at the top of the flow diagram. This also illustrates both the integrative nature and complexity of these control mechanisms. **Figure 4** prioritizes cardiovascular regulation from the standpoint of local control of nutrient delivery to the tissues. Thus, the main determinants of tissue perfusion are arterial blood pressure and vascular resistance. One can again continue to subdivide these determinants into their respective components and essentially re-create **Figure 3**, albeit from a different perspective. While these diagrams are extremely useful in illustrating the variety of factors involved in controlling particular processes, they do not show the interactive feedback control of these processes. As described above, this has not yet been done in detail in the fish cardiovascular system, but by borrowing principles developed in mammalian physiology we can begin to construct some of these pathways.

Examples of Complex and Simple Cardiovascular Regulation Using Negative Feedback Loops

Baroreceptor-Mediated Restoration of Arterial Blood Pressure Following Hemorrhage

Figure 5 shows the cardiovascular reflexes that accompany hemorrhage. This is a relatively sophisticated feedback system involving both central nervous system, endocrine and local responses. The initial loss in blood volume decreases central venous blood pressure by decreasing mean circulatory filling pressure. This is detected by low-pressure baroreceptors, presumably in or near the heart. In addition, the decrease in venous return sequentially decreases EDV, stroke volume, cardiac output, and arterial blood pressure. The fall in arterial blood pressure is detected by high-pressure baroreceptors in the gill and probably systemic arteries. A variety of reflexes are then initiated to restore both venous and arterial blood pressure. Fluid is rapidly transferred from the interstitial space into the vasculature both passively and actively; the drop in arterial pressure decreases capillary hydraulic pressure which promotes capillary reabsorption of interstitial fluid, and an active arterial vasoconstriction further reduces capillary pressure and augments fluid reabsorption. Long-term restoration of fluid volume is accomplished through regulation of water and salt balance by the gills, skin, and kidney. This, combined with venous constriction, increases central venous pressure and increases filling of the heart (EDV), which increases stroke volume. Stroke volume is also enhanced by an increase in ventricular contractility. An increase in heart rate plus the increase in stroke volume increases cardiac output and this combined with a baroreceptor-mediated increase in peripheral vascular resistance restores arterial blood pressure. This basic

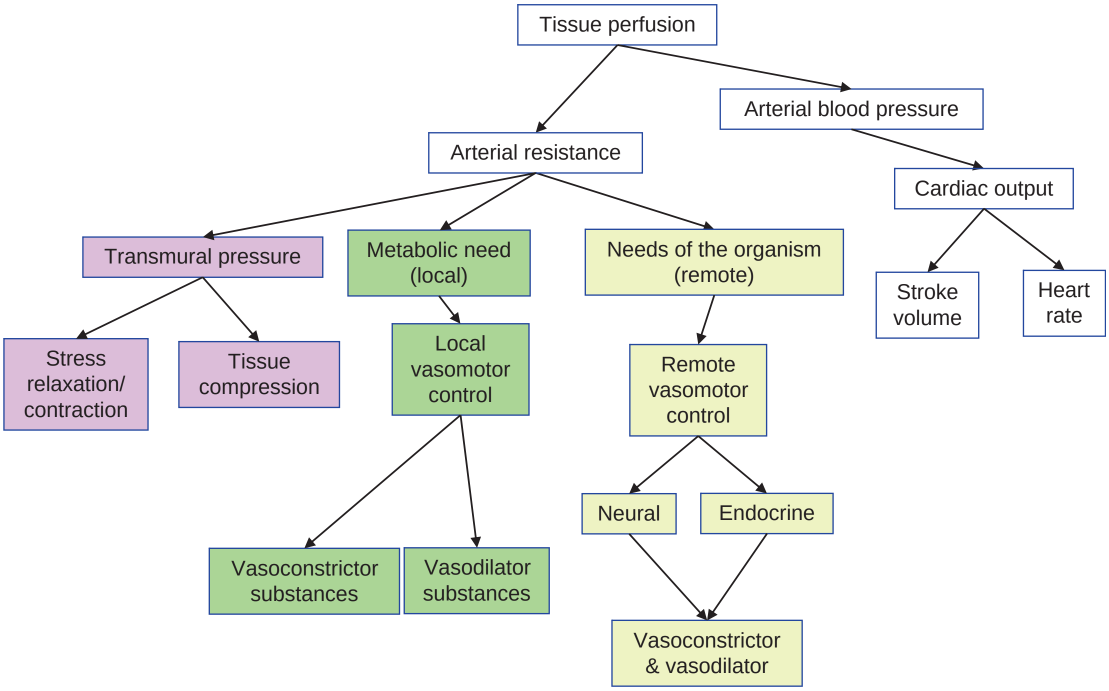

Figure 4 Flow diagram of the factors that affect tissue perfusion. These factors are essentially the same as those that affect arterial blood pressure in **Figure 3**, but rearranged from the perspective of blood flow to tissues. The cardiac factors affecting arterial blood pressure have been abbreviated for simplicity. See text for details.

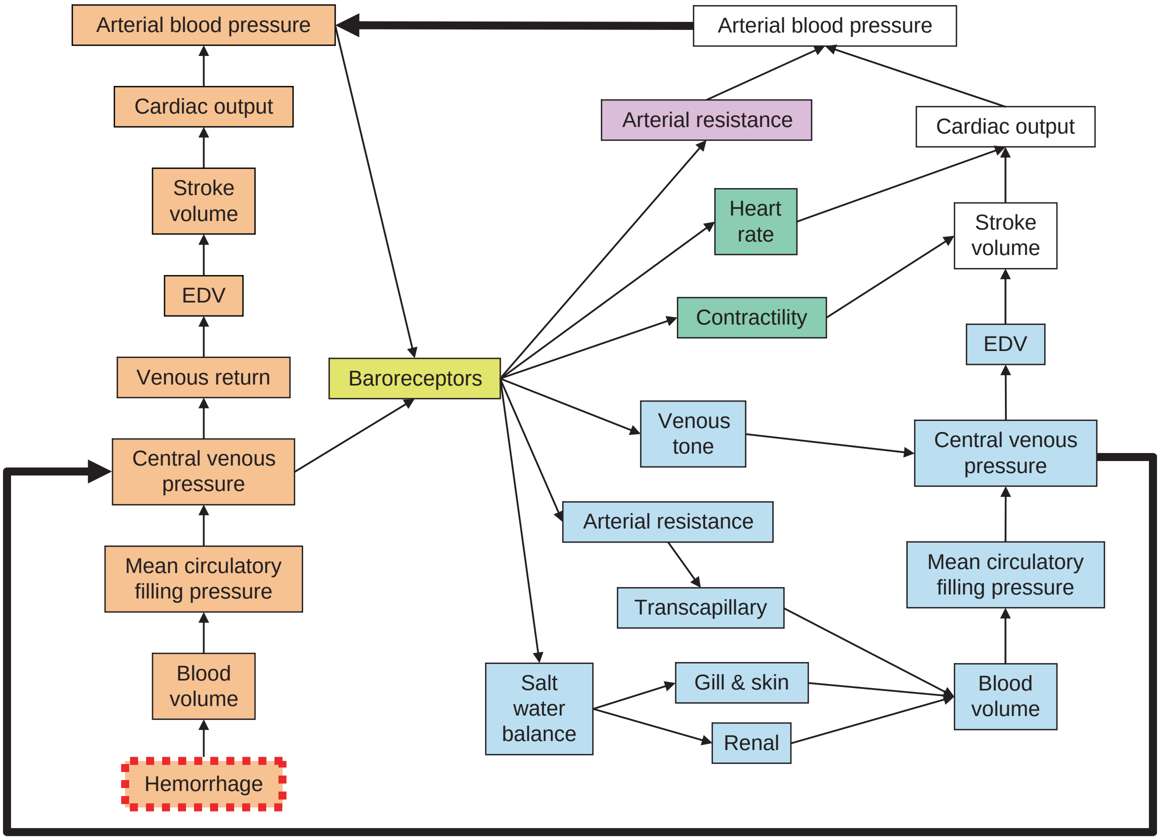

Figure 5 An integrated baroreceptor-mediated negative feedback mechanism for restoring arterial blood pressure following hemorrhage. The immediate effects of hemorrhage are shaded in red. See text for details.

mechanism, with a few minor modifications, can be utilized to respond to hypovolemia accompanying freshwater to saltwater adaptation, or utilized in the opposite direction during saltwater to freshwater adaptation.

Local Regulation of Blood Flow in Response to Oxygen Demand

Figure 6 shows a relatively simple feedback loop in the peripheral vasculature. Here, an increase in tissue metabolism increases oxygen consumption which lowers the partial pressure for oxygen (P_{o_2}) in and around the tissue and nearby blood vessels. The decreased P_{o_2} in the vascular smooth muscle cell is detected by an as-yet unknown O_2 sensing mechanism and results in vasodilation. This increases tissue blood flow and the increased oxygen delivery restores P_{o_2}.

Other Feedback Mechanisms

There are many examples of negative feedback regulation in the cardiovascular system. Two of the most dramatic are the cardiovascular changes accompanying exercise and digestion. Additional information on these can be found in **Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming and Integrated Responses of the Circulatory System to Digestion.

Examples of Cardiovascular Regulation Using Feedforward Mechanisms

Feedforward mechanisms anticipate the need for a change in a regulated parameter without directly monitoring that parameter and they are typically transient in nature. There are numerous feedforward responses. One example is the gastric phase of digestion whereupon eating a meal, the distention of the stomach increases arterial blood pressure in anticipation of the need to increase blood flow through the gastrointestinal tract (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion). Another example is the startle reflex which is often initiated by an unexpected environmental cue such as noise. The startle reflex in mammals is characterized by an increase in heart rate and blood pressure which is the opposite of that in fish where heart rate and blood pressure decrease.

Examples of Cardiovascular Regulation Using Rheostasis

Reactive Rheostasis

In reactive rheostasis, the setpoint is changed to accommodate two disparate parameters either of which by itself would have untoward consequences. The cardiovascular response to hypoxia is a good example of reactive rheostasis. When environmental oxygen (P_{o_2}) falls to a critical level, most fish exhibit a decrease in heart rate and arterial blood pressure. This in turn decreases cardiac work and lowers the energy requirements of the heart. Thus, while the blood pressure setpoint is now lowered below the optimal value, the reduction in cardiac work permits conservation of limited resources (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia). Another good example of reactive rheostasis can be found in euryhaline fish moving from freshwater to saltwater (or vice versa). When a fish moves from freshwater to saltwater, it is now faced with hypovolemia due to osmotic loss of water and hypernatremia due to a net inward sodium gradient. Under these circumstances the fish drink seawater to replenish the lost volume but this further increases the sodium load. Typically when this occurs the fish tolerates an elevated plasma sodium load and at the same time maintains blood volume at a slightly lower level. Thus, both the plasma sodium and fluid volume are regulated at slightly different values. Exercise and digestion are also examples of reactive rheostasis in that the blood pressure is elevated in order to provide better perfusion of working muscle in the former, and the gastrointestinal tract in the latter.

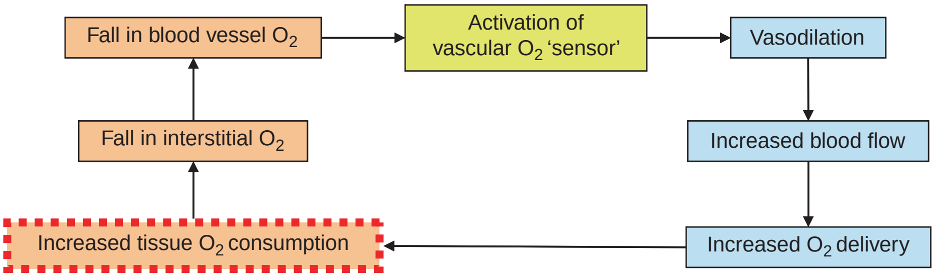

Figure 6 Local negative feedback mechanism for increasing oxygen delivery to tissues in response to increased tissue oxygen demand. The immediate effects of increased tissue metabolism are shaded in red.

Programmed Rheostasis

Programmed rheostasis accompanies a change in life-cycle. A good example of programmed rheostasis is the parr-smolt transformation that accompanies anadromous migration of salmonids. Programmed rheostasis also accompanies transformation of larval to adult phenotypes and the many physiological changes accompany the reproductive cycle, including spawning migrations.

Glossary

Antidromic stimulation Electrical stimulation of efferent axons in a nerve toward the CNS (i.e., a reversal of their normal direction of conduction of impulses) in order to identify their cell bodies for recordings with microelectrodes inserted into the brainstem.

Capsaicin The chemical irritant in red hot chilli peppers, recognized as stimulating J-receptors in vertebrates that cause changes in ventilation and heart rate to protect the gills or lungs from chemical damage.

Cardiac vagal preganglionic neurons (CVPNs) VPNs that supply the cardiac ganglion.

Cardiorespiratory coupling (CRC) Modulation of cardiac intervals by the respiratory rhythm resulting in specific temporal relationships.

Cardiorespiratory interactions (CRIs) Modulation of cardiac intervals by the respiratory rhythm resulting in an identifiable respiratory component in the pattern of heart rate variability.

Cardiorespiratory synchrony (CRS) Modulation of cardiac intervals by the respiratory rhythm resulting in 1:1 coupling between heart beats and ventilation.

Dorsal motor nucleus of the vagus (DVN) The concentration of cell bodies in a group close to the 4th ventricle in the medulla oblongata of preganglionic neurons supplying efferent axons to the vagus nerve.

Power spectral analysis A statistical analysis of the variability in timing of activity in a rhythmically active system such as heart beat that identifies the separate components contributing to this variability (such as the respiratory cycle).

Respiratory sinus arrhythmia (RSA) Central control mechanism integrating heart rate with the respiration cycle. The increase in heart rate and gating of the baroreceptor response during inspiration described for mammals but lately suggested to be shown by reptiles such as the rattlesnake.

Vagal preganglionic neurons (VPNs) Neurons with their cell bodies in the brainstem that supply efferent axons to ganglia situated on target organs in the viscera such as the heart or intestine.

Vagal tone The chronic inhibitory control of heart rate exerted by the parasympathetic nervous system via the vagus nerve.

Vagus nerve The X cranial nerve (from Greek; vagari, the wanderer) that travels from the brain stem to innervate the heart, respiratory muscles, and chemo- and mechanoreceptors on the gills, as well as much of the intestine and other visceral organs.

Introduction

The jawless fishes (Cyclostomata) ventilate gill pouches with tidal water flow while the jawed fishes ventilate their gills unidirectionally, with water streaming in at the mouth and out over the gills (**see also Hagfishes and Lamprey**: Hagfishes and **Hagfishes and Lamprey**: Lampreys: Energetics and Development). In jawed fishes, there is a close matching of respiratory water flow and cardiac output, according to their relative capacities for oxygen (the ventilation/perfusion ratio), with water flow regulated at 10–20× blood flow. These different water and blood flows are needed to match their relative capacities to carry oxygen, which in water is limited by its solubility but in blood is increased by its reversible combination with hemoglobin in red cells (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin). This flow matching has been shown to optimize respiratory gas exchange over a functional countercurrent at the exchange surfaces of the gills (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). As the heart delivers blood directly to the gills along the ventral aorta and water is pumped over the gills by a double-action buccal and opercular or septal pump (**see also Gas Exchange**: Respiration: An Introduction), both these flows are

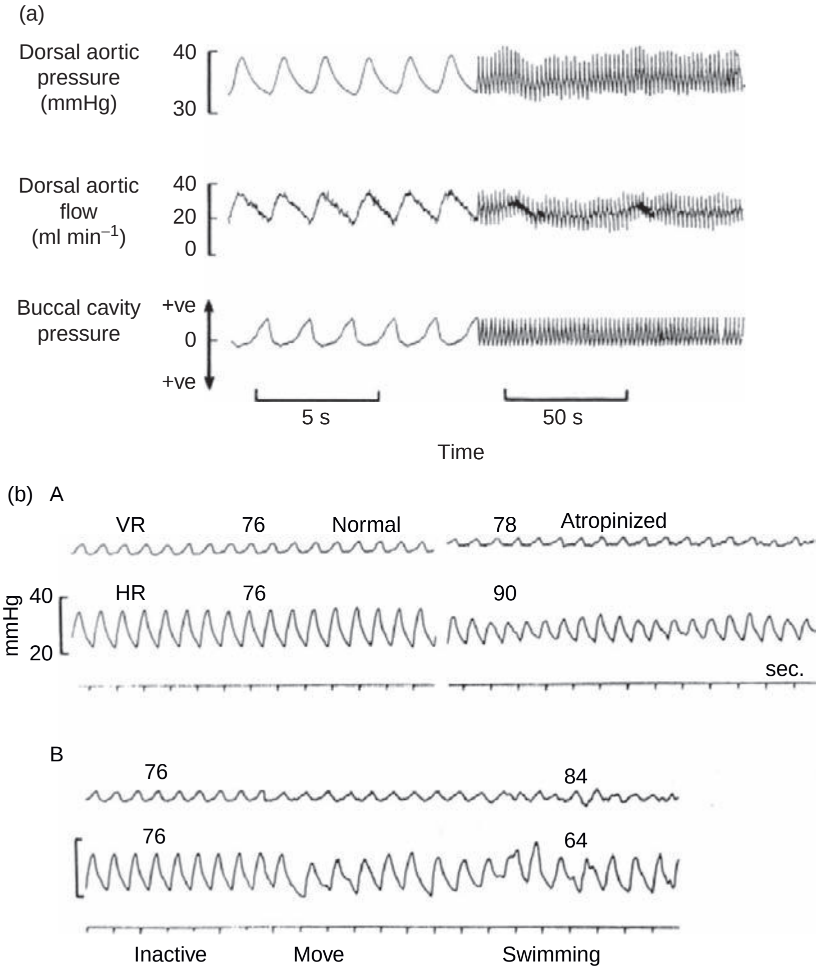

Figure 1 (a) Blood pressure and flow in the dorsal aorta measured from unrestrained cod, *G.* morhua held in aerated seawater are highly pulsatile and often in phase with ventilation, measured as water pressures in the buccal cavity. (b) Ventilation (VR) and heart (HR) rates recorded as pressures from unrestrained and inactive dogfish, *S. canicula* at 23°C show long periods of apparent CRS that is abolished following injection of atropine (A) and lost during a spontaneous period of activity (B). markedly pulsatile (**Figure 1**). Consequently, close beat-to-beat temporal relationships between them would seem necessary to achieve close matching of flows.

A 1:1 ratio of the cardiac frequency and the ventilatory frequency, termed cardiorespiratory synchrony (CRS), has long been hypothesized as being important for the optimization of respiratory gas exchange in fish. However, recordings of CRS have proved elusive and many fish biologists have denied that it is anything other than a transient effect. Failure to observe CRS may have been due to over-invasive techniques of measurement, and reluctance to accept its existence has now been overcome by a series of long-term observations on Atlantic cod (*Gadus morhua*). Theoretically, CRS should be particularly advantageous during periods of respiratory distress or when conserving energy, which appears to be the case. Fish in normoxia showed a variety of phase relationships between pulsatile blood flow and ventilation, but during progressive hypoxia the heartbeat became synchronized with a specific part of the ventilatory cycle (**Figure 2**). Thus, there is direct evidence for fine control of heart rate, including its beat-to-beat modulation by the respiratory cycle that generates cardiorespiratory interactions (CRIs), culminating in CRS. In addition, more subtle modulation of heart rate by respiratory activity, termed cardiorespiratory coupling (CRC), has been demonstrated by power spectral analysis of cardiac intervals. The relevance of CRC to gas exchange was demonstrated by its abolition following cardiac vagotomy that affected oxygen uptake (**Figure 3**).

The autonomic nervous system is the main short-term modulator of heart rate in fish (**see also Brain and**

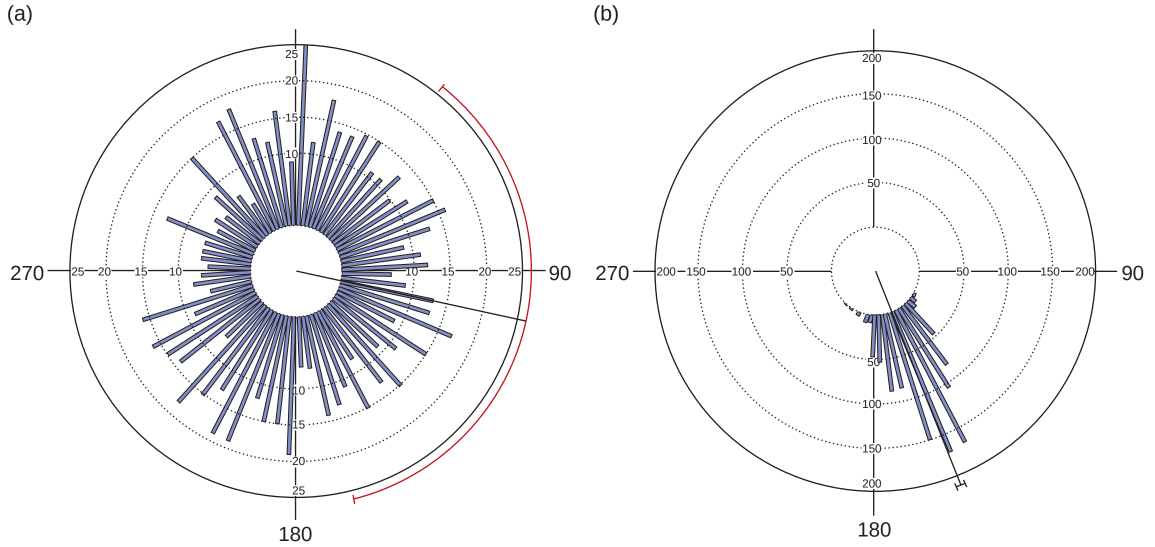

Figure 2 Polar diagrams of the phase relationship between heart beats and the ventilatory cycle in cod. The ventilatory cycle is depicted as a 360-degree circle with the occurrence of heart beats plotted as histograms around this circle. In normoxic fish (a) the heart beats occur at a range of phases but during hypoxia (b) they cluster in a specific phase. Redrawn from unpublished data of L. Jensen, R. Varne, I. Findorf, P. Domenici, DJ. MacKenzie and JF. Steffensen.

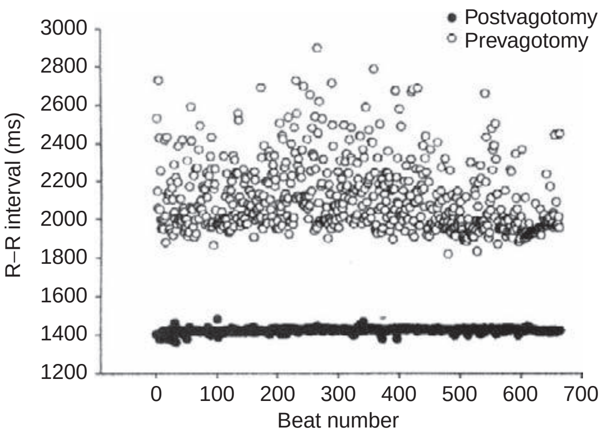

Figure 3 Sculpin, *M. scorpius*: the effect of vagotomy on heart rate variability: in the intact fish heart rate is highly variable. Vagotomy (sectioning of the vagus nerve on both sides of the fish) caused heart rate to rise (cardiac interval R–R was reduced) and to become unvarying, illustrating that the variability was generated via the vagus. From Campbell HA, Taylor EW, and Egginton S (2004) The use of power spectral analysis to determine cardio-respiratory control in the short-horned sculpin *Myoxocephalus scorpius*. *Journal of Experimental Biology* 207: 1969–1976.

Nervous System: Autonomic Nervous System of Fishes). In all fish except cyclostomes, the heart receives inhibitory innervation from the parasympathetic division via the vagus nerve. Removal of cardiac vagal tone in the sculpin (*Myoxocephalus scorpius*), by cutting the cardiac nerves, increases heart rate and decreases cardiac interval. In addition, heart rate is much less variable (see **Figure 3**). An important source of this heart rate variability is modulation by the respiratory rhythm. This respiratory modulation of heart beat is exerted predominantly by variations in inhibitory vagal tone imposed by activity in cardiac vagal preganglionic neurons (CVPNs) within the medulla oblongata. So efferent control via the vagus nerve both slows the heartbeat and couples it to the respiratory cycle. The neural basis of respiratory modulation of heartbeat seems to vary between the major groups of fishes so they are considered separately.

Elasmobranchs

The elasmobranch fishes (class Chondrichthyes) are likely the earliest vertebrates with clearly differentiated parasympathetic and sympathetic components of the autonomic nervous system. They are also the earliest group known to have an inhibitory vagal innervation of the heart (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes). However, nervous cardioregulation in elasmobranchs solely depends on variations in the degree of cholinergic vagal tonus on the heart because the sympathetic nervous system does not extend forward into the head so that they have no sympathetic nerves supplying the heart and branchial circulation. Continuous stimulation of the vagus nerve, as well as application of its neurotransmitter acetylcholine, inhibits heart rate. As in other vertebrates, this effect is antagonized by atropine, implying that it is mediated by muscarinic cholinoceptors. A cardiac vagal tonus increases during hypoxia and slows heart rate, is abolished by hyperoxia resulting in an increased heart rate, and is augmented when temperature increases. Furthermore, the long periods of 1:1 synchrony between heartbeats and ventilation that are present in unrestrained dogfish (*Scyliorhinus canicula*) allowed to settle in normoxic seawater are abolished by injection of atropine (**Figure 1**(**b**)).

In the dogfish, the vagus nerve divides to form, at its proximal end, branchial branches 1, 2, 3, and 4, which contain skeletomotor fibers innervating the intrinsic respiratory muscles of gill arches 2, 3, 4, and 5, respectively (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish). The vagus also sends two branches to the heart, on each side of the fish, the branchial cardiac (BC) that arises from the post-trematic, fourth branchial branch of the vagus, and the visceral cardiac (VC) that arises close to the origin of the visceral branch of the vagus (see **Figure 4**). High levels of spontaneous efferent activity can be recorded from the central cut end of a BC branch of the vagus in decerebrate, paralysed dogfish (**Figure 5**). This activity can be attributed to two types of unit. Some units fired sporadically and increased their firing rate during hypoxia. Exposure to hypoxia caused a bradycardia that was abolished by atropine. Injection of capsaicin into the ventilatory stream of the dogfish was accompanied by a marked bradycardia. Both of these stimuli powerfully stimulated activity in the non-bursting units recorded from the central cut end of the BC. Consequently, it is activity in these units that likely causes reflex changes in heart rate, as well as playing a role in the determination of the overall level of vagal tone on the heart. Other, typically larger, units recorded from the BC fired in rhythmical bursts that were synchronous with ventilatory movements or with bursts of activity in respiratory branches innervating the gills, but were unaffected by hypoxia (**Figure 5**). Thus, it is hypothesised that these units showing respiration-related activity may serve to synchronise heartbeat with ventilation in dogfish. Injection of neural tracers located 90% of vagal preganglionic neurons (VPN) in the dorsal motor nucleus of the vagus (DVN) of the dogfish. About 8% of the total population of VPN were in a clearly distinguishable group of cells with scattered distributions outside of the DVN, identified as cardiac VPN (CVPN), innervating the heart via the BC nerve (see **Figure 4** and **Figure 6**(**a**)). They constitute about 45% of CVPN, with the rest located in the DVN. The ray, *Raja clavata*, has only one cardiac vagal branch on each side. This nerve is supplied by CVPN in the DVN and others in lateral locations outside the DVN that again constitute about 45% of total CVPN. This dual location of CVPN

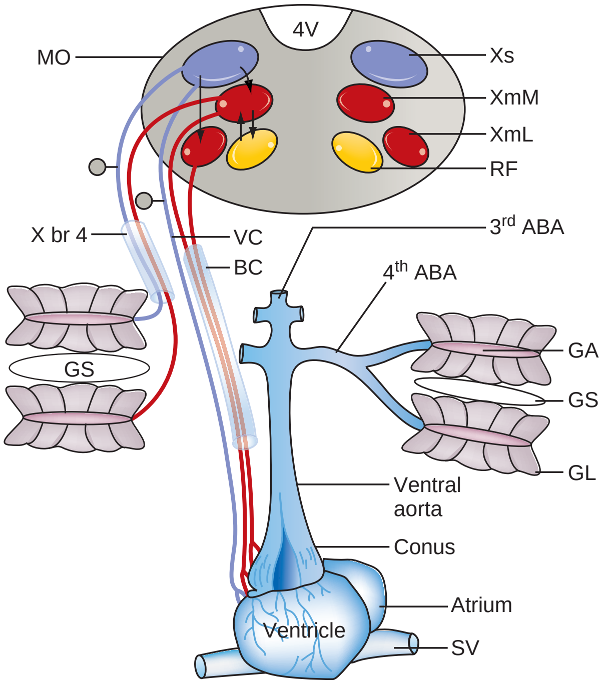

Figure 4 Schematic diagram of the central projections of cardiac and respiratory branches of the X cranial nerve, the vagus to illustrate the nervous control of CRIs in the dogfish. The branches of the vagus are: BC, branchial cardiac branch; VC, visceral cardiac branch; Xbr4, 4th branchial branch. The nuclei in the medulla oblongata (MO) integrating central control are: RF, reticular formation; XmL, lateral vagal motor nucleus; XmM, medial vagal motor nucleus; Xs, vagal sensory nucleus. ABA, afferent branchial artery; GA, gill arch; GL, gill lamellae; GS, gill slit; SV sinus venosus; 4V, 4th ventricle. See text for details of mechanisms.

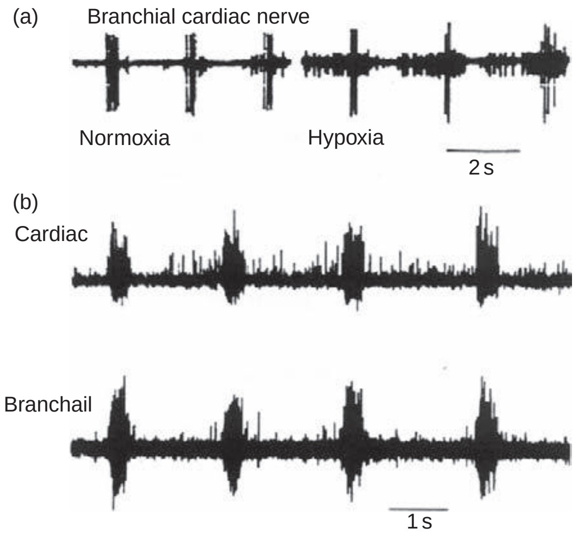

Figure 5 Dogfish: Efferent activity in cardiac and branchial vagi of decerebrate and paralyzed fish. (a) Recordings from individual nerve fibres in a cardiac branch before and after hypoxia (nonbursting activity seems to be responsible for reflex control of heart rate and generation of vagal tone, which increases during hypoxia). (b) Efferent activity recorded simultaneously from the cardiac branch and a branchial (respiratory) branch of the vagus to show sychronous bursts. From Taylor EW (1992) Nervous control of the heart and cardiorespiratory interactions. In: Hoar WS, Randall DJ, and Farrell AP (eds.) *Fish Physiology, Volume 12, Part B*, pp. 343–387. New York: Academic Press.

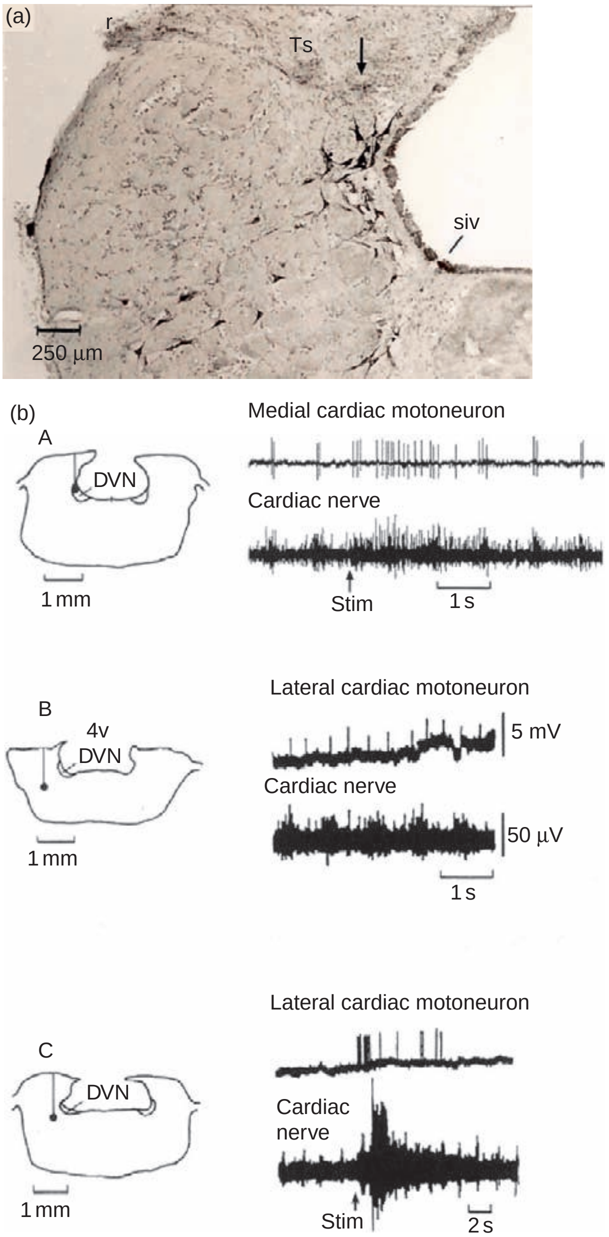

Figure 6 A neuranatomical study revealed two locations for CVPN in the brainstem: a medial group in the dorsal vagal motor nucleus and a scattered ventro-lateral group outside the DVN. (a) A transverse section taken through the brainstem of the dogfish, *S. canicula*, through the midpoint of XmM and XmL (see **Figure 4**) to show CVPN labeled black after application of horseradish peroxidase to the branchial cardiac nerve. They are located in the DVN close to the 4th ventricle (grouped directly below the vertical arrow) and in scattered locations ventro-lateral to the DVN. (r, rootlet of vagus nerve; siv, sulcus intermedius ventralis in the wall of the 4th ventricle; Ts, sensory projection from the cardiac vagus). (b) Dogfish: central recordings of activity in CVPN: extracellular recordings from CVPN in the brainstem of the dogfish, identified by antidromic stimulation of the cardiac nerve followed by dye injection (the course of the electrode and the recording position are shown by the line and filled circle); together with simultaneous recordings of activity in the ipselateral cardiac nerve. A unit located in the DVN (A) fired in bursts that contributed to the respiration-related activity recorded from the cardiac nerve and responded to mechanical stimulation of a contralateral gill septum (stim). Units recorded from lateral locations, outside the DVN, fired regularly (B), sporadically, or were silent (C), except when responding to mechanical stimulation of a gill septum (stim). Fish were decerebrated and paralyzed, with the gills irrigated by a continuous flow of aerated water, removing any phasic influences from peripheral receptors or centers higher in the CNS. From Taylor EW (1992) Nervous control of the heart and cardiorespiratory interactions. In: Hoar WS, Randall DJ, and Farrell AP (eds.) *Fish Physiology, Volume 12*, *Part B*, pp. 343–387. New York: Academic Press.

has been shown to have important functional implications.

In the dogfish, the visceral cardiac branch (VC) has all of its CVPN in the DVN. Efferent activity recorded from the VC was less closely coupled with respiration and this nerve was less effective than the BC in slowing the heart when stimulated peripherally (i.e., toward the heart) with trains of electrical pulses. However, central stimulation of a VC (i.e., toward the brain) with a BC intact caused a major bradycardia, suggesting that the VC carries afferent nerve fibers that innervate the heart and that its primary role may be sensory (see **Figures 4** and **13**).

The separation of efferent cardiac vagal activity recorded from the BC into respiration-related and non-respiration-related units is based on the distribution of their neuron cell bodies in the brainstem, as described above. Extracellular recordings from CVPN identified in the hindbrain of decerebrate, paralyzed dogfish by antidromic electrical stimulation of a branchial cardiac branch, revealed that neurons located in the DVN were spontaneously active, firing in rhythmical bursts that contributed to the respiration-related bursts recorded from the intact nerve (see **Figure 6**(**b**)A). Direct connections between bursting CVPN and RVM are possible in the dogfish hindbrain, as both are located in the DVN with an overlapping rostro-caudal distribution (**Figure 4**; **see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish). As the bursts are synchronous, the innervation of CVPN is likely to be excitatory rather than inhibitory, as described for the mammal, and it is equally possible that a direct drive from a central pattern generator operates both on the RVM and the CVPN (see **Figures 4** and **13**, and figure 2 in **Control of Respiration**: Generation of the Respiratory Rhythm in Fish). Neurons located ventro-laterally outside of the DVN were either spontaneously active, firing regularly or sporadically but never rhythmically (**Figure 6**(**b**)B), or were silent (**Figure 6**(**b**)C). Thus, the two types of efferent activities recorded from the cardiac nerve arise from the separate groups of CVPN, as identified by neuranatomical studies. As activity was recorded from the central cut end of the cardiac vagus, or centrally from CVPN, in the decerebrated, paralyzed dogfish, provided with a constant, nonpulsatile supply of aerated water, the respiration-related activity recorded from CVPN in the DVN must have been generated by central interactions. However, all of the spontaneously active CVPN from both divisions and some of the silent CVPN fired in response to mechanical stimulation of a gill arch (**Figures 6**(**b**)A and C), indicating that stimulation of mechanoreceptors on the gills may recruit CVPN in normally breathing fish, possibly reinforcing central feed-forward control as described for control of ventilation (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish). Thus, in the intact fish, normal breathing movements that stimulate peripheral mechanoreceptors on the gills may, by a reflex pathway, generate activity in CVPN and consequently in the cardiac vagi, affecting heart rate. This implies that the typical reflex bradycardia in response to hypoxia may arise both directly, following stimulation of peripheral chemoreceptors and indirectly, via increased ventilation, which by stimulating branchial mechanoreceptors may increase vagal outflow to the heart. This is reminiscent of, but opposite in kind to, the hypoxic response in the mammal, where stimulation of lung stretch receptors causes an increase in heart rate.

Besides slowing the heart, respiration-related efferent activity in the cardiac vagi may entrain the heart. This possibility was confirmed by peripheral electrical stimulation of branchial cardiac nerves in the prepared dogfish. Although continuous vagal stimulation normally slowed the heart, it proved possible to drive the denervated heart at a rate either lower or somewhat higher than its intrinsic rate with brief bursts of stimuli, delivered down one BC. Interestingly, similar results were obtained from a mammal. In the anaesthetized dog, electrical stimulation of the vagus nerve toward the heart with brief bursts of electrical stimuli caused heart rate to synchronize with the stimulus over a wide range of frequencies.

Teleosts

In teleosts (class Teleostei), the vagus nerve is cardioinhibitory, again through muscarinic cholinoceptors on the heart. Variations in vagal tone affect heart rate and there is an inhibitory vagal tonus that varies with temperature in a variety of teleost species. In addition, the sympathetic chains extend into the head in teleosts, where they contact cranial nerves, forming a vagosympathetic trunk, and adrenergic fibers innervate the heart of some teleosts such as rainbow trout (*Oncorhynchus mykiss*). Thus, teleosts may be considered the earliest group of vertebrates with both sympathetic and parasympathetic control of the heart (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes). Even so, work on a range of vertebrates, including mammals, has demonstrated that fine control of the heart likely needed to generate CRIs is predominantly parasympathetic. Accordingly, studies on the mechanisms of respiratory modulation of heart rate in teleosts have focused on cardiac control from the parasympathetic nervous system, via the X cranial nerve, the vagus, and its interactions with activity in the cranial nerves supplying the respiratory muscles, that are inserted around the orobranchial cavity (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish).

A distribution of VPNs and CVPNs similar to that described above for the dogfish is recognized for Atlantic cod and rainbow trout. About 12% of VPNs were located outside the DVNs and although most of these were CVPNs, some of them innervated the gills, possibly supplying vasomotor input to branchial blood vessels. In pacu, *Piaractus mesopotamicus*, CVPNs are distributed in separate nuclei within the DVNs, a ventral group containing about 60% of cell bodies and a dorsal group containing about 40% of cell bodies. In addition, a small number of cell bodies, scattered laterally outside of the DVN, constitute only about 2% of the total number of CVPNs. Therefore, the neuranatomical basis for control of the heart and CRI is inconsistent within the teleost fishes.

Work on teleosts has stressed the importance of peripheral receptor inputs in the genesis of CRS. In rainbow trout, *O. mykiss*, an exact synchrony can develop between ventilation and heart beat during progressive hypoxia. Normoxic heart rate is faster than ventilation and so the hypoxia-induced increase in ventilation rate and the reflex bradycardia converged to produce a 1:1 synchronization of the two rhythms. Both bradycardia and synchrony are abolished by atropine, showing that both are generated by efferent vagal control. In addition, hypoxic heart rate in the trout synchronized with an imposed phasic flow of water rather than the spontaneous breathing efforts of the intubated fish. Clearly, this synchronization was generated by reflex pathways, presumably arising from stimulation of mechanoreceptors on the gills.

Respiration-related bursting activity is absent from the cardiac nerves in resting normoxic pacu, *P. mesopotamicus*, and is only recorded from the cardiac vagus when fish hyperventilate or cough, implying that the bursts arise reflexly, following stimulation of branchial mechanoreceptors. Each burst is accompanied by an increased cardiac interval (**Figure 7**). Brief cessation of water flow to the gills of a lightly anaesthetized fish stimulated a bout of increased ventilatory effort, accompanied by bursts of activity in the cardiac vagus, with consequent transient bradycardia (**Figure 8**). In fish rendered moderately hypoxic by reduction of the flow of water irrigating the gills, a period of spontaneously increased ventilatory amplitude was accompanied by respiration-related bursts of activity in the cardiac vagus, which appeared to recruit the heart (**Figure 9**). As in the dogfish, phasic peripheral stimulation of the cardiac vagus (**Figure 10**) or central stimulation of respiratory branches of cranial nerves VII, IX, and X (**Figure 11**) can entrain the heart over a wide range of frequencies. Thus, increased ventilatory efforts generate bursting activity in the cardiac vagus, which can recruit the heartbeat.

Thus, we are left with apparently conflicting evidence on the mode of generation of CRS. In elasmobranchs, it may be primarily generated by central interactions in inactive, normoxic, or hyperoxic fish when cardiac vagal tone is low. In teleosts, it appears during hypoxia perhaps as a result of stimulation of branchial mechanoreceptors during forced ventilation and is generated reflexly by increased vagal tone. There is, however, some evidence that central interactions may generate some CRS in

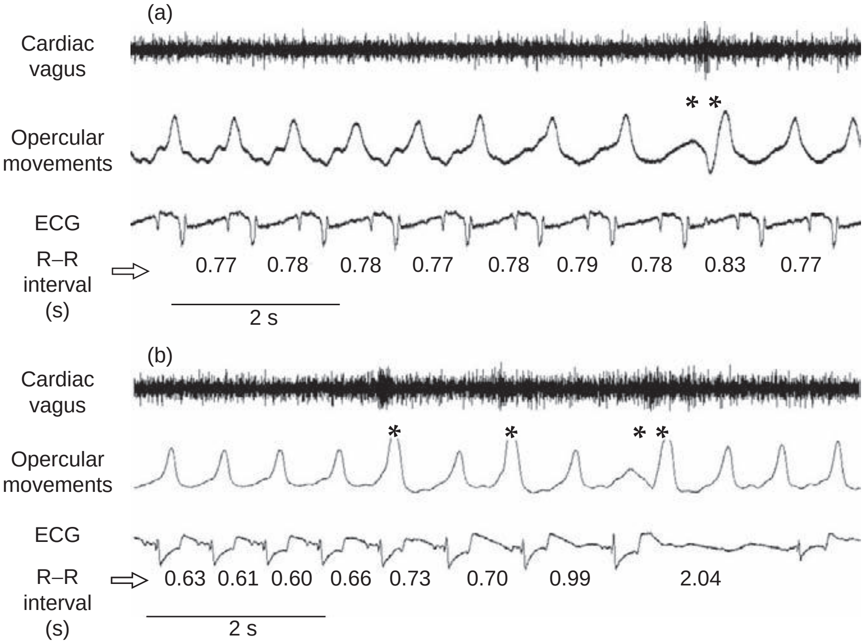

Figure 7 Pacu, *P. mesopotamicus* – recordings from the cardiac vagus, ventilation and ECG. There are no routinely respiration-related bursts in cardiac vagus in normoxic fish. * increased ventilatory effort; ** cough. From Leite CAC, Taylor EW, Guerra CDR, Florindo LH, Belão T, and Rantin FT (2009) The role of the vagus nerve in the generation of cardiorespiratory interactions in a Neotropical fish, the pacu, *Piaractus mesopotamicus Journal of Comparative Physiology A* 195: 721–731.

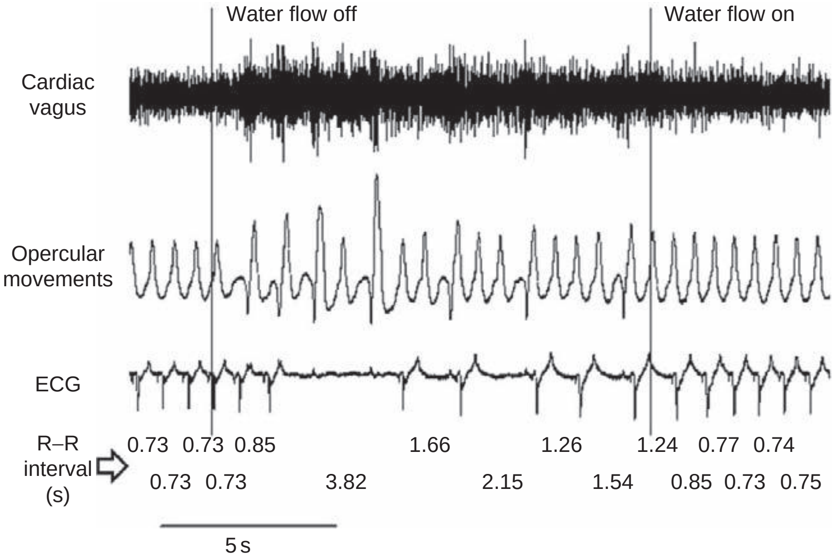

Figure 8 Pacu – effect of stopping the water flow irrigating the gills. Increased activity in cardiac vagus is associated with increased ventilatory effort and generates a bradycardia. From Leite CAC, Taylor EW, Guerra CDR, Florindo LH, Beläo T, and Rantin FT (2009) The role of the vagus nerve in the generation of cardiorespiratory interactions in a Neotropical fish, the pacu, *Piaractus mesopotamicus Journal of Comparative Physiology A* 195: 721–731.

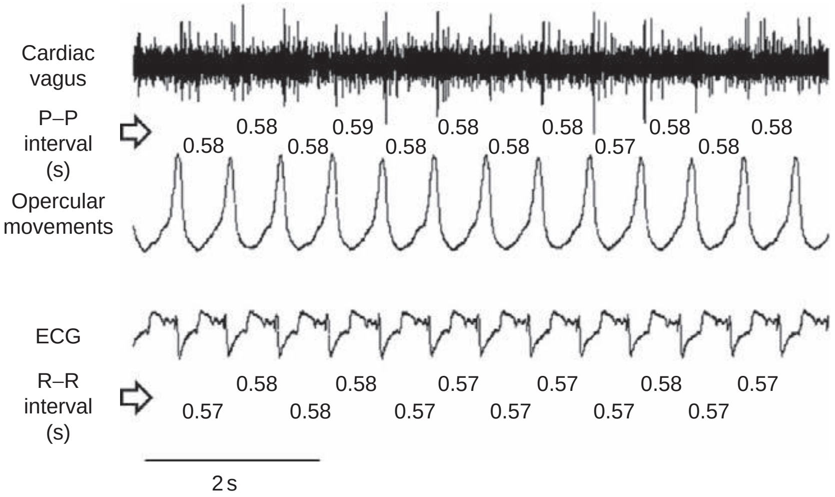

Figure 9 Pacu – restricting water flow increased ventilation amplitude, generated bursting activity in the cardiac vagus that recruited the heart. From Leite CAC, Taylor EW, Guerra CDR, Florindo LH, Beläo T, and Rantin FT (2009) The role of the vagus nerve in the generation of cardiorespiratory interactions in a Neotropical fish, the pacu, *Piaractus mesopotamicus Journal of Comparative Physiology A* 195: 721–731.

teleosts. Recordings of respiration-related bursting activity in the cardiac nerve of pacu were concurrent with bursts in the mandibular branch of the V cranial nerve and both anticipated activity in the respiratory branches of the VII, IX, and X cranial nerves (**Figure 12**(**a**)). This was also the case in recordings from dogfish (see figure 4 in **Control of Respiration**: Generation of the Respiratory Rhythm in Fish). In both elasmobranchs and teleosts, the distribution of motor neurons supplying the V nerve in the brainstem does not overlap with the distribution of CVPN or with neurons supplying the other respiratory nerves (see **Figure 12**(**b**)). In addition, central electrical stimulation of the mandibular branch of the V in pacu is without effect on heart rate, while central stimulation of respiratory branches of the VII, IX, and X cranial nerves either slows or recruits the heart (**Figure 11**). Accordingly, concurrence of bursting activity in the cardiac nerve with activity in the V cranial nerve is very likely to be generated centrally, possibly by inputs to both groups of neurons from the central respiratory pattern

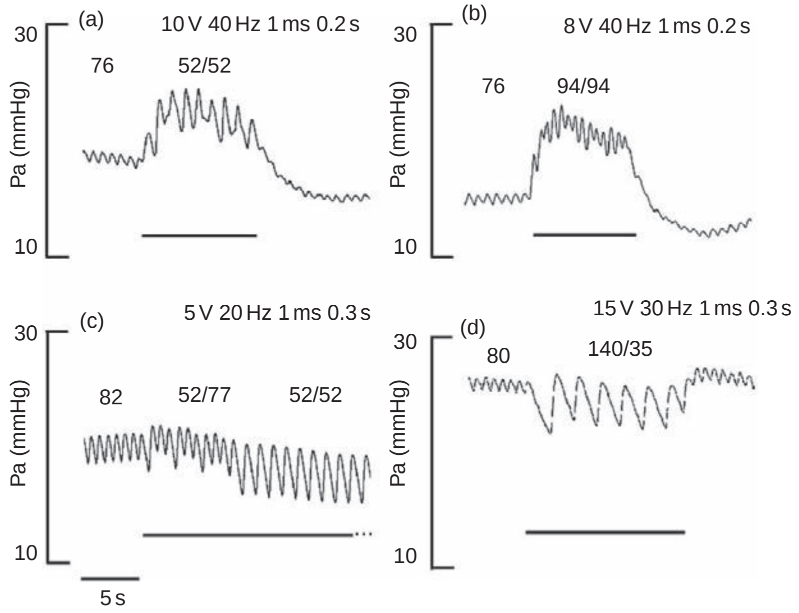

Figure 10 (a–d) Pacu – pulsed efferent stimulation of the cardiac vagus can drive the heart both slower (a, c) or faster (b) than its intrinsic rate. At high stimulation rates the heart was recruited at a simple fraction of the rate (e.g., 1:4) (d). Stimulation protocol is shown above each recording. From Taylor EW, Leite CAC, Florindo LH, Beläo T, and Rantin FT (2009) The basis of vagal efferent control of heart rate in a Neotropical fish, the pacu, *Piaractus mesopotamicus. Journal of Experimental Biology* 212: 906–913.

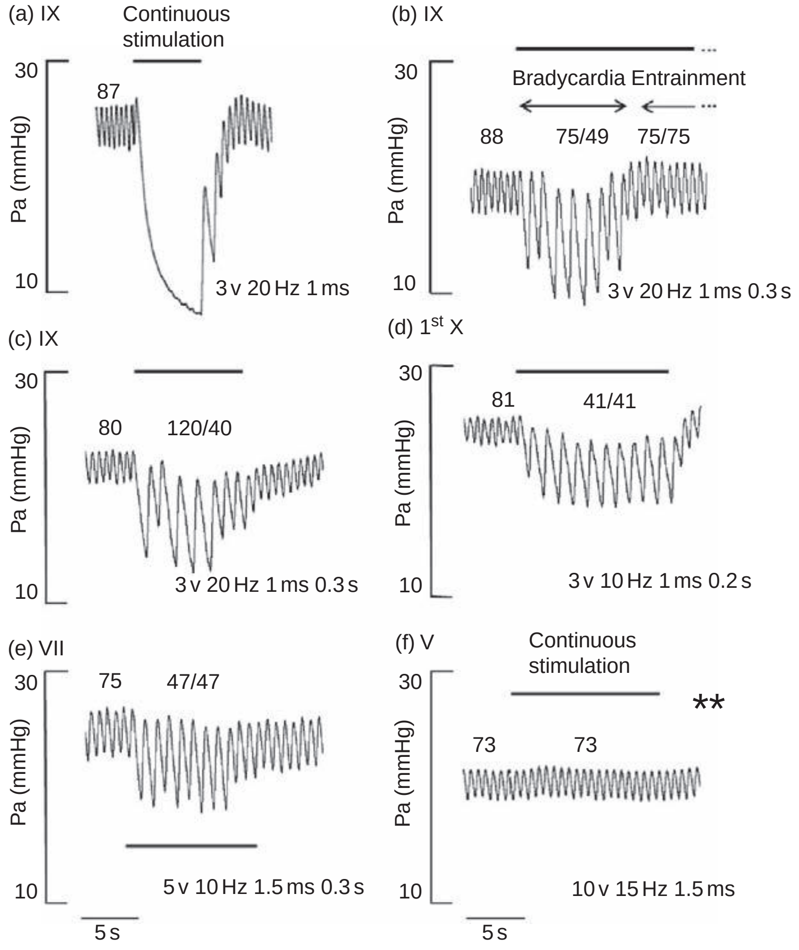

Figure 11 Pacu – effects on heart rate of central stimulation of cranial nerves IX, X, VII, and V supplying respiratory muscles. Continuous stimulation of IX caused cardiac arrest. Pulsed stimulation of VII, IX, and X recruited the heart but stimulation of V was without effect. Stimulation protocol is shown below each recording and the intrinsic and recruited rates are added above each trace. From Taylor EW, Leite CAC, Florindo LH, Beläo T, and Rantin FT (2009) The basis of vagal efferent control of heart rate in a Neotropical fish, the pacu, *Piaractus mesopotamicus. Journal of Experimental Biology* 212: 906–913.

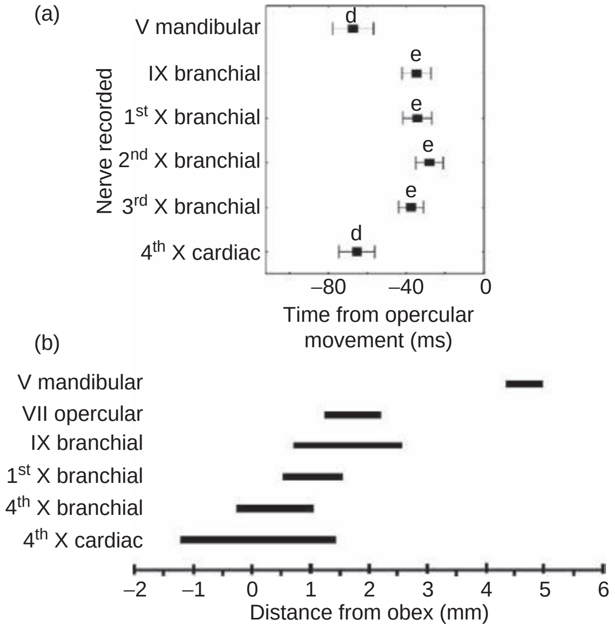

Figure 12 (a) Pacu – recordings of efferent activity in cardiac and respiratory nerves revealed that the bursts of activity in cardiac nerves are synchronous with activity in the V cranial nerve and both anticipate activity in the IX and X cranial nerves (modified from Taylor EW, Leite CAC, Florindo LH, Beläo T, and Rantin FT (2009) The basis of vagal efferent control of heart rate in a Neotropical fish, the pacu, *Piaractus mesopotamicus. Journal of Experimental Biology* 212: 906–913.). (b) Pacu – rostro-caudal distribution of neurons supplying cranial nerves that innervate respiratory muscles and the CVPN (Xcardiac). All except those supplying the V cranial nerve have an overlapping distribution with CVPN. Modified from Taylor EW, Leite CAC, Florindo LH, Beläo T, and Rantin FT (2009) The basis of vagal efferent control of heart rate in a Neotropical fish, the pacu, *Piaractus mesopotamicus. Journal of Experimental Biology* 212: 906–913.

generator when respiratory drive is high, as in hypoxia. This possibility is represented in **Figure13** and merits further investigation in dogfish.

Air-Breathing Fish

Many of the primitive ray-finned fishes are air breathers and air breathing also seems to have evolved numerous times within teleosts. The anatomy and physiology of the air-breathing organs vary enormously among species, but its characteristic is that heart rate increases during air breathing.

Changes in heart rate during ventilation are evident in the jeju, *Hoplerythrinus unitaeniatus*, a teleost fish that uses a modified swimbladder as an air-breathing organ. Heart rate decreases during expiration, but increases drastically during the subsequent inhalation that inflates the swimbladder. These heart rate changes are primarily of cholinergic origin, and an in-depth analysis of heart rate variability in this species indicates that the heart rate changes are qualitatively similar to RSA in higher vertebrates. An example of the rapid change in heart rate upon an air breath in *Synbranchus marmoratus* is shown in **Figure 14**. In lungfish (Dipnoi), a vagal innervation of the heart is well established, while the sympathetic chain seems poorly developed. Heart rate does not change much with air breathing but pulmonary ventilation is associated with a marked rise in pulmonary blood flow in all species of lungfish. Control of pulmonary blood flow involves branchial shunts which are neurally regulated by cholinergic vasoconstriction of the pulmonary artery. Lungfish are endowed with pulmonary stretch receptors as well as both central and peripheral chemoreceptors, making it likely that feedback from these receptors is involved. In all of these respects lungfish anticipate the mechanisms described in amphibians and reptiles.

The Neural Basis of CRIs

In mammals heart rate increases during inspiration, a phenomenon known as respiratory sinus arrhythmia (RSA). It is driven by respiration-related fluctuations in the efferent, inhibitory supply to the heart via the cardiac vagus. This is generated centrally by an inhibitory input to CVPNs in the ventro-lateral nucleus ambiguus (NA) from inspiratory neurons in the neighboring ventral respiratory group. The consequent gating of vagal outflow causes heart rate to rise during inspiration. Its functional role in improving pulmonary oxygen uptake, particularly in athletes, has recently been discussed. This subtle relationship between heart beat and ventilation is not restricted to mammals as a similar relationship has been identified by power spectral analysis in rattlesnakes, *Crotalus durrisus*. As detailed above, beat-to-beat control of the heart, necessary to generate CRS, has been reported in both resting dogfish and Atlantic cod as well as in hypoxic trout, species that have CVPNs located both in the DVNs and in a ventro-lateral location outside the DVNs that may constitute a primitive NA. However, in fish the central interactions are between CVPNs and respiratory neurons in the DVNs that drive the CVPNs rather than inhibiting them. The evolution of RSA from CRI in fish, via amphibian and reptilian ancestors, is a subject of immediate interest.

Finally, we are left with an apparent paradox: if the vagus, which is normally inhibitory, delivers pulses of activity to the heart that can override the cardiac pacemaker, how can pulsatile activity mechanistically recruit the heart at rates similar to or even above its intrinsic rate? By its nature, this is likely to be a direct induction of the heart beat rather than an effect on cardiac intervals. When bursts of electrical stimuli were delivered peripherally down the cardiac vagus of the dogfish at 43 bursts min^{-1},

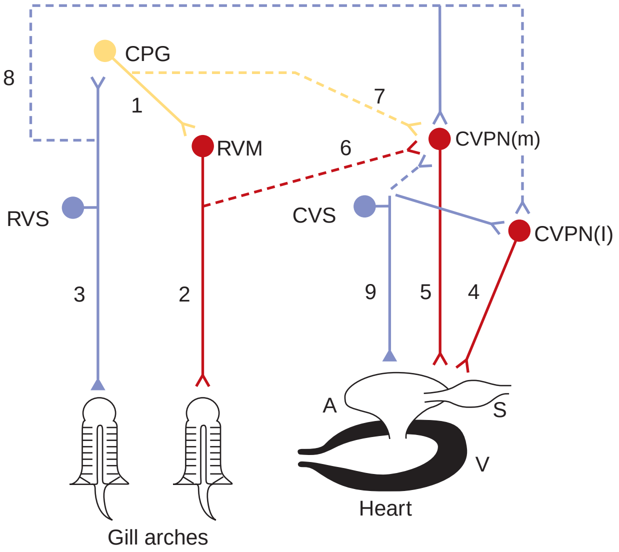

Figure 13 A schematic model of possible connections in the central and peripheral nervous systems generating CRIs in fish. There are several established connections in the nervous control of ventilation: (1) the respiratory central pattern generator neurons (CPG) show endogenous bursting activity that drives respiratory motoneurons (RVM); (2) the RVMs innervate respiratory muscles via the V, VII, IX, and X cranial nerves; (3) the activity of the CPG is modulated by feedback from mechanoreceptors and chemoreceptors located in the orobranchial cavity, innervated by sensory neurons (RVS). Heart rate is controlled by inhibitory input from the vagus nerve that receives axons from CVPNs, which are topographically and functionally separable into: (4) a ventrolateral group (CVPN (l)), some of which fire continuously and may be responsible for reflex changes in heart rate (e.g., hypoxic bradycardia) and for the varying level of vagal tone on the heart, and (5) a medial group (CVPN (m)), which burst rhythmically and may cause the heart to beat in phase with ventilation. Other more speculative connections may determine the activity in CVPN: (6) collateral's from neighboring RVM may have an excitatory effect on bursting CVPN (m) (or release a tonic inhibition); (7) the CPG may connect directly to CVPN (m); (8) stimulation of receptors in the orobranchial cavity, innervated by the, VII, IX, and X cranial nerves but apparently not by the V may directly modify activity in CVPN; (9) stimulation of receptors in the cardiovascular system close to the heart, innervated by vagal sensory neurons (CVS) may affect vagal outflow to the heart. In the dogfish these neurons may project via the visceral cardiac branch of the vagus. This diagram ignores the existence and possible roles of interneurons and inputs from and to higher centres in the CNS. Λ, efferent termination; ▲ afferent termination; S, sinus venosus; A, atrium; V, ventricle. CPG, central pattern generator; CVPN, cardiac vagal motor neuron; CVS, cardiac sensory neuron; RVM, respiratory motor neuron; RVS, respiratory sensory neuron. Modified from Taylor EW (1992) Nervous control of the heart and cardiorespiratory interactions. In: Hoar WS, Randall DJ, and Farrell AP (eds.) *Fish Physiology, Volume 12*, *Part B*, pp. 343–387. New York: Academic Press.

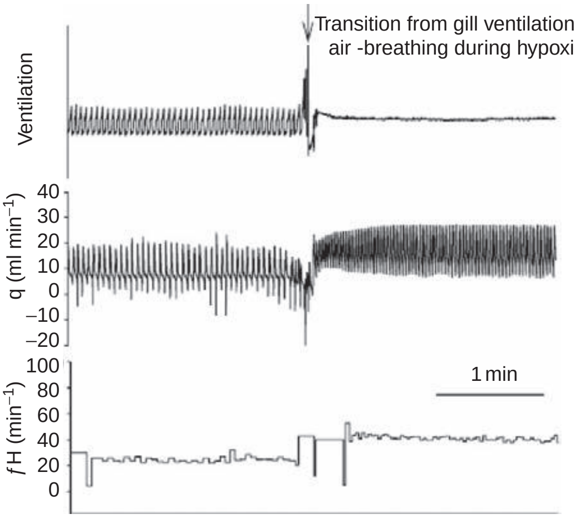

Figure 14 Changes in the blood flow (Q) and heart rate (f_H) during transition from gill ventilation to air breathing in S. *marmoratus* in hypoxic water (P_{O_2} 50mmHg). Gill ventilation in water ceases following the air breath (indicated by the arrow). Heart rate increased 5-fold immediately after the air-breath. Modified from Skals M, Skovgaard N, Taylor EW, *et al.* (2006) Cardiovascular changes under normoxic and hypoxic conditions in the air-breathing teleost *Synbranchus marmoratus:* Importance of the venous system. *Journal of Experimental Biology* 209: 4167-4173.

the heart slowed but to exactly half the bursting rate, implying that it was induced to beat by alternate bursts. Similar data exist for pacu (see **Figure 10**(**d**)). This question has long intrigued mammalian physiologists as well. In mammals, the cardiac vagi show bursting activity of variable frequencies and the heart can be entrained by bursts of electrical activity delivered down the cardiac vagi over a range of stimulation frequencies both lower and higher than the intrinsic heart rate. A relationship between the phase of the cardiac cycle that brief stimulation of the cardiac vagus is delivered and its chronotropic effect has been established in mammals, with the effect of each burst dependent on the phase of the cardiac cycle at which it is applied. Thus, the vagal effect on the heart cannot be measured merely in terms of the amount of acetylcholine delivered per unit time. Detailed analysis of the relationship between pulsatile activity in the cardiac vagus and phases of the cardiac cycle is not yet available for fish.

Summary

Beat-to-beat modulation of heart beat by the respiratory rhythm may be ubiquitous in vertebrates. Studies on fish and mammals and, to a lesser extent, on reptiles and amphibians imply that heart rate and heart rate variability in vertebrates are determined by phasic activity in CVPN. Spontaneous efferent activity in cardiac vagi contains bursts of respiration-related activity. In elasmobranchs this activity seems to originate primarily from central interactions between respiratory neurons and CVPN, and is characterized by relatively low levels of vagal tone on the heart. In teleosts, there may be a fundamental difference in that the bursts seem to be driven reflexly by stimulation of peripheral chemoreceptors and mechanoreceptors when respiratory drive and cardiac vagal tone are high. Ultimately, reflex control from peripheral receptors is important in determining heart rate in all fish and evidence from current investigations suggests that there are elements of central feed-forward control of CRIs in some teleosts. Consequently, it seems probable that variable combinations, relating to conditions and possibly to species differences, of feed-forward control via central interactions plus feedback control from peripheral receptors determine activity in CVPN in fish. This in turn can recruit the heart to the respiratory rhythm, though it may subserve different roles in different groups of fish.

Glossary

Autocrine A signaling mechanism in which the signaling molecule stimulates the cell from which it was released.

Cardiac output (V_b) Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.

Circulation time The time it takes for blood to make one complete loop around the cardiovascular system.

Endocrine system The signaling system in which the signaling molecule (hormone) is conveyed from the site of release to the target cells by way of the bloodstream.

Endothelial cells Thin cells that line the blood vessels and form a barrier between blood and tissue cells.

Half-time The time it takes for a parameter to decrease by one half ($t_{1/2}$).

Hormones Signaling molecules released by a cell that stimulate cell of origin (autocrine), nearby cells (paracrine), or travel via the bloodstream to distant cells (endocrine).

Hydrophilic hormone Hormones that are more soluble in water than in lipid. These include epinephrine, norepinephrine, serotonin, histamine, and numerous peptides. They typically bind to surface receptors on the cell membrane and activate second messenger systems within the cell.

Lipophilic hormone Hormones that are more soluble in lipid than in water. These include estrogen, progesterone, testosterone, aldosterone, cortisol, thyroid hormones, prostaglandins, and vitamin D. They typically bind to intracellular receptors and act within the cell nucleus.

Neurotransmitter The signaling molecules released by nerves. This is a specialized form of paracrine signaling.

Paracrine A signaling mechanism in which a signaling molecule is conveyed to nearby cells via the interstitial fluid bathing the cells.

Peptides Molecules made by joining from two to as many as several hundred amino acid molecules.

Perfusate A blood substitute that does not contain red blood cells and is often used in isolated organ studies.

Pillar cells Post-like cells in fish gill respiratory lamellae that enclose the blood space in the gas-exchange tissue and prevent the lamellar structure from ballooning out under blood pressure.

Rate constant A unitless number that is equivalent to the fractional decrease of some variable as a function of time. The rate constant (k) is related to the half-time ($t_{1/2}$) by $k=0.693/t_{1/2}$.

Receptor-mediated endocytosis A process in which a molecule binds to a receptor on the cell membrane and then the molecule–receptor complex is internalized.

Hormones and the Endocrine System

The endocrine system and nervous system are the two means of communicating signals between different parts of the body. The endocrine system transmits its signals as chemicals called ‘hormones’ that are carried in the blood. As a result, the endocrine system has the advantage of transmitting its signals to every organ in the body, since all organs receive blood flow. This broad communication between different organs typically takes minutes to hours, possibly days, to reach a maximum response and the system can take equally long to turn off.

The intensity of an endocrine signal is set, in large part, by the concentration of the hormone in the blood, the amount of blood flow directed to an organ, the number of receptors, and the affinity of the receptors for the hormone. Hormone concentrations can be reduced by decreasing their release and through inactivation sites.

In contrast, the nervous system transmits signals within the axon of a nerve cell to very specific areas by way of nerve action potentials, and this action potential is communicated to other cells by means of neurotransmitter chemicals. The nervous system rapidly (<1 s) transmits signals from one area of the body to the next and the signals can be quickly turned on and off. The intensity of the neural signal is encoded in the frequency and pattern of action potentials, and the nature of the neurotransmitter. In some instances, such as the hypothalamus and pituitary, the two systems are combined into a neuroendocrine system. Here, the nerve action potential releases its neurotransmitter hormone directly into the circulation.

Hormones are broadly defined as signal molecules that are secreted by a cell to either communicate directly with that cell (autocrine transmission), communicate with neighboring cells (paracrine transmission), or communicate with distant cells via the bloodstream (endocrine transmission). This article focuses on how endocrine signals are modulated by the removal of hormones from the blood by the cardiovascular system. Therefore, the term hormone is restricted here to the context of endocrine signaling. In this context, hormones are typically classified as circulating or noncirculating. Circulating hormones may make several or many transits around the cardiovascular system because they remain in the circulation longer than the typical circulation time (1–2 min). Noncirculating hormones, however, are rapidly removed from the blood and therefore typically stimulate target tissues immediately downstream from their point of release.

Types of Hormones

The mechanisms of hormonal removal from the blood relate to the chemical characteristics of the hormone, which fall into several categories. Hydrophilic hormones, namely amines and peptides, are water soluble. They are typically synthesized and stored prior to secretion and when secreted they dissolve in the plasma and are transported in the blood without the need for a specific carrier molecule. The amines include: (1) the catecholamines; dopamine, epinephrine (adrenaline), and norepinephrine (noradrenaline); (2) the indolamine, serotonin (5-hydroxytryptophan; 5-HT); and (3) histamine. Peptides range from the short, three-amino-acid peptide, thyrotropin-releasing hormone (TRH), to proteins of nearly 200 amino acids, such as growth hormone and prolactin.

The lipophilic hormones include the steroid derivatives of cholesterol (such as sex hormones and adrenal cortical hormones), derivatives of arachidonic acid (such as prostaglandins, leukotrienes, thromboxanes, and prostacyclin), and the thyroid hormones. The steroid derivatives and thyroid hormones are transported in the plasma bound to a carrier molecule because of their very low solubility in plasma. These hormone-specific carrier molecules greatly increase the concentration of hormone that can be transported in blood and also prolong the existence (measured as half-time; $t_{1/2}$) of the hormone in the circulation. Lipophilic hormones, with the exception of thyroid hormones, are generally synthesized immediately prior to secretion.

Plasma hormone concentrations are tightly regulated since their effect is directly related to their concentration. A plasma hormone concentration at any point in time represents a balance between the rates of hormone secretion and inactivation. With a few exceptions, the rate of secretion appears to be the active point of regulation that increases or decreases against a background of constant rate of removal via inactivation. This is analogous to filling a bucket that has a small hole in the bottom; at any point in time, the amount of water in the bucket is controlled by opening and closing the tap filling the bucket. In spite of that, the successful operation of the endocrine system depends upon effectively removing hormones from the circulation because once secretion ceases, $t_{1/2}$ is determined entirely by the rate of inactivation. This is especially true for the noncirculating hormones.

Mechanisms of Hormone Inactivation in Mammals

Most of what is known about hormone inactivation was initially derived from mammalian studies. Several inactivation mechanisms exist and may, or may not be, hormone specific, as summarized in the following paragraphs.

Dilution

If a hormone is released in small, discrete quantities, its concentration will stimulate tissues immediately downstream from the site of release, but the hormone will be progressively diluted due to mixing in the plasma to a point in time when it will no longer be effective distally. Dilution would be greater with secretion into the venous system. Thus, the rate of inactivation is dependent upon tissue blood flow and volume.

Metabolic Inactivation in the Plasma

Enzymes that inactivate hormones can circulate in the plasma or project from the surface of endothelial cells into the plasma. Many peptide hormones are hydrolyzed by a variety of plasma and endothelial proteases that may or may not be peptide specific.

Cellular Uptake from the Plasma and Intracellular Degradation

Uptake may be nonspecific, or may employ selective transcellular transporters or receptors that bind and internalize the hormones. Uptake of lipophilic hormones is generally nonspecific as they are readily dissolved in the plasma membrane, and so there is no need for a special process for cellular uptake (they follow their concentration gradient) prior to intracellular degradation. Amines are typically removed from the circulation by active transport into cells where they are enzymatically degraded. An amine transport mechanism that is relatively nonspecific for different amines, commonly called 'extra-neuronal uptake', or 'uptake-2' accounts for most catecholamine removal from the circulation and may transport histamine and serotonin as well. Receptor-mediated uptake (receptor-mediated endocytosis) occurs through the action of specific hormone receptors, such as the natriuretic peptide receptor-C (NPR-C), which binds a variety of natriuretic peptides and internalizes them for subsequent degradation.

The endothelium, which forms the lining of all vertebrate blood vessels, including those of fish, is a key site of intracellular hormone activation in mammals. The anatomical appearance of endothelial cells as relatively benign, thin barriers lining blood vessels is quite misleading. *In toto*, their mass in mammals is equivalent to that of the liver, but their metabolic potential is enhanced by a much greater surface area.

The location of inactivation sites also critically influences plasma hormone levels. The mammalian pulmonary circulation is in an ideal position to metabolically 'condition' the blood before it is delivered to the systemic circulation as it is the only vascular bed that receives the entire cardiac output in a single pass. Endothelial enzymes projecting into the plasma from the lung endothelial circulation can convert hormones to an active form (angiotensin converting enzyme, ACE, aka kininase I activates angiotensin) and inactivate hormones (kininase II inactivates bradykinin).

Mechanisms of Hormone Inactivation in Fish

Information about hormone inactivation in fishes is in its infancy. The surface area and mass of fish endothelial cells is unknown but probably comparable to that in mammals. The fish gill is the homolog of the mammalian lung and, like its counterpart, has an ideal location for hormone inactivation. The surface area of gill pillar cells, which are functionally homologous to endothelial cells, is also considerable. It is not surprising, then, that we know more about hormone removal and metabolism in the gill than in any other tissue.

Significance of the Gill in Hormone Inactivation

The respiratory surface of the fish gill is greatly elaborated in the form of respiratory (secondary) lamellae to enhance the gas-exchange surface; typically, the lamellar surface area is greater than the total non-gill body surface area. As shown in **Figure 1**, the surface of the pillar cells lining the blood channels even exceeds the respiratory surface area, perhaps by nearly 50%. This substantial surface area provides ample opportunity for contact with blood-borne molecules and subsequent metabolism.

The gill has numerous enzymes and uptake mechanisms to clear hormones from circulation. Many of these are located on the pillar cells (**Figure 1**). ACE is especially concentrated in gill pillar cells and approximately 65% of angiotensin I (ANG I) in the blood is converted to angiotensin II (ANG II) by ACE in a single transit through the gill circulation. Atrial natriuretic peptide clearance receptors (NPR-C) are also prevalent in the lamellae, removing up to 60% of the circulating natriuretic peptide in a single pass through the gill (**Figure 2**). Inhibition of clearance receptors effectively blocks natriuretic peptide uptake from the plasma and produces a drop in blood pressure due to the increased concentration of the vasodilator peptide in the circulation. This suggests that there is a tonic release of natriuretic peptides and because the major site of natriuretic peptide secretion is the heart, their rapid removal by the gill, which is immediately downstream from the heart, is an important filtering process to prevent the peptide from entering the systemic circulation and producing hypotension.

Gill pillar cells also actively accumulate both epinephrine and norepinephrine by way of specific catecholamine transport through mechanisms similar to extra-neuronal uptake. The majority of the catecholamines taken up by the gill are metabolized by intracellular enzymes monoamine oxidase and catechol-*O*-methyl transferase. However, some catecholamines may also be released back into the circulation intact. The gills also show selectivity for the type of amine removed: epinephrine extraction is only 5%, norepinephrine extraction is 16%, and serotonin extraction is over 80%. Thus, while the gills are effective in clearing serotonin from the circulation, they allow epinephrine to circulate almost unimpeded after release from the chromaffin cells into venous blood near the heart. Gills are similarly selective in removing arachidonic acid (essentially 100% extraction) but only remove a small percent of the prostacyclin (15%) and hardly any (<5%) prostaglandin E_2. Thus, in fish with 50–100% gill removal rates on a single pass, the classification of a hormone as circulating or noncirculating depends to a large extent on its ability to traverse the gill microcirculation.

The enzyme cytochrome P450IA1 is also especially prevalent in pillar cells. Enzymes such as this are well known for their detoxification properties. However, members of this family can also metabolize arachidonic

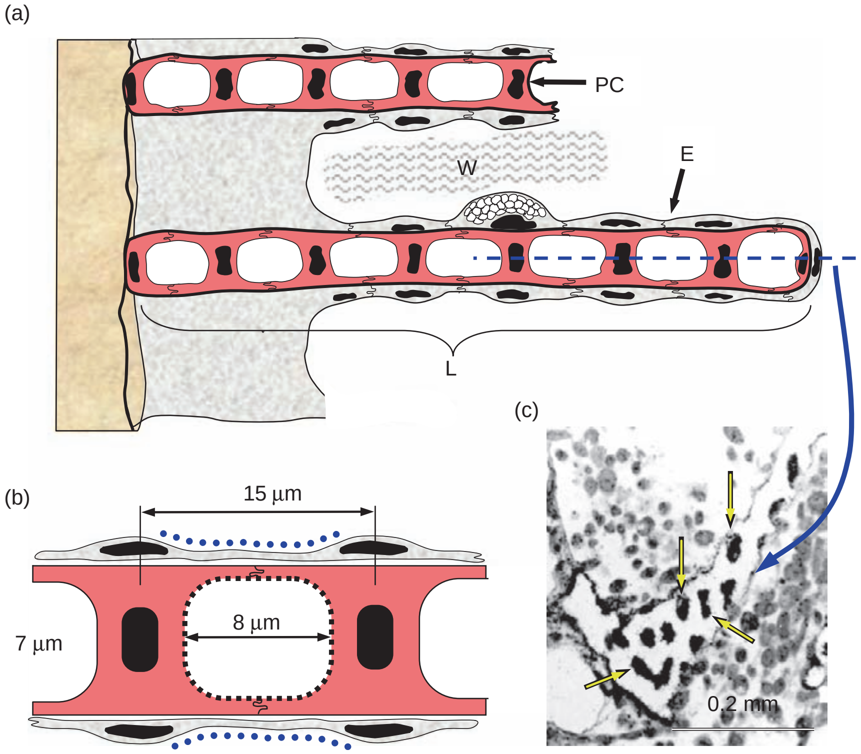

Figure 1 The importance of gill pillar cells in hormone metabolism. (a, b) Cross section through the gill respiratory lamellae (L) showing the arrangement of gill pillar cells (PC, red), epithelium (E), and environmental water (W). The surface area of pillar cells lining the blood space (dashed black line in (b)) is considerably greater than the respiratory surface area of the epithelium (dotted blue lines in (b)). (c) Autoradiograph showing ^{3}H-norepinephrine binding to pillar cells (yellow arrows) in a tangential section through a lamellae, thereby creating a cross section through the pillar cells (blue dashed line in (a) and arrow). (c) Modified from Olson (2002) Gill circulation: regulation of perfusion distribution and metabolism of regulatory molecules. *Journal of Experimental Zoology* 293: 320–335.

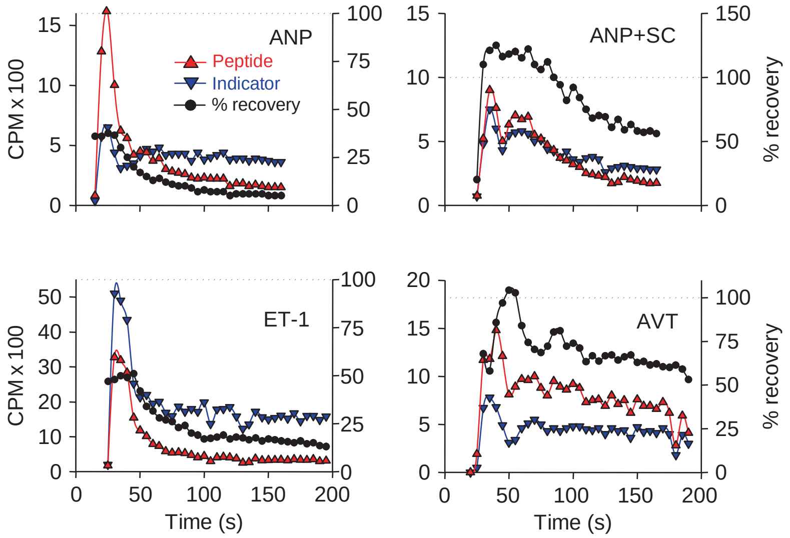

Figure 2 Representative traces showing single-pass recovery (black circles) of radiolabeled peptides (red triangles) and inert volume indicator (blue inverted triangles) from the dorsal aorta of unanesthetized rainbow trout (*Oncorhynchus mykiss*). Indicators were injected into the ventral aorta as a single bolus and 7-μl samples were collected every 5 s from the dorsal aorta. Left ordinate shows radioactivity in counts per minute (CPM); right ordinate is percent recovery of hormone. The spike associated with the initial five to seven samples represents the first pass of radionuclides through the gill. Subsequent radioactivity is due to recirculation and the percent recovery reflects total body extraction. ANP and ET-1 are efficiently removed by the gills in a single pass, whereas inhibiting the clearance receptor greatly inhibited ANP removal and there is little evidence for gill removal of AVT. ANP, atrial natriuretic peptide; ANP+SC, atrial natriuretic peptide plus clearance receptor inhibitor, SC 46542; ET-1, endothelin-1; AVT arginine vasotocin. Modified from Olson KR (1998) Hormone metabolism by the fish gill. *Comparative Biochemistry and Physiology* 119A: 55–65.

acid to form signaling molecules, such as epoxyeicosatrienoic acids (EETs) and hydroxyeicosatetraenoic acids (HETEs). Whether or not these are produced by the gill remains to be determined.

Systemic (Non-Gill) Hormone Inactivation

Comparatively little is known of the metabolic capacity of systemic (non-gill) vasculature, although it undoubtedly contributes to hormone metabolism as well. The relatively low epinephrine extraction by the gill (5%; **Table 2**) would result in an *in vivo* $t_{1/2}$ of over 13 min (**Figure 3**(**b**)) if the gill was the sole site of epinephrine removal. Clearly, this cannot be the case as both the $t_{1/2}$ for physiological inactivation of epinephrine infusion and clearance of radioactive epinephrine (^{3}H-epinephrine) *in vivo* are <5 min (**Table 1**). In fact, this rapid clearance rate indicates that there are multiple systemic inactivation sites for catecholamines. **Figure 2** provides additional evidence for systemic inactivation. In these single-pass experiments, the initial five to seven samples represent the first-pass of radiolabeled peptides across the gill. The appearance of radioactive molecules in later samples results from recirculation through the vasculature and return to the gills. It is evident that even molecules such as arginine vasotocin (AVT), which are not readily extracted by the gill, are still nearly 50% cleared from circulation within 3 min. This could only be accomplished if tissues other than the gills were also actively involved in removing AVT from circulation. ACE also is especially prevalent in systemic tissues. ANG I is completely converted to ANG II in a single transit through many systemic vascular beds.

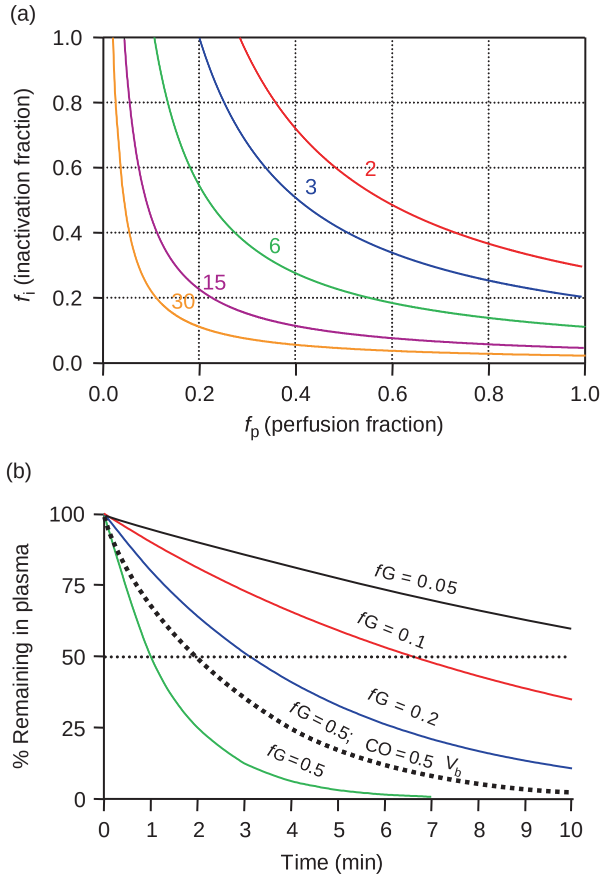

Figure 3 Mathematical expression of hormone inactivation. (a) Relationship between inactivation fraction (f_i) of a tissue and the fraction of cardiac output perfusing that tissue (f_p) for hormones with different $t_{1/2}$ (2, 3, 6, 15, and 30 min). As an example, for a molecule to have a 6-min $t_{1/2}$ in the circulation, gill inactivation fraction would have to be 0.11 (gill f_i is always 1.0), whereas a tissue that receives 20% of the cardiac output ($f_p = 0.2$) would have to have a single-pass inactivation of 45% ($f_i = 0.45$) to produce the same 6-min $t_{1/2}$. The tremendous potential of the gill microcirculation in regulating plasma hormones is evident in these figures. (b) The effect of gill inactivation fraction (f_g) on the theoretical rate of hormone disappearance from plasma. The solid curves assume a ratio of cardiac output (CO; per minute) to blood volume of 1.0. If the gill removes 50% of the hormone in a single pass ($f_g = 0.5$; green line), then $t_{1/2}$ is 1 min, if only 10% is removed in a single pass ($f_g = 0.1$; red line), then $t_{1/2}$ is over 6 min. If the ratio of cardiac output to blood volume (V_b) becomes 0.5 and inactivation fraction remains at 50% ($f_g = 0.5$, CO $= 0.5V_b$; dotted line), then $t_{1/2}$ is 2 min. The black solid line ($f_g = 0.05$) shows the rate of epinephrine disappearance from the circulation based on gill extraction only (see **Table 2**). (a) From Olson KR, Conklin DJ, Conlon JM, *et al*. (1997) Physiological inactivation of vasoactive hormones in rainbow trout. *Journal of Experimental Zoology* 279: 254–264. (b) From Olson KR (1998) Hormone metabolism by the fish gill. *Comparative Biochemistry and Physiology* 119A: 55–65.

Methods for Measuring Hormone Inactivation

Three general methods are used to examine hormone inactivation in fish; physiological inactivation, whole-body uptake, and single-tissue extraction. With the first, the hormone of interest is often infused at a constant rate to change a physiological parameter. When the system reaches steady state, hormone infusion is stopped and the rate of recovery of the physiological parameter is used to provide an index of the overall rate of inactivation of the hormone and recovery of the system. To determine whole-body uptake, the hormone is injected into the fish and blood samples are taken periodically to measure the amount of hormone remaining in the circulation. Single-tissue extraction is measured by injecting a hormone into the arterial circulation of a specific tissue and measuring hormone recovery from the venous effluent or by using isolated perfused organs. Information derived, using these methods, is described in the following sections.

Table 1 Approximate *in vivo* $t_{1/2}$ (min) of common hormones and the volume marker sucrose, determined by physiological inactivation or radionuclide clearance

	Physiological inactivation	Radionuclide clearance
ANG II	3–4	
AVT	18–20	
BK	3–4	
EPI	3–4	1.7–3.3
NEPI	3–4	
Sucrose		1.8–3.3

ANG II, angiotensin II; AVT, arginine vasotocin; EPI, epinephrine; NEPI, norepinephrine.

Physiological Inactivation of Circulating Hormones

The physiological inactivation of circulating hormones entails both biochemical/cellular inactivation and delivery of these hormones to the metabolically active sites. **Figure 4(a)** shows the recovery (decline) of rainbow trout (*Oncorhynchus mykiss*) blood pressure following norepinephrine infusion into the bloodstream. This recovery can be defined as a simple exponential decay:

$$A_t = A_{\mathrm{eq}} + A_i e^{-kt} \qquad [1]$$

where A_t is blood pressure at any time (t), A_{eq} is the blood pressure at equilibrium, that is, resting blood pressure, A_i is the increase in blood pressure produced by the hormone infusion, and k is the rate constant (the fractional change per unit time). Interestingly, the exponential drop in blood pressure when these hormones are administered as a single, bolus injection, displays approximately the same half-time as it does during infusion; thus, a single injection may be a more convenient mechanism to examine $t_{1/2}$. Using these relationships, it was found that the $t_{1/2}$ for the recovery of blood pressure in an intact fish treated with either vasoactive peptides or catecholamines was longer than for the mechanical relaxation of isolated blood vessels *in vitro* when these hormones were removed from the fluid bathing the vessel. Thus, it is evident that the rate-limiting factor for many vasoactive hormones is the circulation time, not the inactivation process *per se*. Some $t_{1/2}$ values for physiological relaxation are shown in **Table 1**.

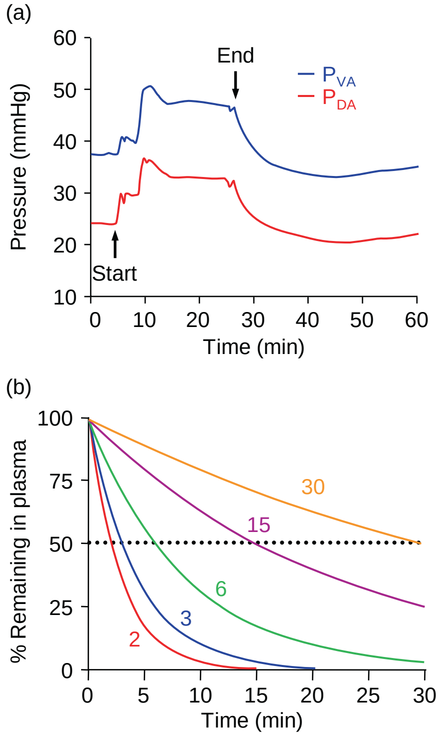

Figure 4 Physiological inactivation of norepinephrine. (a) Norepinephrine is infused into a fish (start) until dorsal aorta (P_{DA}) and ventral aorta (P_{VA}) blood pressures reach a steady state. Infusion is stopped (end) and the exponential decrease in blood pressure is the result of inactivation of circulating norepinephrine and recovery of the heart and blood vessels. (b) Predicted percent hormone remaining in the plasma at different $t_{1/2}$ (2, 3, 6, 15, and 30 min), assuming an exponential decline in hormone concentration and no hormone secretion. From Olson KR, Conklin DJ, Conlon JM, *et al*. (1997) Physiological inactivation of vasoactive hormones in rainbow trout. *Journal of Experimental Zoology* 279: 254–264.

Physiological inactivation of noncirculating hormones can be passively governed by blood flow through the secretory organ, which, in turn, affects the dilution rate. Inactivation of noncirculating hormones can also result from efficient gill metabolism as described later.

Whole-Body Uptake

Removal of hormones from the circulation of an intact fish is most commonly measured by injecting a radiolabeled hormone and monitoring the rate of disappearance of radioactivity through serial blood sampling. Using unlabeled hormone injections is a little more difficult. Hormones with a short $t_{1/2}$, such as catecholamines or some peptides, exhibit a mono-exponential decrease in plasma hormone with a $t_{1/2}$ similar to physiological inactivation measurements (**Table 1**). In fact, the $t_{1/2}$ for clearance of radiolabeled sucrose, an inert marker of mixing and dilution throughout the cardiovascular system and extracellular fluid, is similar to that measured for catecholamines, angiotensin, and bradykinin (**Table 1**). This supports the hypothesis that mixing in the cardiovascular system, not metabolic processes, can be the rate-limiting factor for clearance of certain hormones from the circulation. The impact of $t_{1/2}$ on the percent hormone remaining in the plasma over time is shown in **Figure 2(b)**.

Single-Tissue Extraction

Estimating hormone inactivation by a tissue or organ can be determined in perfused preparations by adding the

Table 2 Fractional extraction of hormones by the rainbow trout (*Oncorhynchus mykiss*) gill *in vivo* (I) or the perfused gill (p)

Class	*Hormone*	*Fractional extraction*
Peptide	ANP (i, p)	0.6, 0.6
	AVT (i)	0.2
	BK (i, p)	0.2, 0.25
	ET-1 (i)	0.55
Amine	EPI (p)	0.05
	NEPI (p)	0.16
	5-HT (p)	0.8
Arachidonic acid	Ar-A (p)	0.99
	PGE_2 (p)	0.4
	PGI_2 (p)	0.13
Purine	ADO (p)	0.4

ANP, atrial natriuretic peptide; AVT, arginine vasotocin; BK, bradykinin: ET-I, endothelin-1; EPI, epinephrine; NEPI, norepinephrine; 5-HT, serotonin; Ar-A, arachidonic acid; PGE_2, prostaglandin E_2; PGI_2, prostacyclin; ADO, adenosine.

Modified from Olson KR (2002) Gill circulation: Regulation of perfusion distribution and metabolism of regulatory molecules. *Journal of Experimental Zoology* 293: 320–335.

hormone to the perfusate and measuring the amount of hormone recovered in venous effluent. The disadvantage of this tissue-specific analysis is that it can potentially fail to reproduce physiological conditions. Half-times of lipophilic hormones may be underestimated due to the absence of carrier molecules in the perfusate, lowering their solubility and stability below that of plasma. In contrast, $t_{1/2}$ of hydrophilic hormones, such as peptides, may be overestimated due to the absence of plasma-born enzymes, such as proteases, that would otherwise inactivate hormones in addition to tissue processes.

Hormone extraction by individual tissues can also be measured *in vivo* using a dual-label technique where the hormone and an inert volume marker are injected simultaneously into the artery supplying the tissue and multiple samples are collected over time from its venous effluent. Values for hormone extraction by the perfused gill are tabulated in **Table 2** and representative experiments are shown in **Figure 2**.

Impact of Single-Tissue Inactivation on Whole-Body Hormone Clearance

The overall rate at which a hormone is removed from the circulation depends on two factors: (1) how efficient a tissue is in inactivating the blood during a single transit through the tissue, and (2) what percent of the total cardiac output passes through this tissue. This is shown graphically in **Figure 3** and can be described mathematically as

$$k_{\mathrm{Tiss}} = -\ln[1 - f_{\mathrm{i}} \cdot f_{\mathrm{p}}] \cdot (\mathrm{CO}/V_{\mathrm{b}}) \qquad [2]$$

where k_{Tiss} is the specific rate constant for each tissue, ln is the natural log, f_{i} is the fractional inactivation of the molecule in a single transit through the tissue (the ratio of the molecule's concentration in venous to arterial blood), f_{p} is the fractional perfusion of the tissue (the ratio of blood flow through the tissue to total cardiac output), CO is cardiac output, and V_{b} is the volume of blood transporting the hormone (usually this is equivalent to plasma volume). The relative importance of tissue blood flow and fractional inactivation is shown in **Figure 3(a)**. It is readily apparent that if a hormone is inactivated by the gill, which is the only tissue in fish to receive the entire cardiac output (i.e., $f_{\mathrm{p}} = 1.0$), the inactivation fraction (f_{i}) will only need to be 0.11 to produce a plasma $t_{1/2}$ of 6 min, whereas inactivation by a systemic tissue, which typically receives no more than 20% of the cardiac output ($f_{\mathrm{p}} = 0.2$), will have to be 55% ($f_{\mathrm{i}} = 0.055$) to achieve the same $t_{1/2}$. The efficacy of the gill in rapidly lowering plasma hormone concentrations at different fractional extractions is shown in **Figure 3(b)**. As an example, if gill fractional extraction (f_{g}) is only 0.2 (20% extraction), the plasma hormone concentration will be halved in less than 4 min.

Glossary

Acclimatize (acclimate) Physiological or morphological changes an organism experiences when exposed to chronic (prolonged) changes in environmental conditions.

Bradycardia A slowing of normal heart rate. In fish, this condition is often associated with hypoxia (low environmental oxygen levels).

Critical thermal maximum (CTM) The maximum temperature that can be tolerated by an organism. In fish, this variable is most often measured by acutely increasing the temperature (e.g., by 2 °C h^{-1}) until the fish loses equilibrium.

Diastole A period of the cardiac cycle when cardiac muscle is relaxed or relaxing. It is associated with filling the heart with blood.

Echocardiography A noninvasive procedure that uses sound waves to study the structure and function of the heart. Measurements that can be taken with this technique include chamber/valve sizes, chamber volumes, and blood flows during particular events in the cardiac cycle.

Eurythermal Able to live over a wide range of temperatures.

In situ Being in the original position; used to describe experiments where measurements are taken on an organ (tissue) while they are still located within the animal.

Phenotypic The observable physical or biochemical characteristics of an organism, as determined by both genetic makeup and environmental influences.

Phylogenetic Relating to the evolutionary development (history) of an organism.

Stenothermal Describes an organism that cannot live in environments that undergo large changes in temperature.

Temperature quotient (Q_{10}) A measure of the rate of change of a biological or chemical system as a consequence of increasing the temperature by 10 °C. The Q_{10} is calculated as: $Q_{10}= R1/R2^{10\ (T2-T1)}$, where R is the rate at a particular temperature and T the temperature in degrees celsius.

Upper incipient lethal temperature (UILT) Maximum temperature at which 50% of the fish acclimated to a temperature survive after a defined period of exposure to the test temperature.

Introduction

Fish have a truly global distribution, and live in water with temperatures ranging from −1.8 to ~42 °C. For many species, water temperature also varies daily or seasonally, and often by >10 °C. For example, carp species can experience seasonal temperature fluctuations from near 0 °C in winter to 30 °C in summer. The frillfin goby (*Bathygobius soporator*), which lives in tide pools along the east coast of South America, is subjected to diurnal fluctuations from 25 to 40 °C.

Given that the body temperature of fish is normally equivalent to that of the water, and that aerobic metabolic rate (oxygen consumption) is positively correlated with temperature (**see also Swimming and Other Activities**: Cellular Energy Utilization: Environmental Influences on Metabolism and **Temperature**: Membranes and Temperature: Homeoviscous Adaptation), fish must be able to adjust the delivery of oxygen and energy substrates to meet temperature-dependent changes in tissue demand. In addition, they must try to accommodate these temperature-related demands while providing for other life processes that are critical to the fish's survival and fitness (e.g., growth, digestion, swimming, migration, and reproduction).

In fishes, the oxygen delivered from the gills to the tissues (T_aO_2, arterial oxygen transport) is determined by cardiac output ($\dot{Q}$, the amount of blood pumped by the heart per unit time) and the amount of oxygen carried in the arterial blood (C_aO_2, arterial oxygen content) according to the following equation: $T_aO_2 = \dot{Q} \times C_aO_2$. Since $\dot{Q}$ can vary by up to threefold in fishes, changes in $\dot{Q}$ can have an enormous influence on how much oxygen is delivered to the tissues. In fact, any environmental change that alters the fish's oxygen consumption usually involves a change in $\dot{Q}$. Furthermore, arterial blood is normally nearly fully saturated with oxygen, and it remains this way when temperature changes. Therefore, changes in C_aO_2 are not appreciable compared with $\dot{Q}$ for most changes in temperature.

Over the past four decades, a great deal has been learned about how temperature affects cardiovascular function in fishes. For example, it is well established that resting $\dot{Q}$ changes in concert with temperature until the fish reaches its maximum tolerable temperature. However, maximum cardiac function has an optimum temperature range below the maximum tolerable temperature that is species specific and varies with the fish's thermal history. Moreover, we have begun to appreciate the structural, biochemical, and metabolic changes that allow the fish's cardiovascular system to have a degree of independence from the intrinsic effects of temperature; e.g., those resulting from temperature acclimation, and those that are a consequence of adaptation to a particular thermal environment over evolutionary time (i.e., the result of natural selection).

Acute Temperature Effects on Resting Cardiac Function

Heart rate (f_H) is the easiest and most often measured cardiovascular variable with respect to the effects of temperature on fish cardiac function. As for most rate functions, resting f_H increases with temperature in a nonlinear manner. This is reflected in Q_{10} values, which describe the factorial change in a rate function for a 10 °C temperature change. Many studies indicate that the Q_{10} for f_H is between 1.3 and 3.0 depending on the range of temperatures and species studied. This means that f_H can increase from 30% to threefold with an increase of 10 °C. Regardless, resting f_H increases until just prior to the maximum temperature that the fish can tolerate (this temperature called the upper incipient lethal temperature (UILT) or critical thermal maximum (CTM)).

Temperature increases resting f_H partially through its effects on the membrane permeability of the heart's pacemaker cells and on the ionic currents contributing to the pacemaker's discharge, and thus its intrinsic rate. Further, the pacemaker cells are innervated by cholinergic (inhibitory) and adrenergic (stimulatory) nerves, and temperature influences the neuronal modulation of pacemaker rate. For example, an acute increase in temperature generally decreases cholinergic tone and increases adrenergic tone on the heart, both of which elevate f_H (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and **Integrated Response of the Circulatory System**: Integrated Cardiovascular Responses of Fish to Swimming).

A curious and unexplained observation for fish that are acutely warmed is that cardiac stroke volume (S_V, the amount of blood pumped per heart beat) remains unchanged. Therefore, the increase in $\dot{Q}$ that accompanies warming directly mirrors that in f_H. The reason why this is curious is because fish can often increase S_V by two- to threefold during aerobic exercise. Why resting fish do not increase S_V when acutely warmed is a hotly debated topic, and the major potential explanations are presented below.

1. The heart cannot fill any more during diastole, and this limits S_V. There are three possible reasons for this: (a) as f_H increases, the time available to fill the heart decreases; (b) it is more difficult to fill the heart via venous pressure because the heart muscle cannot relax fully during diastole (i.e., resting tension increases and the muscle becomes stiffer due to elevated intracellular calcium levels); and (c) cardiac filling pressure decreases at high temperatures. The first two explanations remain plausible and supported by experimental work. However, cardiac filling pressure was recently shown to remain unchanged in salmonids at temperatures between 10 and 20 °C, and actually increased substantially when chinook salmon (*Oncorhynchus tshawytscha*) were warmed from 21 to 25 °C.
2. There is residual volume left in the ventricle when the heart finishes contracting (i.e., end-systolic volume increases. This is a very likely occurrence. Studies with isolated cardiac muscle have repeatedly shown that the isometric force developed (the difference between resting tension and peak force) decreases with increasing contraction frequency (termed a negative force–frequency relationship) and with acute warming (e.g., see **Figure 1(a)**). Although catecholamines (adenaline and noradrenaline) can stimulate calcium influx into the myocytes and thus force development, their stimulatory effect is reduced with acute warming in rainbow trout. Finally, increases in $\dot{Q}$ with temperature in most species examined are greater than the decrease in vascular resistance with warming. Consequently, the heart must develop higher blood pressures to eject blood into the circulation at high temperatures, which adds to the challenge of generating tension at higher cardiac frequencies (**see also Design and**

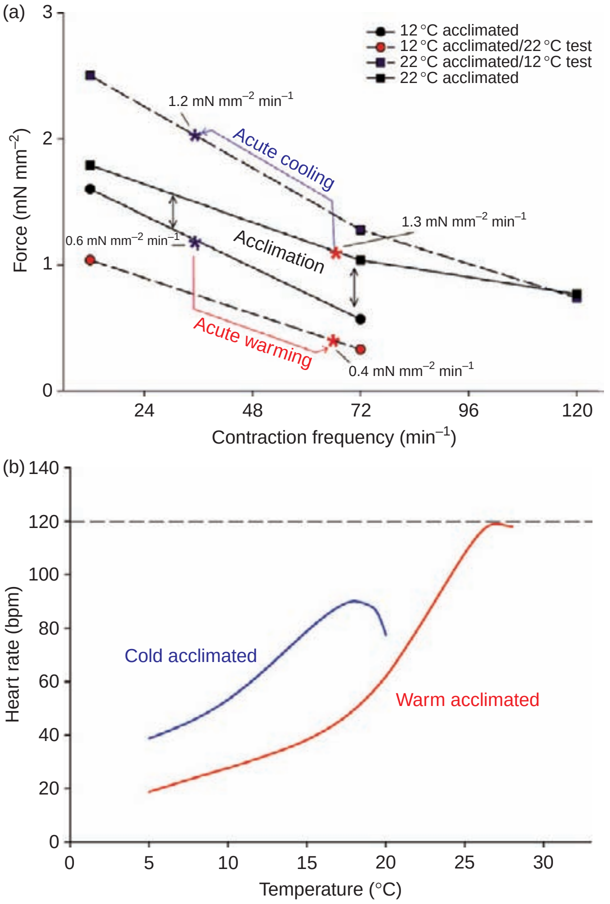

Figure 1 (a) The effect of an acute temperature change and temperature acclimation on isometric force development by isolated ventricular muscle strips from the rainbow trout when paced at various contraction frequencies. The main points are as follows: cold-(12 °C) acclimated ventricular strips (irrespective of test temperature) cannot be paced faster than approximately 72 min^{-1}; acute warming (to 22 °C) severely compromises force development and pumping capacity; warm acclimation (at 22 °C) greatly increases forced developed at a particular temperature, and allows the trout heart to be paced up to approximately 120 min^{-1}; finally, acute cooling increases force development. Asterisk (∗) indicates the approximate heart rate of live rainbow trout at each acclimation temperature, and the numbers associated with each asterisk indicate the heart muscle pumping capacity (product of force development and contraction frequency). (b) Effect of acute changes in temperature on the f_H of cold- and warm-acclimated rainbow trout. 120 beats per minute (bpm) represents the approximately upper limit of f_H in this species. (a) Modified from Shiels HA, Vornanen M, and Farrell AP (2002) The force–frequency relationship in fish hearts – a review. *Comparative Biochemistry and Physiology – Part A* 132: 811–826.

Physiology of the Heart: Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux and Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element).

3. Central cardiac control mechanisms favor an increase in f_H. This appears to be a contributing factor because rainbow trout warmed to 24 °C can double S_V and maintained $\dot{Q}$ when f_H is halved by injecting the pharmacological agent zatebradine – a drug that specifically acts to slow down the heart's pacemaker cells without affecting myocardial force development.

Why fish choose to increase resting $\dot{Q}$ exclusively through changes in f_H when acutely warmed, and avoid increases in S_V is unknown. An increase in S_V could improve oxygen delivery to the myocardium and enhance myocardial function at a time when blood oxygen levels returning to the heart become limiting (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Hypoxia). Further, although a high degree of synchrony between the rate of breathing (ventilation) and f_H has been observed at high temperatures, there is little evidence to support the idea that cardiorespiratory synchrony benefits oxygen transfer across the gills (at least in hypoxia). Thus, elevations in f_H are likely unnecessary for optimal gill oxygen transfer at high temperatures.

Clearly, more research is needed before a definitive answer emerges for this issue. This will require an integrative approach that incorporates techniques such as echocardiography, *in vivo* nerve recordings, and pharmacological intervention.

Temperature Effects on Maximum Cardiac Function and Scope for Cardiac Output

At the whole animal level, temperature tolerance is determined by a fish's metabolic scope (the difference between minimum and maximum metabolic rates). It has been recognized for over 60 years that metabolic scope is greatest within the fish's optimum temperature range, and is reduced as temperature increases or decreases from this range, until it approaches zero at a fish's upper and lower thermal limits.

Of particular relevance to this article is that metabolic scope, aerobic swimming performance, and cardiac scope (the difference between resting and maximum $\dot{Q}$) are very much interdependent when it comes to their responses to temperature. Indeed, *in situ* maximum S_V, cardiac power output ($\dot{Q} \times$ developed pressure), and cardiac scope fall when acclimation temperature is increased beyond a rainbow trout's optimum temperature; this decrease in cardiac function occuring despite increased f_H as temperature increases further.

Based on these findings from work with isolated hearts (i.e., hearts devoid of external nervous or hormonal control), a model was proposed in 1997 to explain the reduction in cardiac scope with temperature. This model proposed that, in a manner similar to metabolic scope, cardiac scope is not maintained across temperatures because resting $\dot{Q}$ continues to increase with temperature to support the elevation in routine metabolic rate until the fish's lethal temperature is reached (as explained in the previous section). In contrast, maximum $\dot{Q}$ (Q_{max}) has an optimum temperature well below the fish's upper temperature limit (see **Figure 2(a)**). Furthermore, the inability to increase or maintain maximum S_V at warm temperatures, unlike f_H, is responsible for the bell-shaped relationship between Q_{max} and temperature (see **Figure 2(b)**).

Interestingly, a recent study showed that sockeye salmon (*Oncorhynchus nerka*), acclimated to 12–14 °C and swum at 75% of their maximum swimming speed (i.e., a swimming speed where aerobic metabolism is near maximal), maintained the S_V recorded at 15 °C (0.7 ml kg^{-1}) while temperature was gradually raised over several hours to 24 °C. Yet, maximum f_H failed to increase after 21 °C, and was equal to that measured in resting fish at 24 °C. These new data (see **Figure 3**) suggest that a different model must be used to explain the temperature dependence of maximum $\dot{Q}$ and cardiac scope (e.g., see **Figure 2(c)**). Based on these data, it appears that maximum f_H is reached at CTM in resting fish and at optimum temperatures in exercising fish, but that maximum S_V can be maintained as temperature approaches the fish's CTM. At present, there is no mechanistic explanation as to how exercising sockeye salmon maintained maximum S_V up to their CTM. The heart's pumping capacity (as determined using isolated ventricular strips) is very limited when acutely exposed to large temperature increases (see **Figure 1(a)**). Further, it has been shown that catecholamines released into the circulation at high temperatures have a reduced ability to support cardiac function.

Responses of the Cardiovascular System to Temperature Acclimation

The studies on maximum cardiac function described above differ in that the *in vivo* work used acute temperature changes, while the perfused heart studies compared temperature-acclimated fish. It is known that, with a reasonable temperature change and allowed adequate time, a fish's cardiac performance can at least partially compensate. This is termed temperature acclimation or acclimatization. Thus, the fish heart has considerable phenotypic plasticity, which enables cardiac function to attain a certain amount of independence from the direct effects of temperature.

There are a number of aspects of cardiac physiology that are known to change appreciably with temperature acclimation. To begin, the heart's intrinsic beating rate (the pacemaker rate) at a given temperature is higher in cold-acclimated individuals (see **Figure 1(b)**). The trade-off is that maximum f_H of isolated hearts from cold-acclimated fish is lower than for warm-acclimated fish. This latter observation has already been related to cellular acclimation, such as a decrease in myocyte action potential duration mediated by an increase in inward Na^+ and outward (rectifying) K^+ currents (**see also Design and Physiology of the Heart**: Action Potential of the Fish Heart for ion movements associated with the action potential), a resetting of the cardiac pacemaker rate (again related to increased K^+ currents), and to an enhanced involvement of the sarcoplasmic reticulum (SR) in cellular calcium dynamics. Second, acclimation to warm temperature increases the maximum rate at which the myocardium can be stimulated to contract and the amount of force developed at a particular contraction frequency (see **Figure 1(a)**). This greatly improves myocardial force development as compared to cold-acclimated fish, and especially when compared with the acute effects of warming on myocardial force development. Third, numerous physiological mechanisms (in addition to an increase in intrinsic f_H) have been identified that

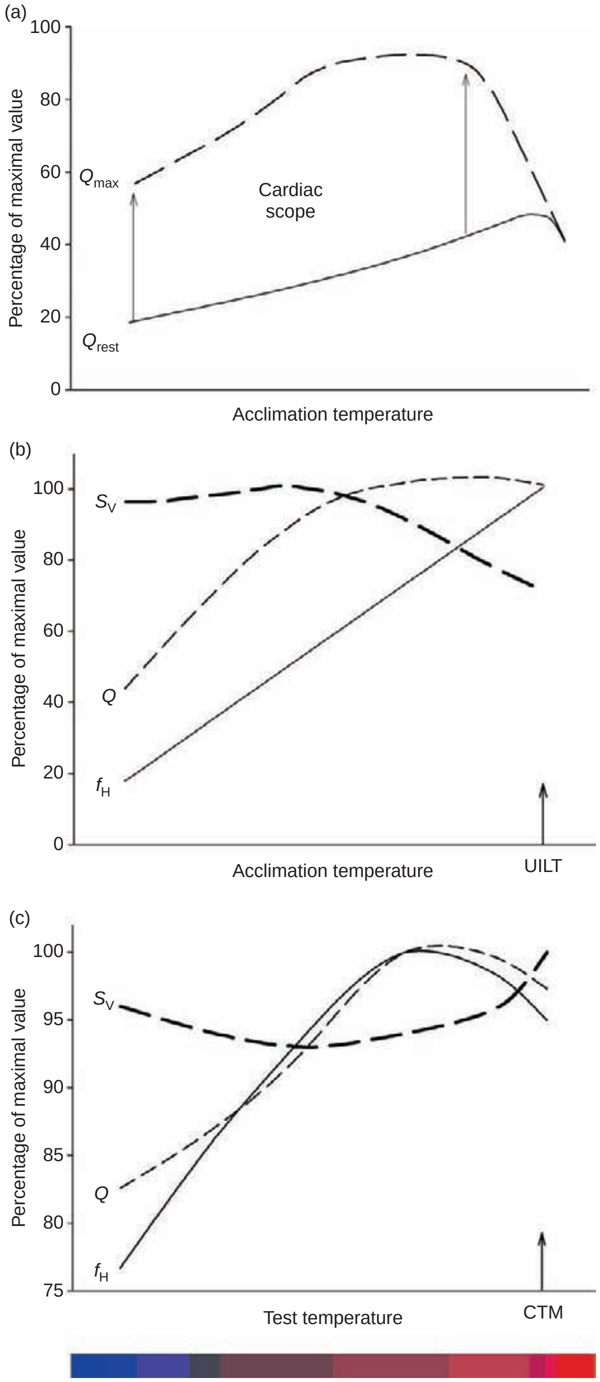

Figure 2 Schematic representations of the influence of acclimation temperature on resting and maximum *Q* (a); and of acclimation temperature (b), and an acute elevation in temperature (by 2 °C h^{-1}) (c), on maximum cardiac variables (heart rate, f_H; cardiac output, *Q*; and stroke volume, S_V). Modified from (a) Farrell (1997) Effects of temperature on cardiovascular performance. Gamperl AK, Swafford BL, and Rodnick KJ (2010) Elevated temperature, *per se*, does not limit the ability of rainbow trout to increase ventricular stroke volume. *Journal of Thermal Biology* 36: 7–14. doi:10.1016/j.jtherbio.2010.08.007.

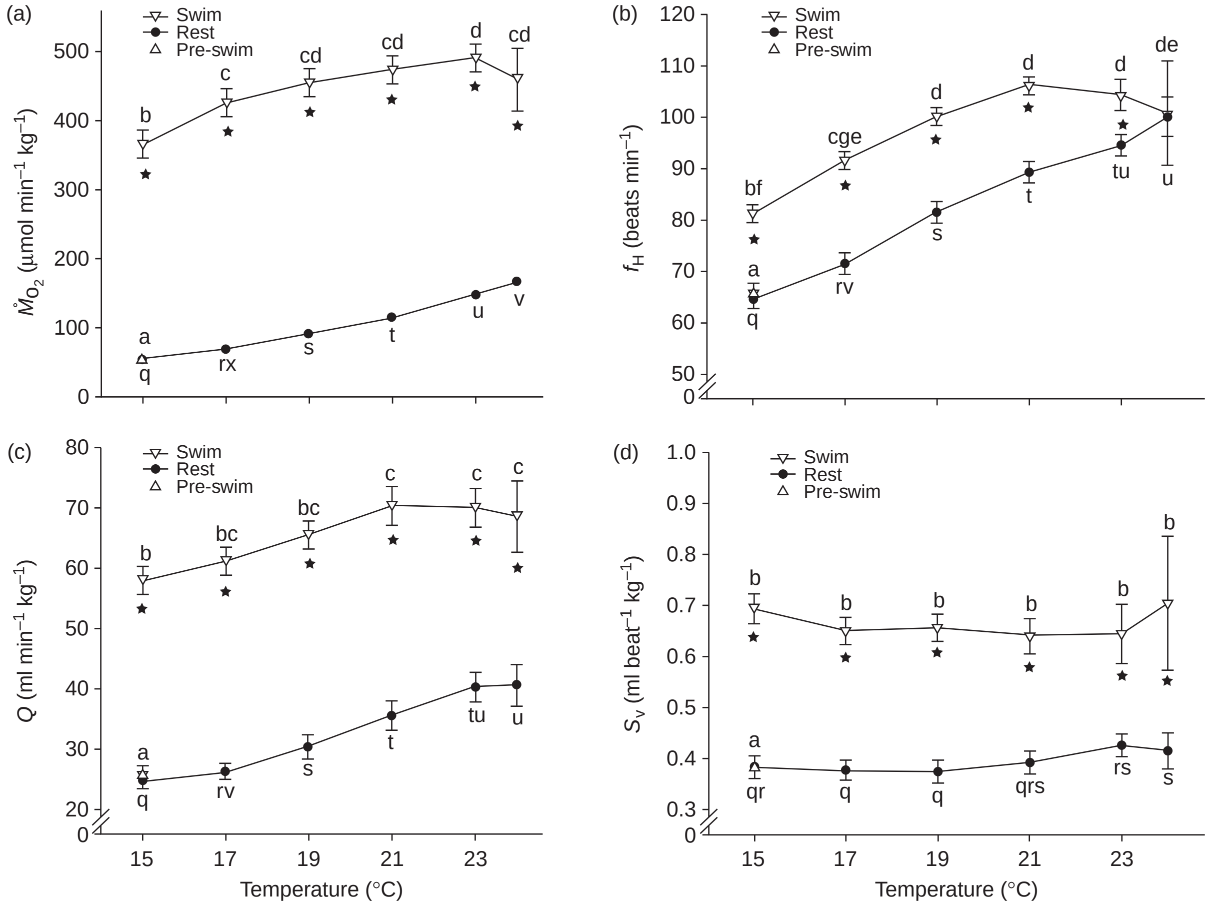

Figure 3 Effect of acute increases in temperature on the resting and swimming oxygen consumption ($\dot{M}_{O_2}$), heart rate (f_H), cardiac output (Q), and stroke volume (S_V) of 12–14 °C acclimated sockeye salmon. The fish were forced to swim constantly at 75% of their maximum aerobic swimming speed. Different letters indicate significant differences between temperatures within the same group (rest or swim). An asterisk (*) indicates a significant difference between resting and swimming fish at a given temperature. Modified from Steinhausen MF, Sandblom E, Eliason EJ, Verhille C, and Farrell AP (2008) The effect of acute temperature increases on the cardiorespiratory performance of resting and swimming sockeye salmon (*Oncorhynchus nerka*). *Journal of Experimental Biology* 211: 3915–3926.

promote positive thermal compensation of the heart's pumping capacity following cold acclimation. These include an increase in the density of L-type calcium channels in the sarcolemma (the main route for Ca^{2+} entry into the cell), an enhanced ability of catecholamines (adrenaline and noradrenaline) to increase myocardial contractility, and a 20–30% increase in ventricular mass in some species. This cardiac enlargement is mainly due to an increase in the size of the heart's myocytes (i.e., hypertrophy), and is hypothesized to increase S_V (to compensate for the negative rate effects of low temperatures on f_H) and probably force development to overcome the increase in blood viscosity at cold temperatures (see below). Finally, this elevated cardiac function at cold temperatures is supported by an enhanced capacity for aerobic metabolism, especially fatty acid metabolism.

With regards to the effects of acclimation temperature on the nervous control of cardiac function, it appears that the response may depend on the taxonomic group. For example, cholinergic tone decreases and adrenergic tone increases with acclimation temperature in rainbow trout, whereas cholinergic tone increases in the sole (*Solea vulagis*) with acclimation to warm temperature.

Adaptations of the Cardiovascular System

Fishes are a diverse taxonomic group, comprised of over 28 000 species, that employ a variety of life-history strategies, experience a range of thermal regimes/environments, and exhibit quite different thermal preferences and tolerances. Thus, it should be no surprise that the response of cardiac function to changes in temperature varies greatly among species (taxonomic groups). Unfortunately, there are few comprehensive studies of thermal sensitivity/adaptation of circulatory functions and their underlying mechanisms in species other than trout/salmon (with the exception of Antarctic fishes, see below). This makes it difficult to discern whether particular response patterns in cardiac function with temperature are characteristic of particular ecotypes (e.g., stenothermal vs. eurythermal, cold inactive vs. active).

Regardless, a number of strategies have emerged that are utilized by fishes when temperature changes. For example, eurythermal species appear to have a lower f_H at equivalent temperatures, thus preserving their scope to increase f_H with temperature. Although the Atlantic cod (*Gadus morhua*) heart does not exhibit cardiac enlargement at cold temperatures or cold-induced enhancement of intrinsic f_H that is typical of other fishes, and is quite insensitive to adrenergic stimulation, a bell-shaped force–frequency relationship (i.e., positive at low contraction frequencies, negative at high contraction frequencies) appears to allow this species to elevate cardiac function at low temperatures and when acutely warmed (e.g., from 4 to 10 °C).

Some species such as the sea raven (*Hemitripterus americanus*) and the crucian carp (*Carassius carassius*), which are inactive in winter and must conserve available energy, display negative (inverse) thermal compensation of f_H (i.e., f_H is lower at a given temperature). Further, in the cold-acclimated crucian carp, action potential duration is prolonged, there is no contribution of the SR to cellular Ca^{2+} management, and myofibrillar adenosine triphosphatase (ATPase) activity (a major determinant of muscle contraction velocity) is greatly reduced. These adaptations appear to be critical to the survival of this species which experiences anoxia (a complete lack of oxygen) in addition to cold water temperatures during the winter.

With regards to adaptations of the cardiovascular system to temperature, the Antarctic fishes are the only example where the influence of activity and temperature on cardiac function has been put into an appropriate phylogenetic framework. Fish in the Antarctic have been geographically and genetically isolated for approximately 25 million years, and live in frigid, glaciated waters characterized by constant temperatures (-1.8 to -1 °C) and high oxygen content. This exposure to permanent cold conditions has led to interesting phylogenetic specializations.

At these extremely cold temperatures, one of the greatest challenges faced by Antarctic fishes is to compensate for the inverse and exponential relationship between temperature and blood viscosity (a component of a fluid's resistance to flow). This increase in viscosity as temperature decreases is due to a number of factors, including:

1. a temperature-dependent increase in the viscosity of the plasma;
2. the accumulation of antifreeze glycoproteins in the blood to prevent the fish from freezing, the levels of these molecules reaching as high 3% (30 mg ml^{-1}); and
3. an increase in the stiffness of the erythrocytes (red blood cells, RBCs) that makes them less deformable and difficult to push through the vasculature.

To compensate for the increase in viscosity with temperature many Antarctic species have a reduced hematocrit (the proportion of the blood composed of RBCs), approximately one-half that of other teleosts (8–15% vs. ~20–40%). Further, these fishes increase the fluidity of the RBC's cell membrane (by altering fatty acid composition) and decrease the amount of hemoglobin per cell (both of these changes increasing the ease at which the cells can be deformed). Finally, they have arteries and veins that are considerably larger than the norm for vertebrates. Collectively, these changes reduce the blood pressure that the heart must generate, while still providing an adequate T_aO_2 to meet the fish's low metabolic demand at these frigid temperatures.

The challenge of increased blood viscosity also appears to have led to a very unique group of fish, the icefish (family Channichthyidae), which some scientists suggest represent an evolutionary dysadaptation permitted because of the extremely stable Antarctic environment. The icefish have a hematocrit <1%, and thus the blood's oxygen-carrying capacity is only approximately 10% of red-blooded Antarctic fish species. In addition, some of them even lack the oxygen binding/transporting protein myoglobin in their heart and muscles. This presents them with a distinct problem – how to deliver enough oxygen to the tissues?

The Channichthyidae have solved this problem by having a cardiac output 6–15 times greater than other teleosts, a blood volume 2–4 times that seen in red-blooded Antarctic fishes, and a heart and vasculature that are well suited to function as a high-flow, low-pressure system. For example, because f_H is no higher in icefish as compared to other fishes at these temperatures, the relative ventricular mass (i.e., g kg^{-1} of body mass; 0.4%) and S_V of icefishes are 3–4 times greater than those of most teleosts and the red-blood Antarctic fishes (**Figure 4**). Correspondingly, the bulbus arteriosus (see **Figure 4**) is greatly enlarged so that it can accommodate the ejection of such a large S_V. Channichthyids have increased the diameter and density of their vasculature, even more than observed in red-blooded Antarctic species. Finally, to overcome the difficulty of oxygen diffusion in the heart due to the lack of myoglobin, the cellular proliferation of mitochondria is appreciable (a mitochondrial volume density twice that measured in Antarctic red-blooded fishes; ~18% vs. 40%).

Given the specializations in cardiorespiratory function/morphology that have accompanied adaptation to Antarctic waters, one would expect that these fishes have a very limited capacity to tolerate or adapt to

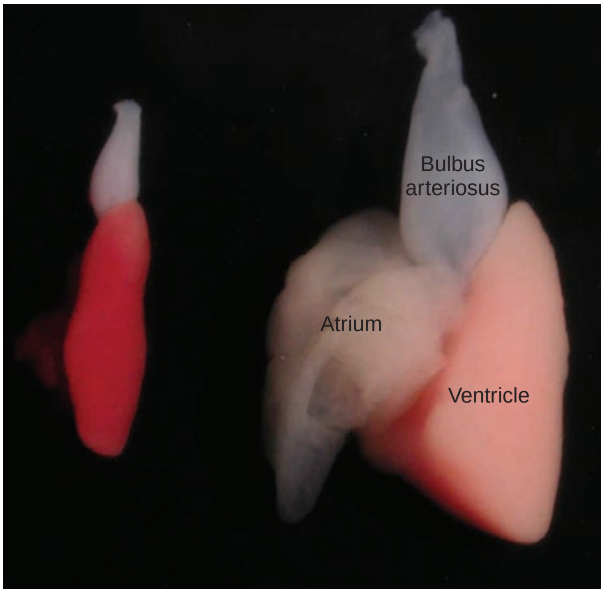

Figure 4 Hearts from approximately 0.25 kg specimens of the red-blooded fish *Trematomus bernacchii* (left) and *Chionodraco hamatus* to illustrate the dramatic increase in heart size displayed by Antarctic icefishes. Photograph courtesy of Dr. Bruno Tota.

temperatures outside their normal thermal range. However, recent studies have shown that the red-blooded Antarctic fish *Pagothenia borchgrevinki* can be acclimated to 4 °C, and that this results in compensatory adjustments in cellular metabolism and cardiovascular function (e.g., see **Figure 5**) that allow these fish to maintain their locomotory performance and cardiac scope until 8 °C. These novel findings for *P. borchgrevinki* suggest that the circulatory system of at least some Antarctic fishes has retained a significant degree of plasticity and that they, and other fish species, may not be as severely impacted by accelerated climate change (global warming) as previously thought.

Summary

Temperature places substantial constraints on the capacity of the fish heart to pump, and thus to support oxygen demand. This is especially true if temperatures are increased or decreased beyond the fish's optimal thermal range over the short term (i.e., acutely), and suggests that temperature-dependent cardiac performance may be the

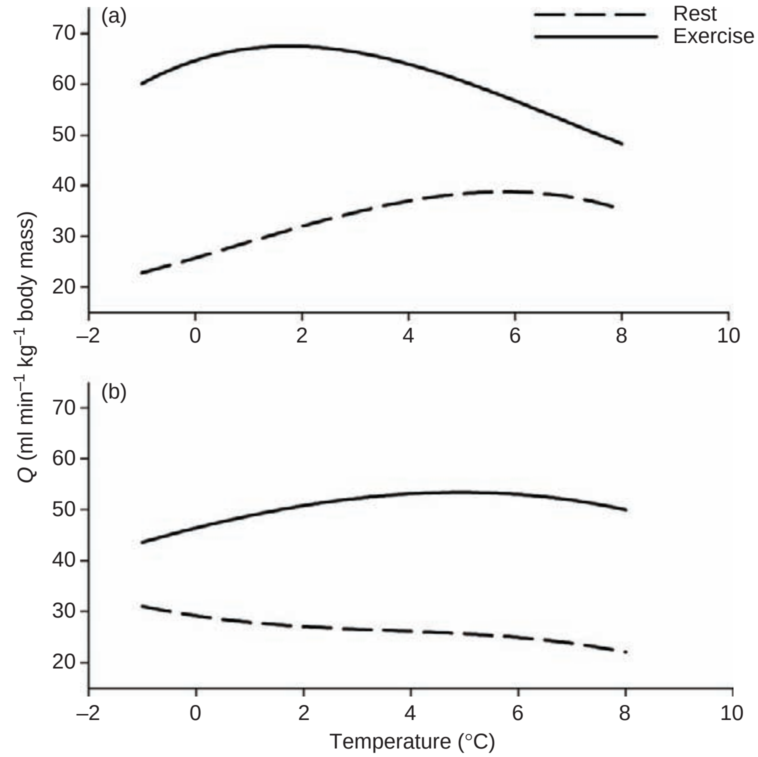

Figure 5 The effect of an acute increase in temperature on resting and maximum (exercise induced) cardiac output (*Q*) in the Antarctic fish *Pagothenia borchgrevinki* acclimated to –1 °C (a) and 4 °C (b). Note the difference in cardiac scope (difference between resting and maximum *Q*) at the higher temperatures in fish acclimated to –1 vs. 4 °C. Modified from Franklin CE, Davison W, and Seebacher F (2007) Antarctic fish can compensate for rising temperatures: Thermal acclimation of cardiac performance in *Pagothenia borchgrevinki*. *Journal of Experimental Biology* 210: 3068–3074.

basis for the thermal tolerance of certain fishes. However, it is also apparent that fish hearts show great diversity in design, control, and function, and that if temperature changes are prolonged (i.e., over several weeks) fishes can compensate to varying degrees for the negative influences of suboptimal temperatures on cardiovascular function. This adaptation is extreme in Antarctic fishes, but surprisingly, does not prevent their hearts from showing considerable flexibility when exposed to variations in temperature.

Glossary

Anabolism Synthesis of materials via metabolic processes; a series of chemical reactions that builds larger molecules from smaller components, usually requiring energy in the process.

Calorie An older unit of energy; today, energy content is normally given in joules (J) and the conversion is: 1 kilocalorie = 4.184 kilojoules.

Cardiac output ($\dot{V}_b$) Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.

Catecholamine Any of a class of amines derived from a catechol that acts as chemical messangers (a hormone or neurotransmitter). The main catecholamines are dopamine, adrenaline, and noradrenaline and these are secreted by neurons of the autonomic nervous system or specific chromaffin cells of the head kidney.

Chyme Partly digested food particles mixed with digestive secretions expelled by the stomach into the intestine.

Digestion The process of solubilization and hydrolysis of ingested nutrients in the gastrointestinal canal into constituent molecules and elements suitable for transport across the intestinal wall.

Hyperemia Increase in blood flow through vasodilation.

In vivo From Latin meaning ‘within the living’ refers to biological processes or experiments occurring or carried out in living organism as opposed to a partial or dead organism.

Postprandial Period after ingesting a meal.

Potentiate To promote or strengthen a biochemical or physiological action or effect.

Temporal Relating to time.

Tetrodotoxin A potent neurotoxin that blocks voltage-gated sodium channels.

Vasoconstriction A decrease in the diameter of a vessel.

Vasodilator A substance that vasodilates a blood vessel, meaning increases its diameter.

Introduction

As organisms grew more complex during the evolution, from simple one-celled life forms to increasingly more complex counterparts, there was a demand for a specialization of different tissues and organs. The development of a gastrointestinal tract (**see also Gut Anatomy and Morphology**: Gut Anatomy, **Integrated Function and Control of the Gut**: Intestinal Absorption, Gut Motility, Gut Secretion and Digestion, and Nervous System of the Gut) necessitated a concomitant development of a specialized gastrointestinal (GI) circulatory system to transport oxygen and nutrients to keep the absorptive tissues alive. Moreover, absorbed nutrients must be removed from the gastrointestinal tract and transported to the main nutrient handling organ, the liver, and tissues beyond.

With this organization came a need to coordinate and regulate the gastrointestinal tract and its blood supply in order to optimize the function during a variety of different conditions that might accompany digestion of a meal, such as exercise, coping with hypoxia and other stressful situations.

Because studies with fish show many instances of physiology and control mechanisms that are similar to those in mammals, the basic control systems were thought to be laid down early during vertebrate evolution. Even so, substantial differences still exist between fish and other vertebrate groups.

Blood Supply of the Gastrointestinal Tract

The blood supply to the gastrointestinal canal differs between elasmobranches and teleosts. In teleosts species studied to date, the primary blood supply to the GI tract is via a single major vessel, the coeliacomesenteric artery (CMA), which is the first caudal branch of the dorsal aorta. The CMA then divides progressively to supply the stomach, intestine and liver, as well as the gonads. Consequently, the terms CMA blood flow and GBF are often used interchangeably – in this article, we use GBF.

The blood supply to the GI tract of elasmobranchs (sharks) shows a more typical vertebrate pattern. Three major vessels branch off the dorsal aorta: the celiac artery, which supplies the liver, spleen, and stomach as well as part of the intestine; the anterior mesenteric artery, which supplies most of the small intestine; and the posterior mesenteric artery, which supplies the large intestine.

This article focuses on the regulation of the blood flow to the GI tract in teleosts because there is very little information for other fish groups. As described above the GI tract is typically supplied (with minor exceptions) by one major vessel, the CMA. Its branches supply for example the gonads, stomach and intestine, as well as the liver with blood. There are notable differences in the branching of the CMA among teleost species, possibly indicating special adaptations of the circulation depending on the habitat and feeding regime. This is discussed in more detail in **Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation.

In most fish species studied, the GI tract regularly receives about 30–40% of the total cardiac output. This is a similar proportion to what has been reported for mammals, perhaps suggesting that the GI tract commands about one-third of the metabolic rate of a fish.

After feeding, the GBF increases appreciably. Routine GBF more than doubles (100–160%) depending on the species and the surrounding environment (see **Table 1** for information on a few selected species). It is unclear at this time whether all of this increase in GBF is related to increased oxygen requirements of the GI tract, the transport of nutrients away from the GI tract, or more likely some combination of the two. The regulation of the GBF in unfed and fed fish is now considered.

Regulation of the Gastrointestinal Blood Flow during Digestion

In order to effectively digest, absorb, metabolize, and distribute the absorbed nutrients after a meal, several physiological adjustments must occur. In particular, there is a large need for the cardiovascular system to adjust in response to the increased oxygen demand related to nutrient absorption and anabolic process related to nutrient uptake.

As food enters the GI tract, there is a substantial increase in the total oxygen consumption of the whole organism, which is referred to as the specific dynamic action (SDA) or heat increment (HI). This increase in oxygen consumption is the result of digestion and absorption, but largely protein metabolism. Thus, without any increase in GBF there would be an unsustainable oxygen dept.

While supplying the metabolically active gut with oxygen is clearly one of the more important functions of the cardiovascular system, the increased GBF is also responsible for supplying the GI tract with many secreted compounds (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion). The blood along with lymph is also important in transporting away the absorbed nutrients and distributing them to the liver or other tissues such as muscles.

The consequence of this is that there is a need for a firm regulation of the GBF before, during and after feeding in order to optimize all these events.

Different Ways to Increase GBF

While there is a need to substantially increase GBF after feeding, most animals studied so far cannot fully perfused all tissues at one time. Thus, there has to be a mechanism whereby blood flow is locally increased when there is a high demand. At the level of the entire GI tract, there are three ways that this can be achieved. First, the heart can pump more blood and the proportion going to each tissue can remain the same. However, this option may become problematic if there are competing demands, such as exercising skeletal muscle, for increased cardiac output. Second, blood flow can be redistributed toward the GI tract from a less active tissues, by constricting blood vessels in the less active tissue (increased vascular resistance) and dilating those in the GI tract (decreased vascular resistance). Third, there could be a combination of increased cardiac output and blood flow redistribution.

Cardiac output

Cardiac output (**see also Design and Physiology of the Heart**: The Outflow Tract from the Heart, Physiology of Cardiac Pumping, Cardiac Anatomy in Fishes, Cardiac Excitation-Contraction Coupling: Routes of Cellular Calcium Flux, Cardiac Excitation-Contraction Coupling: Calcium and the Contractile Element, Cardiac Cellular Length-Tension Relationship, Intracardiac Neurons and Neurotransmitters in Fish, and Cellular Ultrastructure of Cardiac Cells in Fishes) can be increased by means of a increase in either stroke volume (SV) or heart rate (fH) or some combination of these two according to the formula: cardiac output = SV × fH. Most fish indeed increase in cardiac output after feeding. Furthermore, in most cases this increase is enough to account for the entire postprandial increase in GBF. This situation contrasts with mammals, where increased cardiac output is minor (see **Figure 1**).

Redistribution of blood

Redistribution of blood from metabolically less active tissues usually occurs when the vascular resistance of the resistance vessels in the gut decreases, possibly in combination with an increased vasculature resistance in other peripheral tissues. For this to occur, the vessels of the GI tract must vasodilate in response to some stimuli to create a local hyperemia. Since the hyperemia is confined to where food or chyme is present, it is reasonable to speculate that the stimuli are related to the presence of food.

Different Ways of Sensing and Coordinating the Blood Flow with the Presence of Food in the Gastrointestinal Tract

Of substantial importance to the postprandial cardiovascular response is the way in which the GI tract senses the presence of food. Nevertheless, the answer to this question has long eluded scientists and, in large part, still does. We do know that hyperemia is confined to the parts of the GI tract that is filled with food particles or chyme. Thus, there is a selective perfusion of the gut itself. As food enters the stomach, there is a small increase in the blood flow to this region and subsequently when food enters the proximal intestine the blood flow to this region increases (**Figure 2**). Two major hypotheses have been advanced to explain this finding. One hypothesis is that mechanical stimuli are important for the cardiovascular adjustments after feeding; the other is that there is a chemical signal. Working independently or even together, mechanical and chemical stimuli could coordinate the temporal and spatial postprandial patterns seen for GBF. The evidence for each of the sensory modalities is now described.

Mechanical stimuli

When a fish feeds, the stomach or gastric compartment is stretched. The level of the stretching depends on the relative volume of food ingested (often expressed as percentage of body mass) and on the compliance (ability to

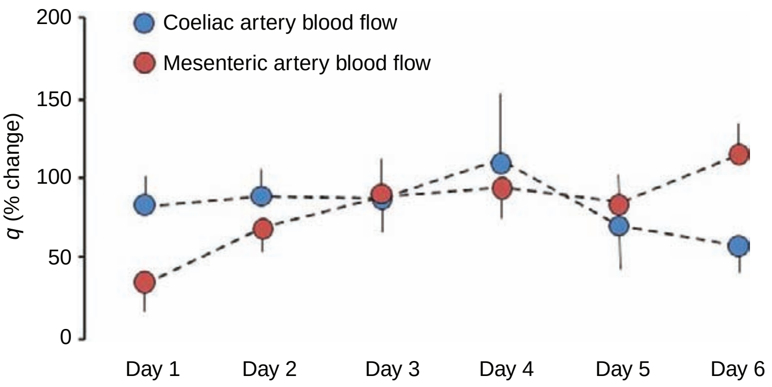

Figure 2 Effect of time on the celiac and mesenteric artery blood flow after feeding. Modified from Axelsson M, Thorarensen H, Nilsson S, and Farrell AP (2000) Gastrointestinal blood flow in the red Irish lord, *Hemilepidotus hemilepidotus*: Long-term effects of feeding and adrenergic control. *Journal of Comparative Physiology B: Biochemical, Systemic, and Environmental Physiology* 170: 145–152.

stretch) of the stomach. Depending on the feeding habit, meals vary considerably in their relative volume.

A salmonid such as the rainbow trout (*Oncorhynchus mykiss*) that feeds on small prey like insects and larvae will only stretch the stomach to a small extent after a meal. Meals are rarely 1% of body mass and a meal of 2% of body mass typically results in satiation. In contrast, an ambush predator such as the shorthorn sculpin (*Myoxocephalus scorpius*) feeds on larger prey and sometimes consume up to 50–80% of their own body mass. These large meals can lead to a very rapid and profound stretching of the stomach.

Limited knowledge exists concerning the importance of mechanical stimuli in triggering and regulation GBF after feeding. Results show that mechanical stimuli by itself will not induce an increase in GBF. This is true for mechanical stimuli applied specifically to the stomach or the intestine. Even so, when the stomach is distended to mimic feeding, a rather large and rapid increase in dorsal aortic blood pressure occurs, which then persists until the mechanical stimuli is reduced (**Figure 3**). This response occurs when the stomach is artificially distended with a fluid-filled balloon as well as when the animal eats a normal diet, indicating that the stimulus is purely mechanical. Moreover, the pressor response seems to be adapted to produce the same vascular response in species with a very different feeding regime when adjusted to the meal size that is typically ingested.

The pressor response is a result of an adrenergic vasoconstriction that is most likely neural in origin. Thus, mechanical stretch of the GI tract causes a generalized systemic vasoconstriction. Consequently, because dorsal aortic blood pressure is the driving force for GBF, this response is a good starting point to increase GBF. All that is needed now for blood flow to redistribute from a region of high vascular resistance to one with a lower resistance is an accompanying vasodilation locally within the GI tract.

Since a mechanically stimulus alone is insufficient to affect the necessary increase in GBF, another type of stimulus is needed. Chemical stimuli seem to produce this local vasodilator response.

Chemical stimuli

After food enters the intestine, the enzymatic breakdown initiated in the stomach continues and results in the release into the gut lumen of small hydrolyzed products such as amino acids, fatty acids, and carbohydrates. It is these hydrolyzed compounds that are important for the induction of a hyperemia. Placing hydrolyzed food directly into the intestine increases GBF. However, placing unhydrolyzed food in the intestine has no effect at all.

What is far from clear for fish is to what extent different nutrients influence and adjust this response. It is also unclear whether or not the caloric content of the food contributes to the hyperemic response. Nevertheless, given other similarities between teleost species and mammals, we can speculate about the importance of chemical stimuli, especially since the few fish studies conducted so far suggest similarities.

All nutrients are certainly not equally potent in inducing the postprandial hyperemia in mammals and fish. In fact, the relative importance of nutrients is likely to vary with diet. Perhaps, the most important consideration among fish is the dietary composition of what they normally eat. For example, a carnivorous fish such as rainbow trout will most likely show a reduced response to carbohydrates because its diet normally contains fewer

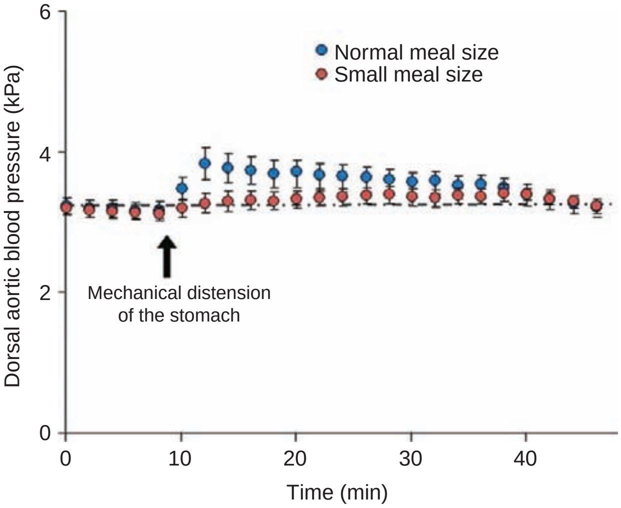

Figure 3 Effect of gastric distension on systemic dorsal aortic blood pressure in rainbow trout. From Seth H, Sandblom E, Holmgren S, and Axelsson M (2008) Effects of gastric distension on the cardiovascular system in rainbow trout (*Oncorhynchus mykiss*). *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 294: R1648–R1656.

carbohydrates relative to proteins and lipids/fats. This contrasts with omnivorous and herbivorous fish like the carps (*Carassius* sp.). Indeed in rainbow trout, a nutrient composition resembling the normal diet is the most effective chemical inducer of the hyperemia, compared to diets rich in either proteins of lipids. There is also a significant temporal difference in how fast the response is induced. This probably reflects the different ways in which nutrients are digested, absorbed, and metabolized.

Another factor influencing the outcome is the caloric or energy content of the different nutrients. Lipids/fats have almost twice the energy density as proteins or carbohydrates. Some results indicate that modest changes in the diet composition while maintaining the same caloric content have no affect on BGF, thus indicating that the caloric content could have an important role. However, it is unclear as to how the caloric content of the diet would be sensed by the gastrointestinal tract. The SDA is larger with a high-protein diet compared to a high-fat diet. Therefore, since the oxygen status of the gastrointestinal tissues is one of the most important regulators of GBF, it is not easy to delineate how the caloric content of the diet would influence the response.

Other factors that in combination to the nutrient composition could affect GBF include the amount of bile secreted, which in mammals potentiates the effects of certain nutrients on GBF.

Integrating the Mechanical and Chemical Stimuli and Relaying the Signal to the Level of the Vessels

Even though we now consider that chemical and mechanical stimuli combine in some way to trigger the postprandial increase in GBF, it is still uncertain in what way these stimuli trigger this response. Several theories have been proposed, some of which are more likely than others. As the knowledge concerning the regulation of GBF increases several of factors, the work in concert to give the overall response will likely emerge as being important.

Extrinsic signals and mechanical stimuli

Mechanical stimuli are most likely sensed by mechano/stretch-receptors in the wall of the stomach. Such receptors are located within the circular muscular layer and relay their signals via the tenth cranial nerve (the vagus) to the central nervous system, where integration and processing can occur. Subsequently, efferent adrenergic pathways to the peripheral systemic vasculature regulate the vascular resistance via α-adrenoceptors (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes). A simple reflex pathway such as this would explain the rapidity of the postprandial response, with the vasoconstriction occurring within seconds after the stimulus (**Figure 3**).

Extrinsic signals and chemical stimuli

The signals that trigger the chemically induced GI hyperemia could be either extrinsic or intrinsic to the GI tract. Extrinsic signals would involve pathways outside of the gut, such as the sympathetic or parasympathetic nervous system as well as endocrine substances (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes). Extrinsic signals are beneficial in that they enable GBF to be regulated in accordance with the needs of the other tissues of the animal. However, this regulation is not as rapid as and possibly also less sensitive than signals working within the GI tract.

The nervous system. The autonomic nervous system, divided into the sympathetic, parasympathetic, and enteric nervous system based on the anatomical as well as the physiological properties, is of fundamental importance to the regulation of blood flow in an animal. It serves to regulate the supply to different tissues depending on the demand of the different tissues such that tissues with high oxygen consumption receive more blood compared to less active tissues. However, tissues that are crucial to the survival of the animal and need a constant supply of oxygenated blood, such as the heart and brain, rely very little on autonomic control of blood flow, but more on local signals. In fish, the vascular system is for the most part under the control of the sympathetic innervation, as well as circulation catecholamines (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes). Whether vasodilation or vasoconstriction occurs depends on adrenergic receptors that are present in that particular tissue (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). There are, however, deviations from this generalization. The vasculature of the gills is for example heavily dependent on parasympathetic innervation as well as circulating hormones.

During fasting, the tone of the GI resistance vessels is under the control of the sympathetic nervous system via the splanchnic nerve. This is to be expected given that there is a redistribution of blood away from the GI tract during stressful situations such as exercise, hypoxia, or general stress as discussed below and in **Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation. However, the role of the autonomic nervous system during postprandial regulation of GBF is far from clear.

Few studies have been conducted as to reveal an involvement of the autonomic nervous system in the postprandial hyperemia and increase in GBF. Nevertheless, results obtained in mammals, as well as from a few fish studies, indicate that the sympathetic and parasympathetic nervous systems are of little importance to the hyperemia. Sectioning the nerves to the GI tract or blocking the effects of these nerves using antagonistic drugs such as atropine (muscarinic antagonist that blocks the action of the neurotransmitter acetylcholine) has very little influence on the GBF response.

Extrinsic nerves could nevertheless be of importance when several tissues compete for a limited blood supply as is the case when a fish has recently ingested a large meal and is subsequently exposed to some sort of a stressor.

Hormones. Hormones such as cholecystokinin (CCK) and gastrin are probably of importance in regulating and coordinating the GBF given their wide range of functions in the gut, including control of gastric emptying as well as bile production and secretion. The few studies that have been conducted show very differing results and it has not been possible to elude whether the effects are primary or secondary to, for example, an increased pancreatic metabolism.

Although the plasma concentration needed to induce an increase in GBF are well above the plasma levels seen after feeding, it is still possible that these substances work in a paracrine fashion (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). This means that there could be much higher levels of the peptide at certain locations along the gut.

In rainbow trout it has been shown that GBF is indeed increased when CCK is injected intra-arterially within a physiological range, possibly through a decrease in the vascular resistance of the gut. Nevertheless, more work in this field is definitely needed in order to gain insight into the role of hormones and how they function in this perspective.

Intrinsic signals and chemical stimuli

Intrinsic regulation of GBF in response to chemical stimuli would allow a very precise regulation of blood flow according to the present demand. Such regulation would resemble for example the regulation that is seen in and around cerebral arteries in the brain

Metabolite signals and oxygen demand (SDA). The most probable trigger for the chemically induced hyperemia is a change in oxygen tension/content, occurring with increased secretion, absorption, and assimilation. The SDA leads to a lowering of the venous oxygen levels, and the regional hypoxia acts either directly on the vessel or induces the release of other vasoactive metabolites, such as lactate, hydrogen ions, adenosine diphosphate (ADP) and nitric oxide (NO) from the surrounding tissues. This creates a localized hyperemia in the parts of the intestine that are filled with hydrolyzed food. A regional hypoxia could also be sensed by red blood cells, leading to the release of adenosine triphosphate (ATP), thus further contributing to the hyperemia.

Proteins or amino acids account for as much as 70–80% of the SDA, due to the assimilation of proteins through catalytic and analytic processes. Even so, proteins are not necessarily the most potent inducer of the postprandial hyperemia.

Processes such as gut motility and peristalsis (**see also Integrated Function and Control of the Gut**: Gut Motility) produce insignificant increases in oxygen consumption and are also of little importance in inducing a hyperemia. Gut motility can, however, lead to a redistribution of blood within the gut wall, thus perhaps affecting absorption. There are also secondary effects and the gut motility also affects the mixing and propulsion of the food through the GI tract. This influences the absorption and hence the GI blood flow.

A change in the osmolarity of the gut tissue is probably also important. Osmolarity increases as nutrients are hydrolyzed.

Local nerves/paracrine signaling. Local nerves that are intrinsic to the GI tract and as such belong to the enteric nervous system (**see also Integrated Function and Control of the Gut**: Endocrine Systems of the Gut) have the potential to relay signals from a sensor (oxygen levels or osmolarity, etc.) to the vasculature. In a very recent study the postprandial hyperemia was abolished after the inhibition of the enteric nervous system using the voltage-gated sodium channel blocking drug TTX. However, since the intrinsic nerves are involved in virtually every aspect of the gastrointestinal physiology, from gut motility to secretion of digestive enzymes and mucus (**see also Integrated Function and Control of the Gut**: Gut Motility), it is still unclear exactly what function or functions are important. Some can be eliminated, leaving only a handful of possibilities. For example, gut motility and digestive enzymes contribute little to the hyperemia. It is likely, therefore, that some of the more integrative roles of the enteric nervous system are crucial to the ability to increase GBF postprandially (see **Video Clip 1** for a short animation showing the different events described above).

Other Factors Influencing the Response of the Circulatory System after Feeding

In ectotherms, body temperature is directly affected by environmental temperature and these animals can only regulate their body temperature behaviorally. Thus, even minor changes in the environmental temperature can have profound effects of the physiology including digestion and absorption (**Figure 4**). Other factors such as stress, hypoxia, hypercapnia, and exercise also affect the postprandial physiology. There is some information

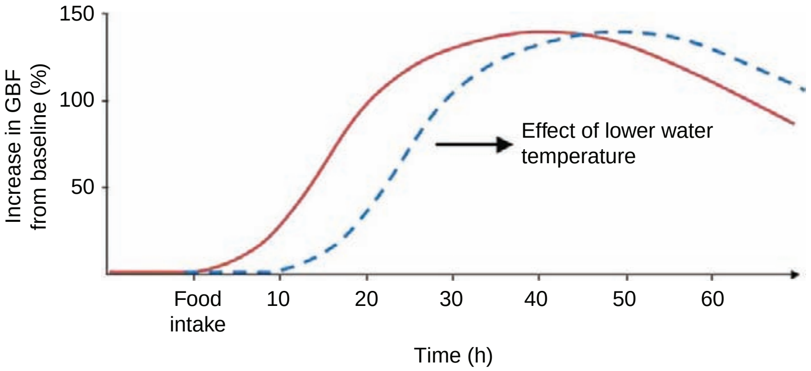

Figure 4 Potential effect of temperature on the gut blood flow postprandially in a fish.

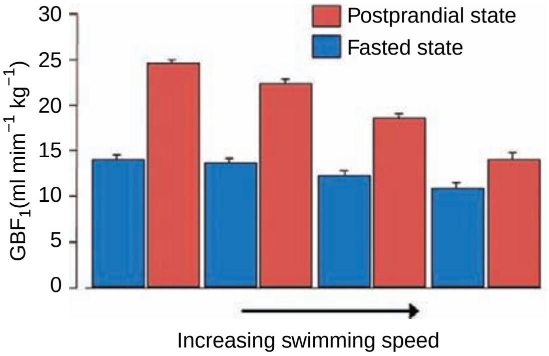

Figure 5 Effect of exercise on gastrointestinal blood flow during routine and postprandial conditions in the sea bass.

available on the effects of this stimulus in fasted animals (**see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation for more information), but little on the effects in postprandial animals. As stated above, most animals studied so far cannot perfuse the entire cardiovascular system at the same time. Instead, there has to be some integration in response to the demands of the different tissues and the subsequent prioritization. For example, during exercise (**Figure 1**; **see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation for more information about this), GBF is reduced to allow more blood to be directed for fight or flight responses. However, salmonids and several other teleost subgroups seem to protect the gastrointestinal blood flow response after feeding and are thus able to maintain some level of digestion and absorption even during exercise. The consequences of this may lead to a reduced maximal swimming performance. Other species such as the agile sea bass (*Dicentrarchus labrax*) show a clear reduction in postprandial GBF exercise (**Figure 5**), presumably reducing GI metabolism and absorption. The portion of the SDA that is related to processes outside of the GI tract could nevertheless be maintained.

Ultimately, the knowledge of the integrated responses of the circulatory system during digestion in fish is based on relatively few studies and given that there are 30 000+ different fish species, (i.e. about half of all vertebrates), any extrapolation to include more species could be problematic.

Glossary

Cardiac output ($\dot{V}_b$) Volume of blood pumped per unit time from the ventricle; the product of heart rate and stroke volume.

Cardiac stroke volume ($\dot{V}_s$) Volume of blood pumped out of the ventricle in a single heartbeat; the difference between ventricular end-diastolic volume and end-systolic volume.

End-diastolic volume Volume of blood in a cardiac chamber at the end of filling (diastole).

End-systolic volume Volume of blood in a cardiac chamber at the end of emptying (systole).

Excess post-exercise oxygen consumption (EPOC) The amount of oxygen that is consumed after exercise has stopped. EPOC represents the oxygen cost of recovering from an exercise bout and includes the replenishment of oxygen stores and metabolites.

Gill secondary lamella(ae) The structures on the gill filaments where the majority of gas exchange occurs between the fish and the surrounding water.

Medulla oblongata Hindmost portion of the brainstem that contains the vagal motor and sensory areas, the respiratory rhythm generator, and cardiovascular control center.

Oxygen consumption ($\dot{M}_{O_2}$) Amount of oxygen consumed by an animal per unit time.

Tissue oxygen extraction The amount of oxygen removed from the blood as it passes through the tissues. It can be calculated from the oxygen content of arterial blood less that of venous blood.

Vis-a-fronte A term for a supplementary cardiac filling mechanism that uses energy directly from ventricular contraction; it is literally the force from in front.

Introduction

Swimming in fishes can be loosely grouped as either pay now (sustained, aerobic swimming activity) or pay later (burst, anaerobic swimming activity) in terms of the cardiovascular system. This simple principle acknowledges that the primary role of the circulatory system is to provide oxygen (O_2) convection to support locomotory muscles either during and/or after activity. Of course, nothing is that simple. The many swimming modes used by fish variably involve anaerobic and aerobic muscle contractions. These contributions are sometimes difficult to separate experimentally. In fact, the prolonged swimming test most commonly used to examine cardiorespiratory responses, the critical swimming speed test, typically involves a gait transition from aerobic to anaerobic swimming as salmonids reach their top speeds. Thus, while pay-as-you-go aerobic swimming is used for most of the prolonged swimming test, the high-speed anaerobic swimming at the end of the test is a pay-later type that can create a substantial, excess post-exercise oxygen consumption (EPOC). Thus, some of the cost of swimming is repaid either after activity has stopped, or at a lower swimming speed when there is capacity to do so. Furthermore, O_2 convection typically lags behind the initial tissue O_2 demand when aerobic swimming starts, creating an initial mismatch between O_2 supply and demand, which also results in an EPOC following aerobic swimming when the debt is repaid.

Nevertheless, the cardiovascular responses following burst activity are qualitatively similar to those during sustained activity. In fact, peak O_2 consumption ($\dot{M}_{O_2}$) for burst and sustained swimming can be similar. An important difference is that the cardiovascular changes that support peak $\dot{M}_{O_2}$ occur during aerobic swimming activity and can be maintained for many hours in some species, whereas peak $\dot{M}_{O_2}$ for burst activity occurs immediately after swimming ceases and decays rapidly, as do the cardiovascular changes. This article first considers the integrated cardiovascular changes that support sustained, aerobic swimming and then briefly turns to those associated with recovery from burst, anaerobic swimming.

Aerobic Swimming

How Is More O_2 Delivered to the Tissues?

The Fick equation for O_2 convection is a useful framework for understanding cardiovascular changes that accompany swimming. It states that $\dot{M}_{O_2}$ is the product of cardiac output ($\dot{V}_b$) and the O_2 extracted from the blood by tissues. Typically, as $\dot{M}_{O_2}$ increases exponentially with swimming speed, there are similar increases in $\dot{V}_b$ and tissue O_2 extraction. Thus, if maximum aerobic swimming results in a fourfold increase in $\dot{M}_{O_2}$, which is easily attainable for many fish species, this increase could come about by doubling both $\dot{V}_b$ and O_2 extraction. The following considers how such increases come about.

How Is $\dot{V}_b$ Increased?

$\dot{V}_b$ is increased by increasing both heart rate (f_H) and cardiac stroke volume ($\dot{V}_s$) in some combination. As described in **Design and Physiology of the Heart**: Physiology of Cardiac Pumping, Cardiac Cellular Length-Tension Relationship, fishes have a remarkable capacity to increase $\dot{V}_s$. For example, during swimming in rainbow trout (*Oncorhynchus mykiss*), $\dot{V}_s$ increases by up to a threefold but f_H increases by only 50%. Tunas, however, mainly increased f_H in response to swimming activity because $\dot{V}_s$ seems to be routinely near its maximum capacity (**see also Pelagic Fishes**: Physiology of Tuna). Other fish groups increase f_H more so than $\dot{V}_s$, while some show similar increases in f_H and $\dot{V}_s$. Thus, fishes use frequency and volume to varying degrees to modulate the heart's output and thereby increase O_2 convection during aerobic swimming. Swimming studies with considerably more fish species are needed before a generalized picture of the interplay of increasing $\dot{V}_s$ and f_H will emerge.

What is already clear, however, is that when athletic fishes swim at maximum $\dot{M}_{O_2}$, their heart is operating at or very near its maximum capacity. In fact, some argue that the circulatory system ultimately limits the maximum level of aerobic swimming.

How Is f_H Increased during Aerobic Swimming?

The cardiorespiratory control centers in the medulla oblongata of the brain (**see also Control of Respiration**: Generation of the Respiratory Rhythm in Fish) regulate the increase in f_H during swimming by changing autonomic nervous output to the heart (**see also Brain and Nervous System**: Autonomic Nervous System of Fishes), as well as to other organs such as the spleen and head kidney.

Routine f_H is normally under simultaneous but opposing inhibitory (vagal cholinergic) and stimulatory (sympathetic adrenergic) control. Thus, f_H can increase during swimming by reducing or removing vagal cardiac tonus, much like the acceleration of a car going downhill when you remove your foot from the brake. Fish can also press the accelerator to increase f_H during swimming by increasing adrenergic cardiac stimulation. This stimulation may come directly from cardiac sympathetic innervation, if present (as in some teleosts), or from catecholamines released into the circulation from the chromaffin tissue of the head kidney, typically as a result of sympathetic nervous stimulation. However, this humoral mechanism is recruited only in stressful swimming situations (**see also Hormonal Responses to Stress**: Hormone Response to Stress and Catecholamines). Therefore, given that many fish species lack cardiac sympathetic innervation, the extent of routine vagal tone is the primary determinant of how much f_H increases during aerobic swimming. However, handling and surgical stress can reduce vagal cardiac tonus, which means fish should be fully rested and recovered when assessing the contribution of vagal tone to increased f_H.

How Is $\dot{V}_s$ Increased during Aerobic Swimming?

First the conditions for venous return must be such that they fill the heart with more blood (increased end-diastolic volume) between heartbeats. Then, cardiac muscle must contract more forcefully to empty the extra blood in the heart (to keep end-systolic volume small) (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). Cardiac contraction can become more forceful because of either the heart's intrinsic response to increased filling (the Frank–Starling effect; **see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping and Cardiac Cellular Length-Tension Relationship) or an adrenergic stimulation of cardiomyocytes (**see also Design and Physiology of the Heart**: Action Potential of the Fish Heart). Likely, a combination of several mechanisms increase venous return to the heart during aerobic swimming, including mobilization of blood from venous capacitance vessels, probably as a result of sympathetic vasoconstriction (**see also Design and Physiology of Arteries and Vein**: Physiology of Capacitance Vessels); increased venous blood pressure; a greater suction of blood into the heart created by increased force of cardiac contraction (see *vis-a-fronte* cardiac filling in **Design and Physiology of the Heart**: Physiology of Cardiac Pumping); and skeletal muscle contractions physically compressing veins and massaging blood toward the heart.

How Is Tissue O_2 Extraction Increased during Aerobic Swimming?

Hemoglobin in arterial blood remains at or near full O_2 saturation (for details, **see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin and O_2 Uptake and Transport: The Optimal P_{50}) during swimming. Therefore, increased tissue O_2 extraction is produced by reducing the O_2 partial pressure (P_{O_2}) and the O_2 content of venous blood. Normally, as much as two-thirds of the O_2 contained in arterial blood is returned unused in venous blood to the heart. Thus, theoretically, tissue O_2 extraction can increase threefold. In reality, the O_2 content of venous blood never becomes fully depleted by locomotory muscles during aerobic swimming. This is just as well because the last organ to be supplied by the circulatory system in most fishes (**see also Design and Physiology of the Heart**: The Coronary Circulation) is the heart. Many fishes do not have a coronary circulation and the heart therefore depends entirely on the O_2 contained in venous blood.

Where Does Cardiac Output Go to during Aerobic Swimming?

Besides more blood being pumped around the circulatory system, the distribution of blood flow changes during aerobic exercise. Blood flow is redistributed by altering vascular resistance among tissues, which is achieved through vasoactivity, the control of the diameter of arterioles through various neural, humoral, and local mechanisms (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). An increase in $\dot{V}_b$ without any vasoactivity would simply increase blood flow to all tissues by the same percent.

Increasing blood flow to locomotory muscles is achieved in part by decreasing the resistance of its blood vessels (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). How central and local arteriolar control mechanisms are integrated to bring about this vasodilation is unknown. Even so, the potential importance of local control should not be underestimated. For example, increased CO_2 production during aerobic swimming and tissue lactate and H^+ production during anaerobic swimming can lead to vasodilation. Of course, improved muscle blood flow also improves waste removal.

The heart does not have the capacity to fully perfuse all circulations at one time (**see also Design and Physiology of the Heart**: Physiology of Cardiac Pumping). Therefore, blood flow to tissues with a lower O_2 priority must be reduced at some point. In what order fish prioritize circulations during aerobic swimming has yet to be studied. Even so, the integument is clearly a lower-priority circulation that can account for about one-third of $\dot{V}_b$ in fish (**see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation). Not only is gut blood flow reduced during swimming, this decrease is linearly related with the increase in $\dot{M}_{O_2}$, suggesting tight integration with swimming effort. Integration of blood flow among tissues requires central controls, but their nature is not understood for fish.

The other reason for blood flow redistribution during aerobic swimming is because central arterial blood pressure is tightly regulated (**see also Integrated Control and Response of the Circulatory System**: Integrated Control of the Circulatory System). Vasodilation of locomotory muscles would decrease central arterial blood pressure unless there was a corresponding increase in vascular resistance of another tissue or an increase in $\dot{V}_b$ (i.e., one that matched the increase in muscle blood flow). As it turns out, aerobic swimming results in a modest increase in arterial blood pressure. Thus, the decrease in overall systemic vascular resistance associated with blood flow redistribution does not quite offset the increase in $\dot{V}_b$. Therefore, central control of vascular resistance among vascular beds, in concert with increased $\dot{V}_b$, is a hallmark of efficient O_2 convection during activity. Exactly how this is integrated requires further study.

How Is Oxygen Loading at the Gills Improved?

Fish increase gill ventilation rate to bring more water and hence more O_2 to the gill secondary lamellae. However, breathing water with faster and deeper ventilations (**see also Control of Respiration**: The Ventilatory Response to CO_2/H^+ and Generation of the Respiratory Rhythm in Fish) has a substantial O_2 cost. Ram ventilation can help by transferring O_2 costs of ventilation to the locomotory muscles. Some fishes, typically the athletic ones, cease respiratory movements completely when they attain a certain swimming speed and rely solely on ram ventilation. They simply adjust mouth gape to regulate gill ventilation rate.

Circulatory adjustments also benefit gill O_2 uptake during aerobic swimming. These are best appreciated in the context of the Fick equation for diffusion (**see also Ventilation and Animal Respiration**: Efficiency of Gas Exchange Organs). When applied to the gills, it states that the rate of O_2 diffusion is proportional to the product of the lamellar surface area available for diffusion (**see also Ventilation and Animal Respiration**: Gill Respiratory Morphometrics and Plasticity in Gill Morphology) and the P_{O_2} gradient, and inversely proportional to the O_2 diffusion distance between the water flowing over the secondary lamella and the blood they contain.

Changes in blood flow to and within secondary lamellae result in a faster rate of O_2 diffusion by increasing the surface area for gas exchange and decreasing the effective diffusion distance. Not all secondary lamellae receive blood flow at rest. Thus, by opening blood flow to all secondary lamellae (termed lamellar recruitment) during swimming can increase the total gill surface area for exchange by as much as 50%. Various vasoactive and physical mechanisms are involved in opening up lamellae (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels). Lamellar recruitment decreases the vascular resistance of the gills because secondary lamellae represent parallel vascular beds (**see also Circulation**: Circulatory System Design: Roles and Principles). While an increase in $\dot{V}_b$ fills these extra lamellae, the increase in $\dot{V}_b$ exceeds the decrease in gill vascular resistance and so ventral aortic blood pressure increases somewhat. This increase in blood pressure and possibly changes in tension of the pillar cells in the secondary lamellae (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy) redistribute blood flow within a secondary lamella, creating a more even blood flow pattern. This redistribution of blood flow within lamellae decreases the overall diffusion distance for O_2 by moving more blood toward regions of the lamella that have a thinner barrier between the blood and the water.

During aerobic swimming, changes in the P_{O_2} of arterial blood leaving the gills are relatively small and have little effect on arterial O_2 concentration (**see also Gas Exchange**: Respiration: An Introduction). Instead, the P_{O_2} gradient across the gills (and hence the rate of O_2 diffusion) increases as a result of a decrease in venous P_{O_2} (see below). Release of stored red blood cells from the spleen (again, under autonomic sympathetic nervous control; **see also Brain and Nervous System**: Autonomic Nervous System of Fishes) can increase the arterial O_2-carrying capacity.

In summary, the increased rate of gill O_2 diffusion required for aerobic swimming comes from a combination of a decrease in venous P_{O_2} to increase the gradient for O_2 diffusion, an increase in the effective surface area for O_2 exchange and a decrease in the overall O_2 diffusion distance. Consequently, fish alter all variables in the Fick equation to improve O_2 diffusion, and then increase the rate at which this O_2 is transported away from the gills to the locomotory muscles by increasing $\dot{V}_b$, releasing more red blood cells into the circulation and redistributing blood flow.

How Is Oxygen Unloading at the Tissues Improved during Aerobic Swimming?

The Fick equation for O_2 diffusion can be applied to the tissues as well. At tissues, the rate of O_2 diffusion is proportional to the product of the tissue capillary surface area and the P_{O_2} gradient, and inversely proportional to the diffusion distance for O_2 between mitochondria and the nearest capillary. The most important circulatory change is increasing blood flow to more capillaries. By doing so, the effective surface area for O_2 diffusion is increased and the O_2 diffusion distance is reduced. Improved diffusion conditions increase tissue O_2 extraction, lowering venous P_{O_2} and O_2 content. However, venous blood rarely becomes fully depleted of O_2 (extreme hypoxia being an important exception). As originally proposed by August Krogh and his wife almost a century ago, this is because any given capillary arrangement for muscle will normally leave a certain amount of O_2 in venous blood because of a diffusion limitation.

Changes to the P_{O_2} at the mitochondia (about 0.1 kPa) and arterial blood are relatively minor by comparison. However, P_{O_2} at the capillary can be drastically altered by increased tissue release of CO_2 and H^+ associated with swimming. Acidification of capillary blood has a profound effect on hemoglobin O_2-binding characteristics (**see also Transport and Exchange of Respiratory Gases in the Blood**: Gas Transport and Exchange: Interaction Between O_2 and CO_2 Exchange), which effectively raises the capillary P_{O_2} and greatly enhances O_2 diffusion into the tissues. Again, a local control mechanism features prominently in O_2 delivery.

The anatomical arrangement of muscle capillaries clearly sets the diffusion conditions for O_2 once all capillaries receive blood flow. Not surprisingly, and in line with their relative O_2 needs, aerobic muscle has a much higher capillary density and lower diffusion distance than anaerobic white muscle (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis). Even so, muscle capillarity in fish is plastic, allowing the anatomical diffusion conditions to be varied. Changes in muscle capillarity are known to occur with temperature acclimation, exercise training, and growth (**see also Design and Physiology of Capillaries and Secondary Circulation**: Capillaries, Capillarity, and Angiogenesis).

Anaerobic Swimming

Swimming modes powered by anaerobic muscle contractions are necessarily brief, but they are typically more powerful than aerobic modes. $\dot{M}_{O_2}$ cannot be measured during such brief swimming events, but is measured afterward. Hence, these swimming modes are loosely grouped as pay later. It is presumed that fish repay the accumulated debt as fast as possible and can recruit the maximum capacity of the cardiovascular system immediately after the swimming bout to do so. Thus, the initial peak $\dot{M}_{O_2}$ during EPOC can approach or equal that reported for maximum aerobic swimming.

Little is known of the cardiovascular changes associated with anaerobic, burst swimming. Those changes that follow burst activity seem to resemble those occurring during aerobic swimming, that is, increased $\dot{V}_b$, f_H, $\dot{V}_s$, arterial blood pressures, and tissue O_2 extraction. The main difference is the decay in these responses following a peak shortly after the activity, unlike during aerobic swimming when steady-state responses prevail. In addition, venous P_{O_2} can decrease below the level seen with maximum aerobic swimming. Visceral blood flow is also reduced when fish struggle, a response that lasts several minutes, even when the burst activity lasts a few seconds (**see also Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation). If burst activity is excessive or chronic, loss of gut blood flow could have negative consequences for digestion time, reducing digestion efficiency (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion) and potentially growth.

An obvious cardiovascular problem will accompany particularly strenuous bursts of activity. When a muscle contracts at ~70% of its maximum tension, it generally closes off capillaries as a result of compression. Thus, a vigorous tail beat temporarily starves skeletal muscle of its blood flow, which resumes during muscle relaxation. However, as tail-beat frequency increases, the time available for muscle blood flow decreases at a time when muscles most need more O_2. This mechanical compression event likely contributes to EPOC.

Maintaining $\dot{V}_b$ during extensive vascular compression would increase arterial blood pressure in proportion to the increase in vascular resistance. Thus, fish briefly slow f_H and reduce $\dot{V}_b$ when they initiate a burst swim, even for a couple of tail beats. Anticipating such events requires central control of f_H via the vagus nerve. Some have argued that this response represents an important mechanism to protect the delicate blood vessel gill secondary lamellae that lie between the heart and the locomotory muscle, a position that exposes the gills to any excessive buildup of blood pressure in the dorsal aorta.

Summary

By examining the cardiovascular changes associated with aerobic swimming within the context of Fick equations that govern O_2 convection and O_2 diffusion, it is clear that fish take advantage of a variety of mechanisms to improve O_2 delivery to their locomotory muscles both during and after swimming. The suite of cardiovascular changes that follow anaerobic, burst swimming are quite similar to those that are maintained during aerobic swimming, but is preceded by a protective temporary slowing of f_H. Major studies are still needed to understand how autonomic neural output from the cardiorespiratory centers of the brain and local controls is mechanistically integrated.

Glossary

Acclimatize (acclimate) Physiological or morphological changes an organism experiences when exposed to chronic (prolonged) changes in environmental conditions.

Adrenergic receptor A receptor located in the cell membrane that binds the hormones adrenaline and noradrenaline. Binding of these hormones to this receptor initiates a signal cascade that results in a number of changes in cellular physiology.

Anoxia Complete absence of dissolved oxygen in water.

Bradycardia A slowing of normal heart rate. In fish, this condition is often associated with hypoxia (low environmental oxygen levels).

Diastole A period of the cardiac cycle when cardiac muscle is relaxed or relaxing. It is associated with filling the heart with blood.

Hyperplasia Growth by increase in the number of cells of an organ or tissue.

In situ Being in the original position; used to describe experiments where measurements are taken on an organ (tissue) while they are still located within the animal.

Myoglobin An oxygen-binding protein in muscle that resembles hemoglobin in function, and enhances the rate of oxygen diffusion.

Partial pressure of oxygen The pressure of a gas mixture is the sum of the partial pressures of the individual components. P_{O_2} is the partial pressure of oxygen, and is approx. 158 mmHg in fully saturated water at sea level: ~760 mmHg total gas pressure × 20.8% oxygen in the atmosphere.

P_{50} The oxygen partial pressure at half-maximal oxygen saturation of blood or hemoglobin.

Systemic vascular resistance An index of the resistance to blood flow in the arterial system. Calculated as arterial blood pressure/cardiac output.

Systole A period of the cardiac cycle when cardiac muscle is contracted or contracting. It is associated with the ejection of blood from the heart.

Teleost A bony fish of the subclass Teleostei, having rayed fins and a swimbladder.

Introduction

Aquatic habitats are subject to variations in many environmental parameters, and one of the most important affecting non-air-breathing vertebrates is dissolved oxygen. Hypoxia, or a subnormal concentration of oxygen, is a phenomenon that occurs in a wide variety of aquatic environments, from the Amazon drainage basin, to ice-covered shallow water bodies in winter and, ever increasingly, to coastal marine areas around the world (including the Black and Baltic Seas, the Gulf of Mexico, and the Gulf of St. Lawrence).

Most fish depend on oxygen contained in the water to supply their metabolic demands. This oxygen is taken up across the fish's gills and then transported to the tissues through the circulatory system. Thus, when water oxygen levels become subnormal (i.e., hypoxic), fish can make a number of adjustments. For example, they will move away from the area of low dissolved oxygen, decrease their activity and thus their requirement for oxygen, or make physiological adjustments that maintain oxygen delivery to the tissues. These changes can include modifications to: (1) ventilation rate or amplitude; (2) gas exchange across the respiratory surface (gills); (3) cardiovascular function; and (4) hemoglobin-oxygen binding and blood-oxygen carrying capacity. Given the critical role that the circulatory system plays in blood oxygen transport, and that fish heart function is solely or partially (for those with coronary arteries, or with lungs or accessory breathing organs) dependent on whatever oxygen is left in the venous blood after it has traversed the fish's other tissues, it is not surprising that the cardiovascular function of fishes during hypoxia has been an active area of research for over 50 years.

This article provides an overview of the cardiovascular responses to hypoxia (anoxia) in fishes. Information is divided into two broad categories for ease of presentation:

1. acute hypoxia, referring to minutes to hours of lowered water O_2 and
2. chronic hypoxia, where decreases in water O_2 levels last days or weeks, that is, long enough for the fish to potentially acclimatize to the limited oxygen conditions through changes in gene and protein expression.

Acute Hypoxia

Heart Rate

There are some taxonomic groups that do not exhibit changes in heart rate (f_H) when exposed to hypoxia (e.g., hagfish and lungfish), or where no clear response pattern to hypoxia has been established (e.g., Antarctic fishes). However, the most common cardiac response to hypoxia is reflex bradycardia (a decrease in f_H). This slowing of the heart is primarily mediated by an increase in inhibitory (cholinergic) nervous tone on the heart's pacemaker cells, and several direct benefits of hypoxic bradycardia to the fish heart have been proposed. These benefits include:

1. improved contractility of the heart muscle (myocardium) due to the negative force–frequency effect (**see also Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Temperature);
2. enhanced oxygen delivery to the myocardium due to an increase in the residence time of blood in the heart's chambers (i.e., more time for oxygen diffusion), and stretching of the myocardium (i.e., decreased diffusion distance) in species that also respond to hypoxia with an increase in stroke volume (S_V, see below);
3. more efficient use of available oxygen due to slower rates of pressure development during systole; and
4. an increase in coronary blood flow (and thus oxygen delivery to the heart), due to an increase in the duration of diastole. Diastole is the part of the cardiac cycle where the majority of coronary blood flow occurs (~75–85%) (**see also Design and Physiology of the Heart**: The Coronary Circulation).

In fishes, the partial pressure of oxygen (P_{O_2}, in mmHg) at which bradycardia occurs varies greatly, from 110 mmHg in the dourado (*Salminus maxillosus*) to as low as 25 mmHg for the Amazonian fish (*Hoplias lacerdae*). What environmental factors determine the P_{O_2} at which bradycardia is initiated has not been extensively studied, but data from a number of investigations suggest that it is related to water temperature, and a fish's lifestyle and hypoxia tolerance. For example, the P_{O_2} at which bradycardia was initiated increased from ~20 to 60 mmHg in spangled perch (*Leiopotherapon unicolor*) acclimated to temperatures between 10 and 30 °C. The largemouth bass (*Micropterus salmoides*), which prefers shallow/weedy areas (i.e., a habitat prone to large fluctuations in dissolved oxygen), initiates bradycardia at least 45 mmHg later than the smallmouth bass (*Micropterus dolomieu*) which inhabits deeper and colder waters. Finally, the dourado and rainbow trout (*Oncorhynchus mykiss*), which are very active species that normally inhabit well-oxygenated waters, have thresholds for the induction of bradycardia of >70 mmHg, while those for the hypoxia-tolerant carp (*Cyprinus carpio*) and tench (*Tinca tinca*) are <40 mmHg. These relationships make sense given the increase in metabolism with temperature (two- to threefold change per 10 °C) and the negative influence that temperature has on the solubility of oxygen in water and on the capacity of hemoglobin to carry oxygen (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin).

From a physiological perspective, hypoxia-tolerant species often possess hemoglobins with a lower P_{50} value for hemoglobin-oxygen binding. Without a low P_{50}, the arterial blood would not be fully saturated at low water oxygen tensions, but this important aspect is covered elsewhere in this encyclopedia (**see also Transport and Exchange of Respiratory Gases in the Blood**: Hemoglobin).

Cardiac Output and Stroke Volume

With the exception of hagfish, all fish examined to date show an increase in S_V when hypoxia-induced bradycardia develops. The difference among species, however, lies in the oxygen level at which they initiate increases in S_V and the extent that the increase in S_V compensates for the effect of bradycardia on cardiac output (Q; the product of f_H and S_V). In general, fish exhibit three patterns as illustrated in **Figure 1**.

In response pattern 1 (e.g., dourado; sea bass, *Dicentrarchus labrax*), S_V increases are either simultaneous with the onset of bradycardia or begin once bradycardia is initiated (often near the limit of hypoxia tolerance). However, these increases in S_V do not compensate for the decrease in f_H and so Q falls almost continuously (albeit slower than f_H) as hypoxia progresses.

In response pattern 2 (e.g., dogfish shark, *Scyliorhinus canicula*; winter flounder, *Pleuronectes americanus*), S_V increases when bradycardia is initiated and this increase maintains Q at, or near, normoxic levels until hypoxia becomes severe.

In response pattern 3 (e.g., rainbow trout; Atlantic cod, *Gadus morhua*), S_V starts to increase well before the onset of hypoxic bradycardia (resulting in a significant increase in Q) and further increases in S_V once bradycardia is initiated maintain Q above normoxic levels until the fish reaches its hypoxic limit.

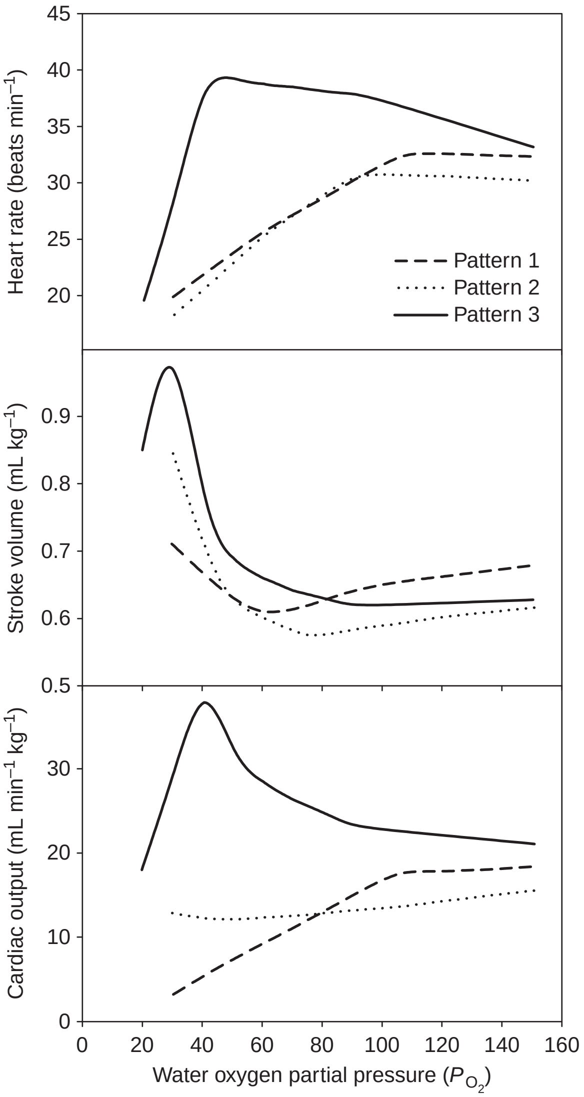

Figure 1 Schematic representation of the three patterns exhibited by fish cardiac parameters when exposed to acute hypoxia.

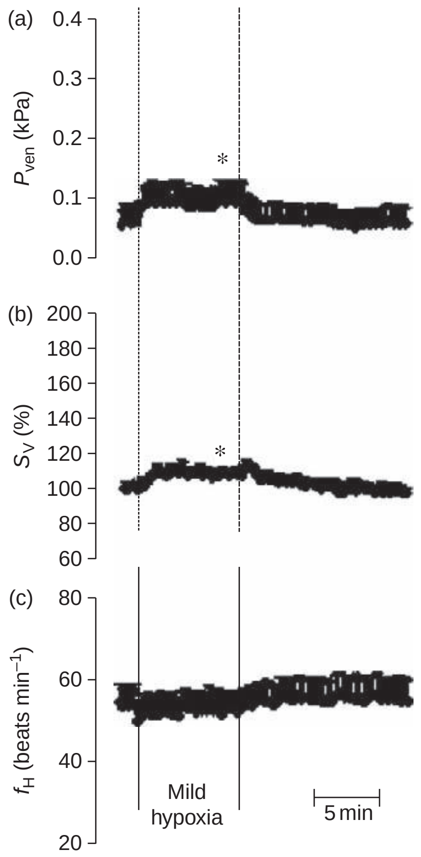

Figure 2 Effect of 8 min of mild hypoxia (P_{O_2} ~ 85 mmHg; section located between dotted lines) on central venous pressure (P_{ven}), stroke volume (S_V), and heart rate (f_H) in rainbow trout (*Oncorhynchus mykiss*). The asterisks indicate a significant difference between the average value for the normoxic period and the average value of the last 2 min of the hypoxic period. Modified from Sandblom E and Axelsson M (2005) Effects of hypoxia on the venous circulation in rainbow trout (*Oncorhynchus mykiss*). *Comparative Biochemistry and Physiology A* 140: 233–239, with permission from Elsevier.

Given the limited number of species on which direct measurements of $\dot{Q}$ and S_V have been performed under well-controlled experimental conditions, the extent that inter-specific variability in the responses of these parameters to environmental hypoxia relates to differences in activity, lifestyle, and/or hypoxia tolerance is unknown. However, we have some understanding of how S_V is controlled during hypoxia in fishes. For example, active regulation of venous tone (primarily through the stimulation of α-adrenergic receptors) is critical for regulating S_V in fishes during hypoxia. Venous pressure and mean circulatory filling pressure increase during hypoxia (e.g., see **Figure 2**), and these parameters are major factors promoting cardiac filling and increases in S_V, and therefore $\dot{Q}$, during hypoxia (**see also Design and Physiology of Arteries and Veins**: Physiology of Capacitance Vessels).

Vascular Resistance and Arterial Blood Pressure

Generalizations about how these parameters are affected by hypoxia are difficult because of varied protocols and the species-specific nature of the response of arterial blood pressure to hypoxia (there are reports of no change, as well as large increases and decreases in blood pressure). However, considerable knowledge exists on the effects of hypoxia on gastrointestinal (GI) blood flow in teleosts, which then provides important insights into the regulation of systemic vascular resistance (R_{sys}) and blood flow distribution (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels, **Integrated Response of the Circulatory System**: Integrated Responses of the Circulatory System to Digestion).

Vascular resistance of vessels supplying the stomach, intestines, and other digestive organs increases by

1.5 times during severe hypoxia, and this decreases blood flow to these organs by 40–60%. The large increases in gut vascular resistance in Atlantic cod do not increase R_{sys} because the rest of the somatic (body) circulation is dilated at these water oxygen levels. This results in a redistribution of blood flow from the GI circulation to the body. Finally, the relative proportion of *Q* reaching the gut of sea bass during hypoxia depends on whether the fish has eaten or not: gut blood flow following exposure to hypoxia decreasing by approx. 50% in unfed sea bass but by only 20% after feeding. This indicates that locally released substances can offset the effects of hypoxia on GI vascular resistance and blood flow (i.e., the response is plastic).

Recent experiments have also revealed that hydrogen sulfide (H_2S) plays a very important role in regulating blood pressure and R_{sys} in fish during hypoxia. This may seem surprising given that H_2S is best known as a noxious and toxic gas. Yet, research has shown that H_2S is synthesized by vascular smooth muscle cells, that concentrations of H_2S in rainbow trout plasma reach levels that produce vasoactive effects in isolated vessels, and that hypoxia and H_2S evoke the same response irrespective of whether the particular vessel's response is contraction or relaxation.

Hypoxia Tolerance of the Heart

Even with the varied cardiac responses to hypoxia among species (see above), and with few exceptions (e.g., see the crucian carp below), there is a lower level of oxygen (i.e., P_{O_2}) at which cardiac function can no longer be sustained. This limit is again species specific, and depends highly on temperature and the cardiac workload being performed when oxygen levels fall. For example, when the *in situ* rainbow trout heart is perfused with saline that has a $P_{O_2} < 5$ mmHg (i.e., a severe level of hypoxia) at 10 °C, resting *Q* slowly falls to just 25% of initial levels within 30 min. By contrast, maximum *Q* cannot be maintained when P_{O_2} is < 70 mmHg, and the heart fails completely when pushed to develop maximum *Q* at P_{O_2} values < 20 mmHg. Further, with intense exercise, the venous blood becomes acidotic (has a lower pH) and hyperkalemic (elevated potassium ion concentration) due to the release of protons and K^+ from the working muscles. These perturbations in blood chemistry raise the P_{O_2} level at which hearts fail when asked to pump maximally to between 35 and 50 mmHg. Because saline does not contain as much oxygen as whole blood, these P_{O_2} thresholds for routine and maximum cardiac performance will be lower *in vivo*, but the results still stress the point that a less severe hypoxia (and associated conditions) impairs maximum cardiac function compared with routine cardiac function.

Temperature and severe hypoxia also have interactive effects on cardiac function. First, although severe hypoxia decreases *in situ* rainbow trout heart performance at all temperatures, the extent of the loss of performance is inversely related to temperature (**Figure 3**). This is not surprising given that water O_2 content decreases with temperature, while metabolic demand (and thus *Q*) generally goes up by a factor of 2–3 with each 10 °C increase. Nonetheless, lactate production increases proportionally with temperature, and this suggests that factors other than insufficient anaerobic energy production contribute to the inverse relationship between cardiac performance and temperature. Indeed, a faster accumulation of waste products likely contributes greatly to the heart's loss of function at high temperatures. These waste products include intracellular inorganic phosphate coming from the breakdown of creatine phosphate to creatine, and reduced intracellular pH associated with lactic acid production.

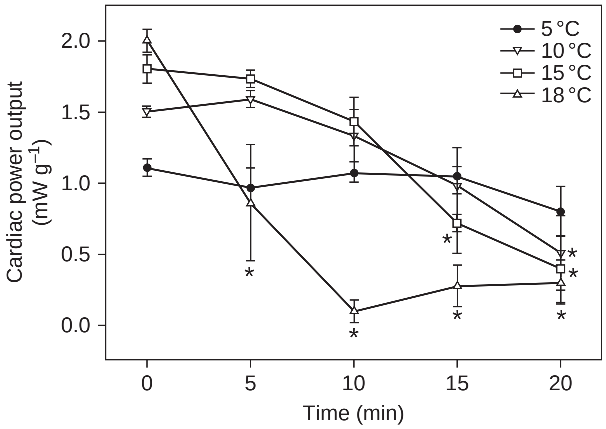

Figure 3 Effect of test temperature on changes in rainbow trout basal cardiac power output during 20 min of anoxic perfusion. An asterisk (*) indicates a value different from pre-anoxic values at a given temperature. Values are means ± SEM, *N* = 6–7. Trout were all acclimated at 10 °C. Note: Cardiac power output = *Q* × output pressure, and is an index of cardiac workload. Modified from Farrell AP and Stecyk JA (2007) The heart as a working model to explore themes and strategies for anoxic survival in ectothemic vertebrates. *Comparative Biochemistry and Physiology A* 147: 300–312, with permission from Elsevier.

Second, cardiac recovery after a hypoxic insult is also inversely related to temperature. This effect is not due to myocardial necrosis (cell damage) or differences in biochemical and energetic parameters, and thus likely caused by myocardial stunning (mechanical dysfunction that persists after reoxygenation due to a decreased responsiveness of myocardial contraction to Ca^{2+}). This decrease in responsiveness is thought to be caused by damage of the contractile proteins by oxygen radicals and/or Ca^{2+} overload, and is dependent on temperature and the duration of anoxia. Thus, the cardiac damage due to severe hypoxia is reduced at a lower temperature.

Finally, circulating catecholamines are very important for supporting cardiac function (i.e., increasing contraction frequency and strength) under conditions that would normally compromise heart function (e.g., hypoxia, acidosis, and hyperkalemia). However, their positive influence on heart function is greatly diminished at high temperatures in rainbow trout. Thus, an inability of adrenergic mechanisms to support cardiac function at high temperatures may limit fish myocardial hypoxia tolerance *in vivo* under conditions that require elevated cardiac performance (e.g., when swimming maximally).

Chronic Hypoxia

Surprisingly, few studies have examined the effects of chronic hypoxia on *in vivo* cardiovascular function. Recently, Atlantic cod were shown to have lower resting and maximum values for S_V and $\dot{Q}$ (by ~28%) after hypoxic acclimation (**Figure 4**). Potential explanations for the decline in pumping capacity of hearts from hypoxic acclimated cod include: (1) myocardial damage by constant exposure to low oxygen conditions;

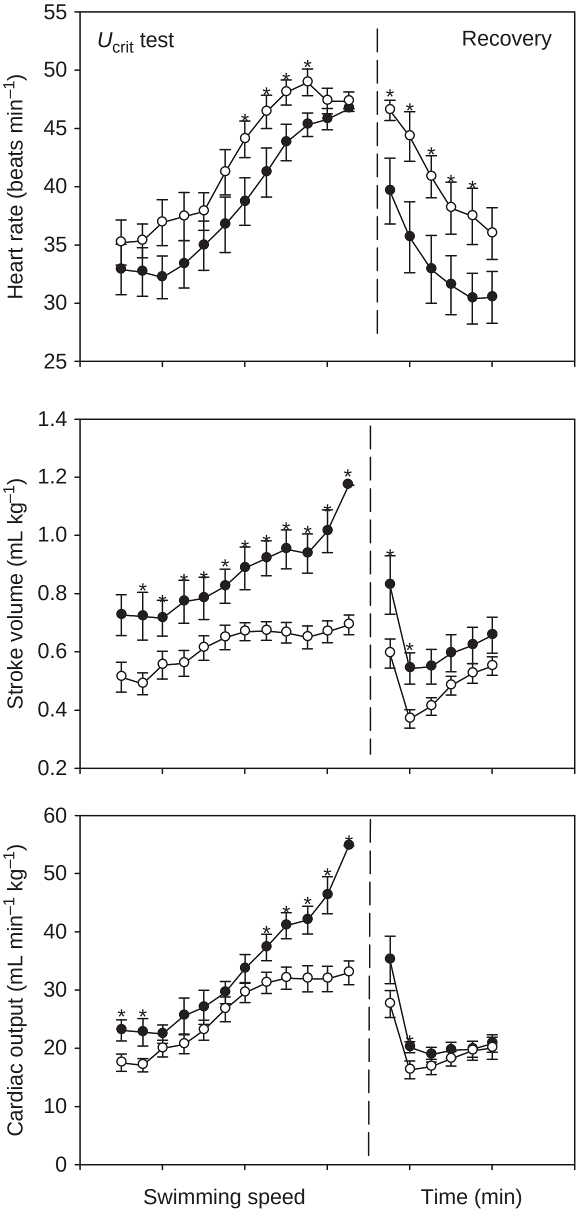

Figure 4 Cardiac parameters and oxygen consumption in normoxic- ($N = 10$, filled symbols) and hypoxic-acclimated (P_{O_2} 60 mmHg; $N = 12$, open symbols) Atlantic cod during a critical swimming speed (U_{crit}) test, and during post-exercise recovery. The asterisk (*) indicates a significant difference ($P < 0.05$) between the normoxic- and hypoxic-acclimated groups at a particular swimming speed. Reproduced from Petersen LH and Gampert AK (2010) Effects of acute and chronic hypoxia on the swimming performance, metabolic capacity and cardiac function of Attantic cod (*Gadus morhua*). *Journal of Experimental Biology* 213: 808–819, with permission from the Company of Biologists.

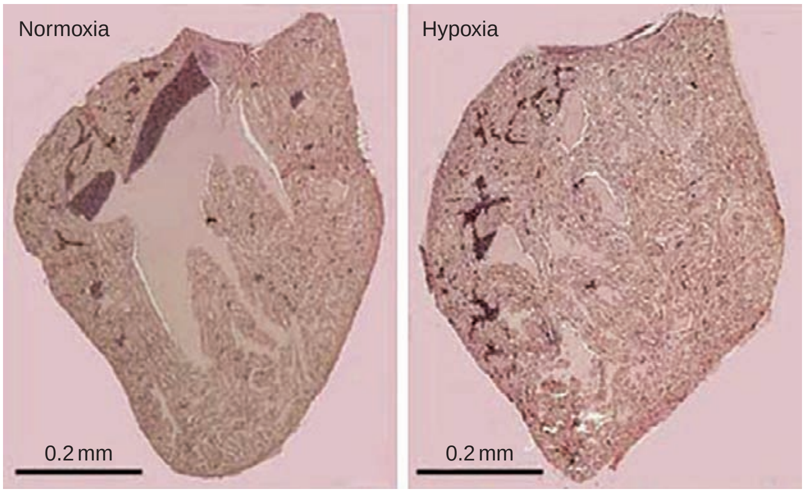

Figure 5 Histological changes in the cichlid (*Haplochromis piceatus*) heart after exposure to chronic constant hypoxia (P_{O_2} ~ 15 mmHg for 3 weeks). Heart of: (a) normoxia-acclimated individual and (b) hypoxia-acclimated individual. Hearts were sectioned and stained with hematoxylin–eosin. Reproduced from Marques IJ, Leito JTD, Spaink HP, *et al.* (2008) Transcriptome analysis of the response to chronic constant hypoxia in zebrafish hearts. *Journal of Comparative Physiology B* 178: 77–92. Reproduced with kind permission from Springer Science and Business Media.

(2) cardiac stunning (see above); and (3) hypoxia-induced myocardial remodeling, without any damage or stunning. In support of this final explanation, acclimation of zebrafish and the cichlid (*Haplochromis piceatus*) to water of 50% O_2 content increased cardiac myocyte density (presumably through hyperplasia) and this resulted in a reduction in the size of the central ventricular cavity (**Figure 5**). Such a decrease in the capacity of the ventricle to fill with blood would contribute to a decrease in maximum S_V, and Q, in hypoxia-acclimated Atlantic cod. Despite the diminished S_V, hypoxic-acclimated Atlantic cod had elevated f_H at rest and during exercise (see **Figure 4**). The mechanism(s) that resulted in the resetting of f_H in hypoxic Atlantic cod is unknown. However, as the f_H of *in situ* (isolated) hearts from hypoxic-acclimated Atlantic cod was similar to that of normoxic-acclimated hearts at resting or at maximal Q, the higher f_H in hypoxic-acclimated cod was clearly a result of altered neural and/or hormonal control. Finally, *in situ* hearts from hypoxia-acclimated Atlantic cod maintained maximum cardiac function longer during severe hypoxia and recover better.

Several strategies can enhance cardiac function during hypoxia, including reducing cardiac ATP demand, increasing cardiac glycolytic ATP production and extending the lower limit at which oxygen can be extracted from the blood. To date, only the first strategy has been identified in most fish species, including the Atlantic cod. Increases in the expression of genes related to glucose transport, uptake, and metabolism are short-lived (<6 days) when Atlantic cod are acclimated to hypoxia, and cardiac lactate dehydrogenase activity, myoglobin, and mitochondrial properties are unchanged. Hearts might reduce ATP demand by decreasing protein synthesis, Na^+K^+ATPase activity, and shortening of the action potential; the latter two possibilities may involve the opening of ATP-sensitive K^+ channels on the muscle cell's surface (i.e., sarcolemmal KATP channels). Finally, it is likely that the improved functional recovery shown by hearts from hypoxic-acclimated cod was at least partially due to an increased ability to protect the myocardium against the negative effects of reactive oxygen species (ROS). Indeed, six genes important for protection against ROS were upregulated in the zebrafish following 21 days of hypoxic acclimation.

Cardiac Function in the Crucian Carp

The crucian carp is the most hypoxia-tolerant fish known, and can survive without oxygen for days to months under the ice of shallow lakes. As such, it seems to be a special case among fishes (**see also Bony Fishes**: Crucian Carp). The exceptional anoxia tolerance of this species is largely attributed to the ability to produce ethanol in skeletal muscle as the major anaerobic end product, and thus avoid the acidosis that is associated with glycolysis. This species also has a unique cardiovascular response to hypoxia (anoxia) as compared to all other fishes studied to date (**Figure 6**).

Crucian carp display a typical reflex bradycardia upon initial exposure to anoxia, with a large compensatory increase in S_V which, in turn, increases Q. However, by 48 h of anoxia, all cardiac parameters return to preanoxic levels and remain stable for at least 5 days. This long-term maintenance of cardiac

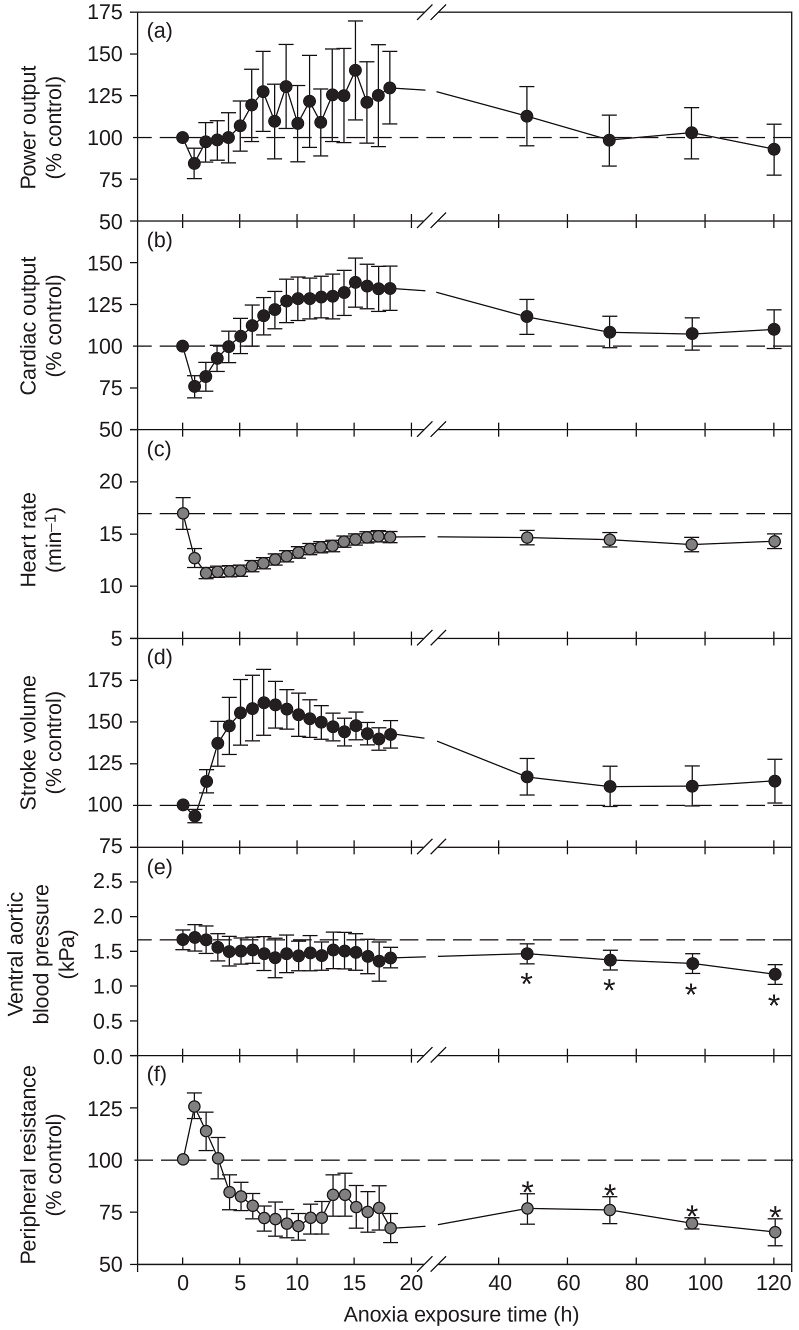

Figure 6 The response of crucian carp cardiovascular function to 5 days of anoxia at 8 °C. Asterisks indicate a significant difference as compared with time 0 (normoxia). Modified from Vornanen M, Steyck JAW, and Nilsson GE (2009) The anoxia-tolerant crucian carp (*Carassius carassius* L.). In: Richards J (ed.), Brauner CJ and Farrell AP (ser. eds.) *Fish Physiology*, vol. XXVII, pp. 302–360. London: Academic Press, with permission from Elsevier.

function is thought to be important for transporting glucose from the liver to metabolically active tissues, and ethanol from skeletal muscle (where it is produced) to the gills where it can be eliminated from the body. Q is maintained in anoxia because the heart's low ATP demand can be met by its maximal capacity to produce ATP through anaerobic glycolysis. In addition, several factors contribute to the low ATP demand of the crucian carp heart during anoxia. ATP demand is greatly reduced by low winter temperatures; f_H is only approximately one-third of other fishes at these temperatures; this species has low arterial pressures at rest; and both blood pressure and R_{sys} are significantly reduced (by 30–40%) upon exposure to anoxia (see **Figure 6**). Collectively, these characteristics reduce cardiac power output (workload) of the heart, and thus its ATP demand.

Summary

When exposed to hypoxia, fish make a number of adjustments in cardiovascular function (Q, f_{H}, S_{v}, venous pressure, and R_{sys}). These highly depend on the duration (acute vs. chronic) and depth of hypoxia (mild vs. severe), and a species' lifestyle and evolutionary history. However, there are general limits to how long the heart can endure under conditions of oxygen limitation, and this is related to the severity of the hypoxic insult, the workload the heart is subjected to, and temperature.

We have only begun to understand how changes in control mechanisms, gene expression, protein levels/function, signaling cascades, and oxidative and anaerobic metabolism result in intra- and inter-specific differences in myocardial hypoxia tolerance and performance. Such studies will be critical for understanding the plasticity of cardiovascular responses to hypoxia, the evolution of fishes, and which fish will survive as hypoxic zones increase.

Glossary

Apical membrane The side of an epithelial cell facing the outer world; for the gut, this is the lumen.

Autonomic nervous system The nerves controlling the inner organs, operating through reflexes without conscious control.

Basolateral membrane The basal and lateral sides of an epithelial cell facing the internal environment.

Chyme Partly digested food particles mixed with digestive secretions expelled by the stomach into the intestine.

Digestion The process of solubilization and hydrolysis of ingested nutrients in the gastrointestinal canal into constituent molecules and elements suitable for transport across the intestinal wall.

Endocrine Mode of secretion in which a chemical is released by a cell into extracellular fluid and then enters the blood.

Enteric nervous system The part of the autonomic nervous system contained within the gastrointestinal wall.

Enterocyte Columnar adsorptive cell of the intestinal gut epithelium.

Epithelium Relatively flat tissue (composed of one or a few cell layers) that lines cavities and surfaces in multicellular organisms.

Exocrine Mode of secretion in which a chemical is released from a cell into a duct that leads to the outside of the organism (including the lumen of digestive tract).

Extrinsic innervation Innervation that comes from outside the organ. A nerve that is extrinsic to the gut has its cell body outside the gut, but sends its axon to the gut.

Gastroenteropancreatic System of endocrine cells located in the stomach, intestine, and pancreas.

Goblet cell A type of mucus-secreting cell in the epithelium.

Lumen Opening in the center of a tubular organ. Within the digestive system, this space is bordered by a single layer of epithelial cells that create a barrier between outside and inside of the organ.

Microvilli Plasma membrane-bound, cellular extensions that often characterize epithelial cells. They provide for an elaboration of the surface, plasma membrane. Common, for instance, in intestinal cells (enterocytes) that absorb nutrients.

Mucosa Layer in the gut wall facing the lumen.

Myenteric plexus Network of neurons, situated between the longitudinal and circular muscle layers of the gut wall.

Oxyntic cells The acid-secreting cells of the gut.

Paracrine effect When a hormone from an endocrine cell affects neighboring cells.

Peristalsis Propagating movements of gut contents by contraction of gut muscle.

Postprandial Period after ingesting a meal.

Secretion The process of releasing compounds from a cell.

Submucosa Layer between the mucosa and muscle layers in the gut wall.

The gastrointestinal tract plays numerous roles in the maintenance of homeostasis in the fish. This includes food conversion, uptake of nutrients, and osmoregulation. The gut also acts as a barrier against unwanted substances and organisms. This section describes the different aspects of the gut itself, as well as the hormonal and neuronal control systems involved in regulating the gut activities. Although important for providing energy and oxygen to the gut tissues, as well as transporting nutrients from the gut to the rest of the body, gut circulation is discussed in **Design and Physiology of Arteries and Veins**: The Gastrointestinal Circulation.

The study of the fish gut has long played an important role in the overall understanding of gut anatomy and control of gut function. The vast number of species, facing a variety of environments and feeding strategies, is reflected in more or less specialized adaptations. Fish as a group also show great similarities with other vertebrates when it comes to the gastrointestinal tract. Significant early anatomical and pharmacological studies on fish gut include, for example, papers by JZ Young, AH Al Hussain, and P Kirtisinghe. The Nobel prize laureate US von Euler together with Östlund isolated one of the first recognized peptidergic transmitters/hormones from the fish intestine. During the period between 1950 and 1970, G Burnstock performed a series of pioneer studies mainly on brown trout (*Salmo trutta*), describing anatomy, innervation, and control of gut motility.

The first article of the section, **Gut Anatomy and Morphology**: Gut Anatomy, gives an anatomical and morphological overview of the gastrointestinal tract in fish, in general, discussing regional characteristics along the gut. It also points out differences among species and groups of fish, such as the presence or absence of a stomach or pyloric appendages (ceca), or different surface enlargement strategies in the intestine. The article concludes by discussing other factors such as food and temperature that may affect gut anatomy and morphology.

Apart from the gastrointestinal tract itself, accessory organs such as the salivary glands, biliary system, and pancreas are often considered a part of the gut. The next article, **Gut Anatomy and Morphology**: Pancreas, describes the anatomy of the latter, including both endocrine and exocrine parts as well as the developmental and evolutionary aspects. It also gives an overview of hormonal and enzymatic pancreatic secretion, and how it is regulated.

Gut activities are tightly regulated to meet the needs of the body, and understanding the control systems is essential to understand the gastrointestinal tract physiology. In **Integrated Function and Control of the Gut**: Nervous System of the Gut, we get an overview of the autonomic innervation of the gut, with special emphasis on the nerves within the gut wall – the enteric nervous system. The structure and distribution of common neurotransmitters are described. General characteristics are outlined, with additional examples from species or groups of fish diverging from the general pattern. Similarly, in **Integrated Function and Control of the Gut**: Endocrine Systems of the Gut, the distribution of endocrine cells releasing local gut hormones to the blood stream is presented. The diverse roles of the hormones are exemplified by selected peptides such as histamine, cholecystokinin (CCK), and ghrelin, and their roles in acid secretion, digestion, and appetite are described.

Gut Anatomy and Morphology: Development of Fish Gut describes early embryological development of the gut, using zebrafish (*Danio rerio*) as a model organism. Much focus is on molecular signals involved in organization of the gut into different regions, as well as in differentiation of the tissues such as smooth muscle and the enteric nerves.

The next three articles describe how food is processed and transported along the gut. While much of our knowledge comes from only a few and mainly teleost species, examples from other fish species, which are included, explain the underlying mechanisms for propagating and nonpropagating contractions involved in breakdown and transport of food. It also describes the control of gut motility (**see also Integrated Function and Control of the Gut**: Gut Motility), with an overview of the current knowledge and an attempt to point to the gaps in our understanding of complex motility pattern. A comprehensive summary of the effects of individual neurotransmitters and hormones, in relation to their distribution in various fish species, is found in **Appendix A** (pp. 1232–1267). **Integrated Function and Control of the Gut**: Gut Secretion and Digestion describes the secretory processes in the stomach, intestine, and pancreas, including water, mucus, acid, and enzyme secretion. The stimuli responsible for increased release are highlighted. Furthermore, digestion of macromolecules (e.g., proteins, carbohydrates, and lipids) is described in detail and related to the type of diet. **Integrated Function and Control of the Gut**: Intestinal Absorption gives a detailed description of the molecular mechanisms behind epithelial transport of carbohydrates, proteins, and lipids. It gives examples of diffusion and active transport as well as discusses the availability and importance of different macronutrients. In addition, regional differences in absorption along the gut are discussed.

Equally important as the uptake of nutrients is the protection provided by the gut against toxic substances and microorganisms. **Integrated Function and Control of the Gut**: Barrier Function of the Gut describes the multiple epithelial barriers, focusing on the intestine. The basis for permeability between and through the epithelial cells is explained, as is the immune system of the gut and its role as a barrier. Examples of bacterial and viral infections via the fish gut are given, and the impact of stress and disease on the barrier functions is discussed.

Supplementary material: Associated with these articles is a spreadsheet that contains extensive lists of the distribution and physiological functions of neurotransmitters and hormones in more than 100 fish species. The spreadsheet is divided into: presence in endocrine cells, presence in nerves in the gut, and effects on gut motility. It also contains the 153 references used to extract this information (**Appendix A** (pp. 1232–1267)).

* in some studies proximal part is called stomach

Stomach stands for cardiac and pyloric stomach, intestine for the proximal intestine down to the rectum.
For references and abbreviations see page 1262–1267.

* in some studies proximal part is called stomach

Stomach stands for cardiac and pyloric stomach, intestine for the proximal intestine down to the rectum. SI, spiral intestine, R, rectum +, contraction/stimulation; −, relaxation/inhibition; no, no response.

For references and abbreviations see page 1262–1267.

Glossary

Epithelium Relatively flat tissue (composed of one or few cells layers) that lines cavities and surfaces in multicellular organisms.

Mucosa The layer in the gut wall facing the lumen.

Myenteric plexus The network of neurons, situated between the longitudinal and circular muscle layers of the gut wall.

Oxyntic cells The acid-secreting cells of the gut.

Submucosa The layer between the mucosa and muscle layers in the gut wall.

Introduction

In general terms, the anatomy of the gastrointestinal tract is similar in most groups of vertebrates, with the gut consisting of a saclike stomach and an elongated tube-like intestine. Likewise, the morphology is similar in most species and regions of the gut. However, at a more detailed level, considerable variations exist both between and within vertebrate classes. These variations largely depend on different feeding strategies and choice of food. In fish as a whole, including cyclostomes, as well as cartilaginous and bony fishes, consistent differences exist between the different groups, as will be explored in more detail below. However, even within the groups, there are variations between families and species.

The gut performs multiple tasks, including osmoregulation and defense against pathogens. The most important role, however, is the breakdown, transportation, and absorption of food and nutrients. The different regions of the gut have specialized tasks, reflected in, for example, the thickness of the muscle layers or the type of epithelial cells present. The morphology may also be affected by external factors, such as the type of food, feeding state, season, or pathogens, leading to up- or downregulation of different signals and, eventually, tissues.

General Anatomy of the Gastrointestinal Tract

A discussion of the gastrointestinal tract or the gut commonly refers to the entire tract, from the mouth to the anus (**Figure 1**). In addition to the gastrointestinal tract itself, the salivary glands, biliary system, and pancreas are often included in the term. These are the so-called accessory organs, which are similar in origin and/or are involved in food processing. The organization of these organs is not covered in this article; for a more detailed

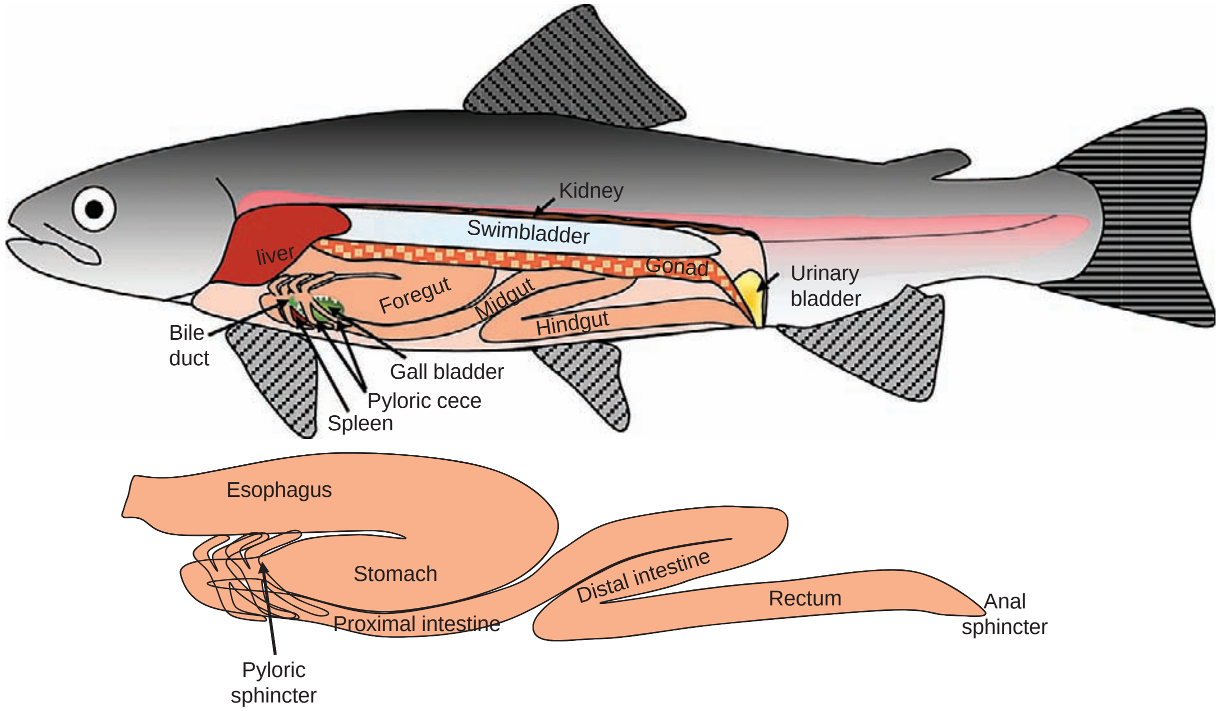

Figure 1 Schematic drawing of the gastrointestinal tract and accessory organs in a teleost (rainbow trout, *Oncorhynchus mykiss*). Courtesy of Albin Gräns.

description of the pancreas **see Gut Anatomy and Morphology**: Pancreas.

The gastrointestinal tract does not develop uniformly but separate regions have slightly different origins (**see also Gut: Anatomy and Morphology**: Development of Fish Gut). The diverse cell types present in the gut wall (see below) also have different origins, including all three germ layers. Of course, the gastrointestinal tract is not an isolated organ but is connected with the rest of the body via blood and lymphatic vessels, and also via autonomic nerves. The nerves as well as circulating and local metabolites and hormones play essential roles in the control and regulation of the gut, in order for it to achieve its many tasks.

Using a gross division of the gut, it is common to refer to the headgut, foregut, midgut, and hindgut. These regions may then be further subdivided. The nomenclature of the different regions of the fish gut varies between authors. Some stick with the mammalian classification, while others use different, usually more relevant, labeling that is more appropriate to fish anatomy and physiology.

Headgut

The headgut includes the mouth and pharynx and is only mentioned briefly here. The fish mouth looks very different among species, partially reflecting the choice of food. Consider, for example, a broad shark mouth, with plenty of sharp teeth, compared with the toothless narrow jaws of a carp fish (*Cyprinidae*). Another extreme is the cyclostomes, with their round, jawless mouth with sharp teeth. The cyclostomes, such as lampreys (*Lampetra*) and hagfish (*Myxine*), use their mouth and teeth to attach to and feed on dead or dying fish. Other fish species may use their teeth for grasping, tearing, or crushing, or to capture and hold prey (**see also Food Acquisition and Digestion**: Energetics of Prey Capture: From Foraging Theory to Functional Morphology).

The position of teeth can also vary. For example, cyprinids have pharyngeal teeth, used to grind mostly the vegetarian food. Most fish also have a tongue that sometimes may aid in the breakdown of the food and hagfish even has teeth on its tongue. Often, however, the tongue is quite immobile.

Foregut

The foregut includes the esophagus and stomach. The esophagus is generally short and wide, and designed to transport food from the mouth to the stomach. However, a substantial number of fish, including cyclostomes, lungfish, and cyprinids, lack a stomach. In such cases, the esophagus empties directly into the intestine (see below).

The stomach serves both as a reservoir and as an important site of degradation of the food, aided by the release of acid and enzymes. It can usually be divided into a proximal and a distal part, often called cardiac and pyloric stomach, respectively. The cardiac stomach corresponds roughly to the fundus and corpus of the human stomach, while the pyloric part is similar to the antrum in both appearance and function, having, for example, thicker muscle layers.

Although a distinct anatomical divider (sphincter) between the stomach and the esophagus often may not exist in fish, the muscle in that region can still be kept contracted, ensuring that stomach contents under normal circumstances will not be transported back to the esophagus. An exception is during vomiting, which has been observed in several fish species. The other end of the stomach has a well-defined sphincter, the pyloric sphincter, which separates the stomach from the proximal intestine (**Figure 1**).

Midgut and Hindgut

In most mammals, there is a clear difference in diameter between the small and large intestine, making the nomenclature very useful. In most fish, however, this is not the case. Furthermore, the mammalian small intestine is divided into three parts (duodenum, jejunum, and ileum) based mostly on histological features. Again, the situation in fish in general is less clear.

The commonly used nomenclature for fish divides the intestine into four regions. The proximal, middle, and distal intestine (collectively termed the midgut) correspond to the small intestine, while what is often called rectum (hindgut) is most likely both the colon and rectum (i.e., the large intestine) (**Figure 1**).

No obvious macroscopic features separate the proximal, middle, and distal intestine. Often the division is arbitrary, corresponding to roughly one-third each. In some species (e.g., elasmobranchs and sturgeons), part of the intestine contains spiral valves making a distinction between regions easier. The bile duct enters the gut in the proximal intestine. In teleost fish, this region often contains one or many appendages called 'pyloric ceca'. However, the hindgut is commonly separated from the rest of the intestine by a valve (ileorectal) and is distinguished by differences in the appearance of the mucosa.

The gut generally ends with an anal sphincter. In elasmobranchs and lungfish, the hindgut ends with a cloaca, which is a common cavity into which the digestive, urinary, and reproductive tracts open.

Morphology

Looking at a cross section of any region of the gastrointestinal tract, it is obvious that the wall consists of several tissue layers (**Figure 2**). Their relative and absolute thicknesses vary between species and regions. Again, the nomenclature used in mammalian literature does not translate well to the fish gut wall, with some layers being less well defined or absent in fish.

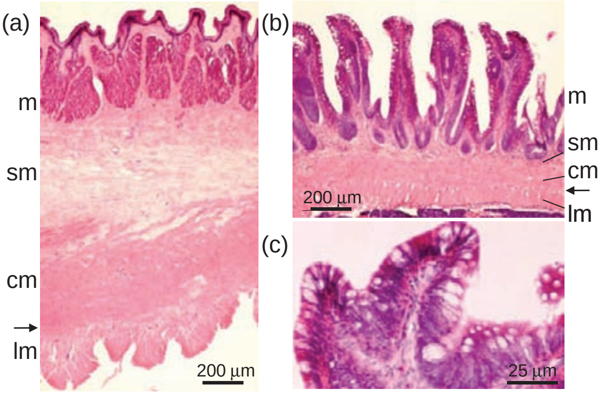

Figure 2 Cross sections of the gastrointestinal tract of shorthorn sculpin (*Myoxocephalus scorpius*) stained with hematoxylin eosin. (a) Cardiac stomach. (b) Proximal intestine. (c) Higher magnification of the epithelium in the proximal intestine. Note the high number of goblet cells. Arrows indicate myenteric plexus. m, mucosa; sm, submucosa; cm, circular muscle layer; lm, longitudinal muscle layer.

Mucosa

The innermost layer (facing the gut lumen) is the mucosa (**Figure 2**), consisting of a single layer of epithelial cells generally in addition to a dense layer of connective tissue (lamina propria) and a thin muscle layer (muscularis mucosa). To increase the surface area of the intestine, the mucosa generally makes folds rather than the finger-like protrusions (villi) seen in mammals. The epithelial cells include, for example, oxynticopeptic cells, mucus cells, endocrine cells, and enterocytes, and there are often clear regional differences in their distribution.

Hydrochloric acid and pepsin are both secreted in the stomach, and interact in the breakdown of proteins. In contrast to mammals, where the parietal cells (oxyntic) release acid while chief cells release pepsin, generally only one cell type in fish is responsible for the release of both acid and pepsinogen. Accordingly, these cells are called oxynticopeptic (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion). These gland cells are found in gastric pits mainly in the cardiac part of the stomach.

Mucus is essential to protect the gastric lining from the digestive juice and mucus-secreting cells are found throughout the gastrointestinal tract. The appearance of the cells varies depending on gut region. In the esophagus and intestine, the so-called goblet cells are abundant, a name that corresponds to their cup-like appearance. This is the result of large amount of mucus present in the apical part of the cell causing this part to bulge out, at the expense of other neighboring cell types. In contrast, in the stomach, mucus-secreting cells lie close to each other and hence do not have room to bulge.

Endocrine cells release numerous different hormones that may either act locally or enter the circulation. The cells may respond to chemicals (food components) in the lumen. For more details on endocrine cells, the reader is referred to **Integrated Function and Control of the Gut**: Endocrine Systems of the Gut. Enterocytes are the cells that absorb nutrients. They are most prominent in the intestine. They have microvilli at their luminal border, to further increase the absorbing surface. The mucosal layer also consists of granular cells likely to be involved in immune responses. For more details on this topic in this encyclopedia, **see also Integrated Function and Control of the Gut**: Barrier Function of the Gut and Intestinal Absorption.

Submucosa

The submucosa lies below the mucosa and consists mainly of connective tissue. It also contains blood and lymph vessels and a relatively high number of nerve fibers that innervate the blood vessels as well as the mucosa. A well-defined submucous nerve plexus similar to that seen in most mammals is generally absent. The submucosa is comparably thick in the stomach of most species, while it is thinner, or even regarded to be absent, in the intestine (**Figure 2**).

Smooth Muscle

In general, two layers of smooth muscle are seen in the stomach and intestine – one circular and the other longitudinal (**Figure 2**). However, deviations from this basic plan occur. For example, in many elasmobranchs, there may be a more or less well-defined oblique layer, situated between the circular layer and the submucosa. This may occur in some, but usually not in all, regions, with some species variations.

In teleosts, as well as in elasmobranchs, the inner circular layer is usually thicker than the outer longitudinal layer. This difference is most prominent in the stomach, especially in the pyloric region. A recent study on yellow catfish (*Pelteobagrus fulvidraco*) reported a 5:1 thickness ratio between the circular and longitudinal layers of the stomach. In the intestine, the circular layer is usually still the thickest, but the overall wall thickness is thinner compared with the stomach (**Figure 2**).

In addition, there are usually striated muscles in the esophagus. Whether these are exclusive to this region and whether they are found in the entire esophagus depends on the species. In many species, there is a gradual transition from striated muscle in the esophagus to smooth muscle in the stomach.

Myenteric Plexus

Between the two muscle layers, there is a dense network of nerve cell bodies and fibers – the myenteric plexus (**see also Integrated Function and Control of the Gut**: Nervous System of the Gut). The plexus is well developed in all fishes. The nerve cell bodies send processes (axons) to all the other layers, innervating muscle cells, blood vessels, and glands.

In mammals, the plexus also contains glial cells and interstitial cells of Cajal (ICCs). Enteric glial cells outnumber the neurons by up to 4 times and have mainly a supporting role, although they may also be involved in signaling. ICCs exist as several morphological subtypes, serving as pacemakers (i.e., they set the frequency of contraction in the smooth muscle) and also conveying signals from nerves to muscles.

So far, there have been few and inconsistent reports on the presence and appearance of these cell types in different fishes. Using mammalian glial markers, positive cells are present in the fish gut; however, their appearance seems to differ. There are no reports of functional studies on the role of enteric glia in fish. Although ICC-like cells have been histologically demonstrated in some species, functional studies of these cells are lacking.

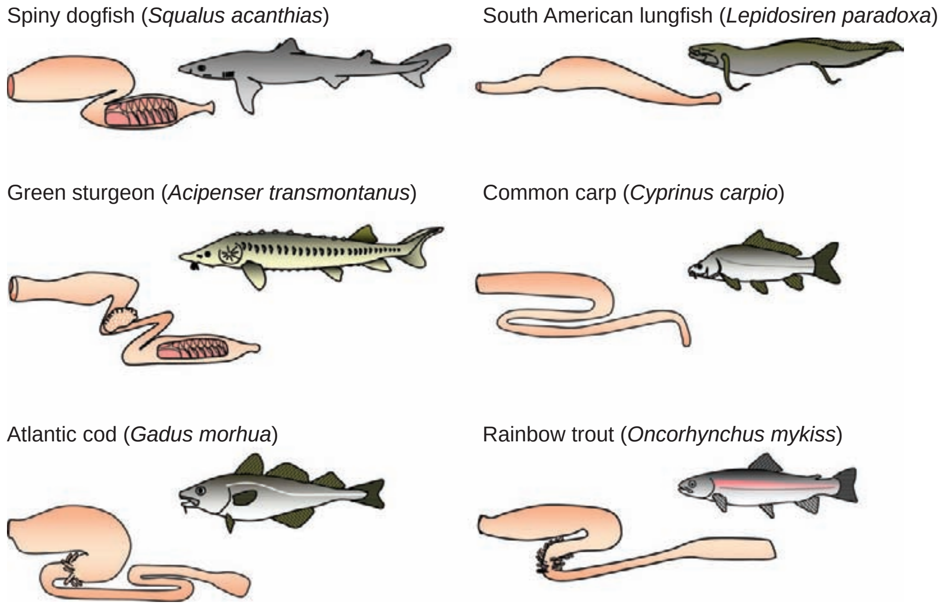
Species Differences

Considering that the total number of fish species exceeds 20 000, it is not surprising that the above description of the basic anatomy of the gut cannot be applied universally (**Figure 3**). Fish live in diverse habitats and rely on very different food sources. While few fish are true herbivores, many rely on a diet consisting of a mixture of plant material and different types of prey. Carnivorous fish may depend on other fish species or different invertebrates, such as insects, mollusks, or crustaceans. Some fish feed mainly on plankton. The composition of the food imposes different demands on digestion, including anything from the types of teeth to the types of enzymes needed.

Fish also differ in feeding frequency. Some fish, such as Northern pike (*Esox lucius*), may capture a large prey at intermittent intervals, while others, such as goldfish (*Carassius auratus*), are nibblers, continuously ingesting small quantities of food. Some main differences between species and groups are described in more detail in the following.

Stomach

Both size and form of the stomach vary widely between different species. The simplest form is a straight tube, seen, for example, in pike. In many other species, there is a bend, resulting in an inner (lesser) and an outer (greater)



Spiny dogfish (*Squalus acanthias*)

South American lungfish (*Lepidosiren paradoxa*)

Green sturgeon (*Acipenser transmontanus*)

Common carp (*Cyprinus carpio*)

Atlantic cod (*Gadus morhua*)

Rainbow trout (*Oncorhynchus mykiss*)

Figure 3 Schematic drawings exemplifying differences in general anatomy of the gastrointestinal tract in different fish species. See **Figure 1** for nomenclature. Courtesy of Albin Gräns.

curvature. The stomach may be further subdivided into U- and Y-shaped stomachs (**Figures 3–5**). The latter, present for example in European eel (*Anguilla anguilla*) and Atlantic cod (*Gadus morhua*), is characterized by a blind sac (or cecum), while U-shaped stomachs like that in salmonids and sharks are more like a siphon. The sac-like stomach usually indicates species that eat large pieces at a time, requiring a stomach that can expand for storage purposes. Nibblers, on the other hand, do not have the same need, and usually have a U-shaped stomach, or may even lack a stomach altogether.

Stomachless Species

A large number of fish species lack a stomach, which is unlike other vertebrate groups. For instance, the cyprinids, a large teleost family consisting of over 2700 species, including carp (*Cyprinus carpio*), goldfish, and zebrafish (*Danio rerio*), are all stomachless. Stomachless species also occur in other teleost families, such as *Labridae* and *Gobidae* and others (one estimation says that up to 50 families may contain some stomachless species). In addition, cyclostomes, like hagfish and lamprey, and lungfish also lack a proper stomach.

To say that a species is stomachless, one must first define a stomach. Most stomachless species have some kind of enlargement of the gut that may look more or less like a stomach that serves for storage. This is often called the ‘intestinal bulb’. However, in contrast to a stomach (in most species), this intestinal bulb does not contain acid- or pepsinogen-secreting epithelial cells. Instead, stomachless species rely mainly on the release of trypsin into the intestine for breakdown of proteins.

A more distinctive feature of stomachless species is the location of the entry of the bile duct. As the duct enters the gut in the proximal intestine, this takes place immediately distal to the esophagus, in contrast to species with a stomach, where it opens after the pyloric sphincter (see **Figure 1**).

Intestine

The length of the intestine also reflects feeding habits. A vegetarian diet is more difficult to digest and, hence, there is a need for a longer intestine to extend processing time. The length of the gut has been measured and compared with the total body length in several species. The ratio varies 100-fold, ranging from 0.4 to almost 40. The species with the longer gut are generally omni- or herbivores, but there are exceptions. A study of three cyprinid species from different feeding habits showed that the carnivore (gudgeon; *Gobio gobio*) had the shortest intestine, the herbivore (common carp) had the longest, and the omnivore (roach; *Rutilus rutilus*) was in between. However, both the omnivore and the herbivore had shorter intestines compared with the average omnivorous or herbivorous species, indicating that other factors, such as species, influence gut length as well.

The differences in gut length between herbivores and carnivores can also be seen during development, when many species change in diet (from carnivorous to more omnivorous). This is generally accompanied by a change in relative gut length. However, there are several other, probably more important, ways to increase the surface area of the gut.

Pyloric Ceca

The pyloric ceca are finger-like appendages found at the proximal intestine in most teleosts. The epithelial layer of the ceca does not differ from the rest of the intestine and it is believed that they increase the absorptive surface. They also may prolong transit time.

The number and size of the ceca vary considerably among teleosts, from absence in stomachless species to up to around a 1000 (**Figures 3** and **5**). Again, a correlation may or may not exist with food type. A general observation is that the ceca are more abundant in carnivores. Even so, the carnivorous wolffish (*Anarhichas*) as well as most elasmobranchs lack pyloric ceca. For example, in cod and sculpin (e.g., *Myoxocephalus* sp.), the ceca sit in a ring at the very proximal end of the intestine. In salmonids, they are more dispersed, covering most of the proximal intestine (**Figures 4** and **5**). In sturgeons (*Acipenser*), the ceca are fused together, forming a multilobed structure. All these species are also carnivorous. Few studies have measured the total cecal surface area or correlated it with intestinal length.

Spiral Valve

Spiral valves, or a spiral intestine, are found in elasmobranchs, lungfish, and chondrosteans (e.g., sturgeon). The spiral valves are not valves as such, but are mucosal (and submucosal) foldings, running along the intestine in a spiral pattern, thereby increasing the epithelial (absorptive) area without affecting the length of the intestine. The valves also delay the passage of chyme.

Spiral valves are mainly seen in species with a short straight intestine. In sharks and ray, the valves occupy the proximal part of the intestine, while in sturgeons they begin halfway down the intestine. The length of the spiral intestine and the number of turns may also differ within a species. The outer diameter of the spiral intestine of white sturgeon is ~1.5 times the diameter of the proximal intestine, and it is even larger in most elasmobranchs.

The spiral intestine in sturgeons is the region with highest nutrient uptake.

Other Factors That May Affect Gut Morphology

As discussed above, the food choice is often reflected in the morphological adaptations of the gut. However, diet also has direct short-term effects on gut morphology. The composition of the diet, like for instance relative protein, fat, and carbohydrate contents, may affect cellular properties such as membrane composition, which, in turn, depending on cell type, may affect uptake and signaling.

Diet composition may also affect different cell populations differently. For example, goblet cells increase in number when crude protein content of the food is increased, whereas the mucosa and muscle layers tend to decrease in thickness.

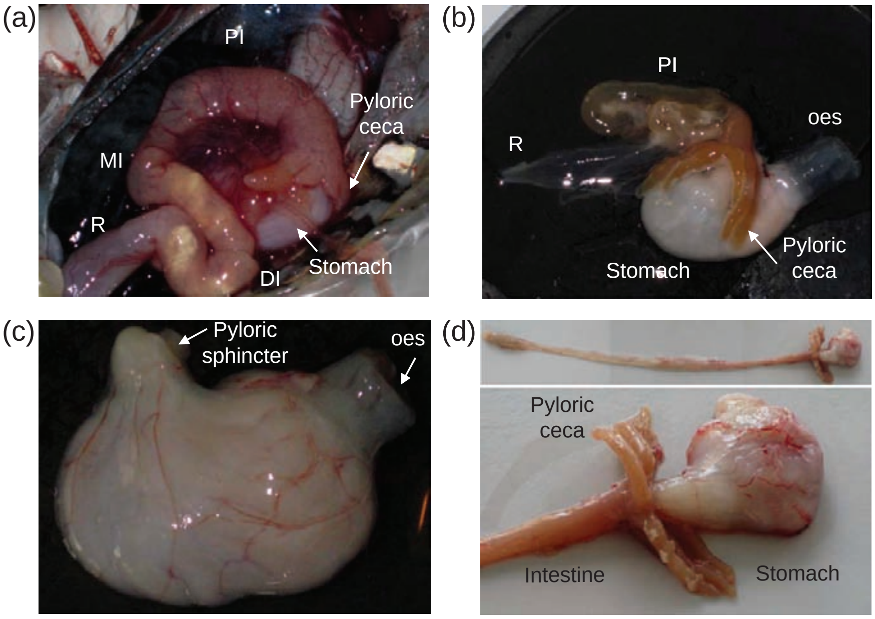


Figure 4 The gastrointestinal tract of Arctic sculpin (*Myoxocephalus scorpioides*) (a), Arctic staghorn sculpin (*Gymnocanthus tricuspis*) (b, c), and shorthorn sculpin (*Myoxocephalus scorpius)* (d). Sculpins have a Y-shaped stomach and a ring of pyloric ceca (note the difference between species in (a) and (b)). DI, distal intestine; MI, mid-intestine; PI, proximal intestine; oes, esophagus; R, rectum.

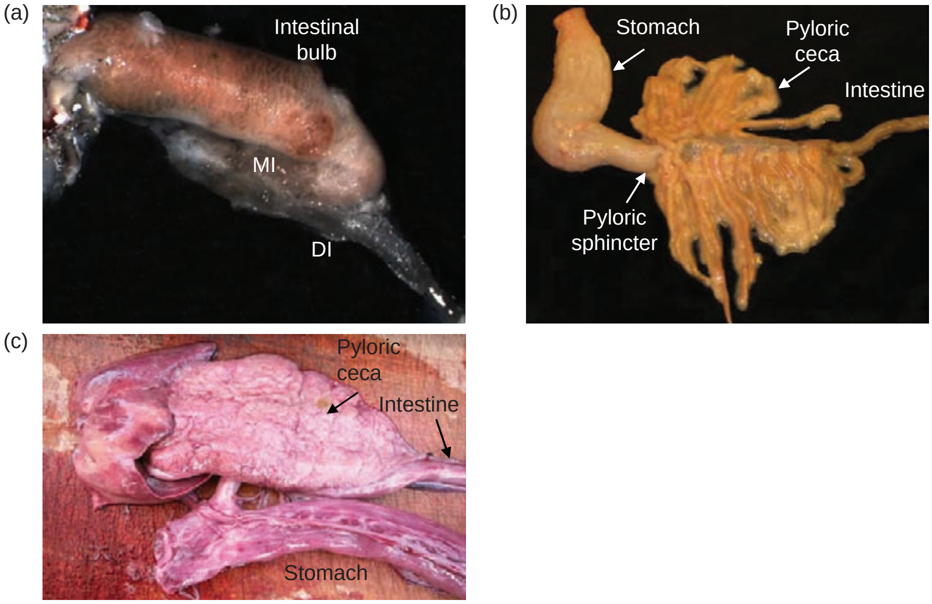

Figure 5 The gastrointestinal tract of: (a) zebrafish (*Danio rerio*) (note the absence of stomach and pyloric ceca); (b) rainbow trout (*Oncorhynchus mykiss*) (note the U-shaped stomach and the widespread pyloric ceca); and (c) wahoo (*Acanthocybium solandri*) (note elongated stomach and numerous pyloric ceca). (c) Courtesy of Fredrik Jutfelt.

In farmed fish, the composition of the diet is essential for optimal growth and there is continuous research to find new and more economic food sources. However, some alternatives have serious drawbacks because they disrupt the mucosa.

Many fishes encounter large seasonal variations in food availability; consequently, they may experience shorter or longer periods of starvation on a regular basis. This also will likely affect gut morphology reversibly, often observed as a decrease in intestinal length and thickness. For example, when salmon return to their natal river to spawn, they stop feeding and the gut atrophies. Some species are more easily affected than others. Similarly, developmental stage and health status play important roles. Other factors that influence the impact of starvation are hormonal levels and environmental parameters, such as temperature and water quality.

Changes in body temperature, due to seasonal or other changes in the water temperature, can also by itself affect gut morphology. In experiments with short-term, cold-acclimated channel catfish (*Ictalurus punctatus*), an increase in intestinal length and weight was observed. In carp, there was no effect on the intestinal length but an increase in mucosal surface area was seen. The increase in intestinal parameters could possibly compensate for a less-efficient uptake at lower temperatures.

Seasonal variations usually depend on a combination of factors, including temperature and food availability; seasonal changes in hormone levels may also play an important role.

Finally, various disease states can also cause morphological disruptions. Several studies have shown serious effects on the gut mucosa, caused by infections of common pathogens (**see also Integrated Function and Control of the Gut**: Barrier Function of the Gut).

Concluding Remarks

The anatomy and morphology of the fish gastrointestinal tract follow a general vertebrate pattern. However, with fish being so diverse, there are many special adaptations to different environments and behaviors. Although the type of food and feeding strategies play an important role, genus- and family-specific traits may be more important in determining the appearance of the gut in species-specific manners.

Glossary

Brockmann body Large aggregate of endocrine pancreatic tissue found especially within teleost fish.

Endocrine Mode of secretion in which a chemical is released by a cell into extracellular fluid then enters the blood.

Enteropancreatic System of endocrine cells located in the intestine and pancreas.

Exocrine Mode of secretion in which a chemical is released from a cell into a duct that leads to the outside of the organism (including the lumen of digestive tract).

Gastroenteropancreatic cells A system of endocrine cells located in the stomach, intestine, and pancreas.

Hydrolyze Chemical reaction in which a water molecule is involved in the process of cleaving a macromolecule by donating hydrogen and hydroxide ions.

Ontogeny Changes in the phenotype of an individual during its life span. Ontogeny is the outcome of a developmental program, encoded in an organism's genes, as well as interactions between the genotype of the individual and the environments it encounters, together with any maternal effects mediated through the egg itself.

Phylogeny Modification of the structure and function of a species or group of species throughout their evolutionary history.

Principal islet Large accumulation of endocrine tissue encircled by a fine rim of exocrine tissue.

Secretogog A chemical that stimulates a cell to secrete another chemical.

The Pancreas Has Many Functions

The pancreas plays a central role in digestion, metabolism, growth, and development in vertebrates. The functions of the pancreas are essential for integrating physiological and developmental events within the organism as well as for coordinating such events with the environment. The pancreas has two chief functions: to secrete enzymes into the digestive tract and to secrete hormones into the bloodstream.

Fish have been used as experimental models from the dawn of research on pancreatic function in the late nineteenth century to the present. The study of fish has provided essential information about the structure and evolution of the pancreas, as well as about the structure, biosynthesis, evolution, and function of the hormones and enzymes it produces. For example, fish insulin was one of the first vertebrate insulins to be isolated. Furthermore, the yield of this hormone from fish pancreata (formal plural form of pancreas) has remained better than that from any other group, including mammals, despite sophisticated extraction techniques. This article describes the basic aspects of the structure, development, and evolution of the pancreas of fish. We also discuss the principal hormones and enzymes produced by the pancreas and highlight their major actions.

Structure of the Adult Pancreas

The anatomy of the gastrointestinal tract and associated organs, including the pancreas, greatly varies among different species of fish (**see also Gut Anatomy and Morphology:** Gut Anatomy for more details on gut anatomy). The pancreas of fish, similar to that of all vertebrates, has two major components: an exocrine component and an endocrine component. The cells of the exocrine component form ducts closed at one end, the open ends of which connect to the lumen of the gastrointestinal tract. A common feature of exocrine glands is their ducted nature. The ducts provide avenues through which the secretory products of the exocrine pancreas, primarily digestive enzymes, reach the lumen of the gut. As discussed subsequently, the exocrine pancreas produces a number of enzymes.

The cells of the endocrine component typically form closely packed balls of cells called 'islets', so named because they resemble small islands in a microscopic section. A common feature of endocrine glands is their ductless nature. The secretory products of the endocrine pancreas, hormones, are first released by cells into the extracellular fluid before they enter the capillaries, and are distributed throughout the organism via the blood. In general, four different types of islet cells are present, each defined by the hormones they produce. These include glucagon (produced by α cells), insulin (produced by β cells), somatostatin (produced by δ cells), and peptide YY (PYY) (produced by F cells).

In some groups of fish, especially the elasmobranchs (sharks and rays), the pancreas is well developed and possesses clusters of endocrine cells arranged within a compact organ containing extensive exocrine tissue. Among the bony fish (teleosts), the pancreas typically is not a distinct organ, but aggregates of exocrine and endocrine cells are dispersed between or on internal organs and blood vessels. Pancreatic tissue, especially exocrine tissue, may surround or be found within the submucosa of the intestine and pyloric ceca, and in liver, gall bladder, and/or adipose tissue.

In many groups of teleosts, the endocrine cells are organized into one or two principal islets (often called the Brockmann bodies) plus a number of accessory or satellite islets. The Brockmann bodies (**Figure 1**) can exceed 500 μm in diameter, which is 5 times the size of a typical islet in a mammalian pancreas. The relatively unique structure of the teleost pancreas, in which the endocrine portion is anatomically separated from the endocrine portion coupled with the large size of the islet, has made it an extremely useful model for pancreatic research. Notably, recent work on transplantation of fish pancreata into mice shows promise as a cure for diabetes mellitus.

Pancreatic tissue, especially islet tissue, is well vascularized and innervated. This enables an extensive communication network in which hormones can interact with islet cells to influence the production/secretion of other hormones as well as with nearby exocrine cells to influence the production/secretion of digestive enzymes. Both sympathetic and parasympathetic nerves innervate the pancreatic tissue to release adrenaline and acetylcholine, respectively, as well as neuropeptides (e.g., cholecystokinin (CCK) and galanin), all of which affect hormone and digestive enzyme production/release.

Embryological Development of the Pancreas

The pancreas develops from the gastrointestinal endoderm (which together with mesoderm and ectoderm make up the three primary germ layers), and begins with the budding of the gut endocrine cells from the mucosal epithelium. Unlike the development of the Agnathan or jawless fish (hagfish and lamprey) pancreas that originates from the epithelium of the intestine or bile duct, the Gnathostome (vertebrates with jaws) pancreas expands from the dorsal and ventral outgrowths of the small intestine. For example, the teleost pancreas buds laterally to the foregut and spans the intestinal wall innervated with blood vessels. The nature of the contributions from the ventral and dorsal regions of the gut plays a role in the type of islet organ that is found in each species of teleost, and, in more recent Gnathostomes, this consists of one dorsal and two ventral outgrowths. Exceptions are noted in which zebrafish (*Danio rerio*) pancreata develop from only a single cell mass located on the dorsal gut epithelium (**see also Gut Anatomy and Morphology:** Development of Fish Gut). Both endocrine and exocrine cells arise from the same endodermal rudiment, and, generally, the endocrine cells start to differentiate before the exocrine cells.

All four of the different islet cell types are derived from the same precursor stem cell. The sequence of appearance of the islet cell types during embryonic development follows in order as β cell, α cell, δ cell, and F cell. Co-expression of different hormones by the same cell is often observed at early stages. In rainbow trout (*Oncorhynchus mykiss*), islets are diffusely distributed in the adipose tissue that surrounds the pyloric ceca and the spleen, which may give rise to hormonal secretion from these organs. Development after hatching involves growth in pancreas size and an elevation in enzyme concentration.

Evolution of the Pancreas

Fish provide critical insight into the evolution of pancreas and the hormones as well as the enzymes it secretes. In almost all aquatic and terrestrial Gnathostomes, four different endocrine cells (α, β, δ, and F) are present in the pancreas. The exception here is the Agnathans that contain a primitive gastroenteropancreatic (GEP) system, more accurately referred to as the enteropancreatic (EP) system as indicated by no definable stomach (**see also Gut Anatomy and Morphology:** Gut Anatomy). Agnathans also display an uncommon feature in which endocrine and exocrine cells are segregated. For example, larval lampreys possess a one-hormone islet organ that is then followed by a three-hormone gland in adult lamprey. Hagfish have a separate islet organ at the junction of the

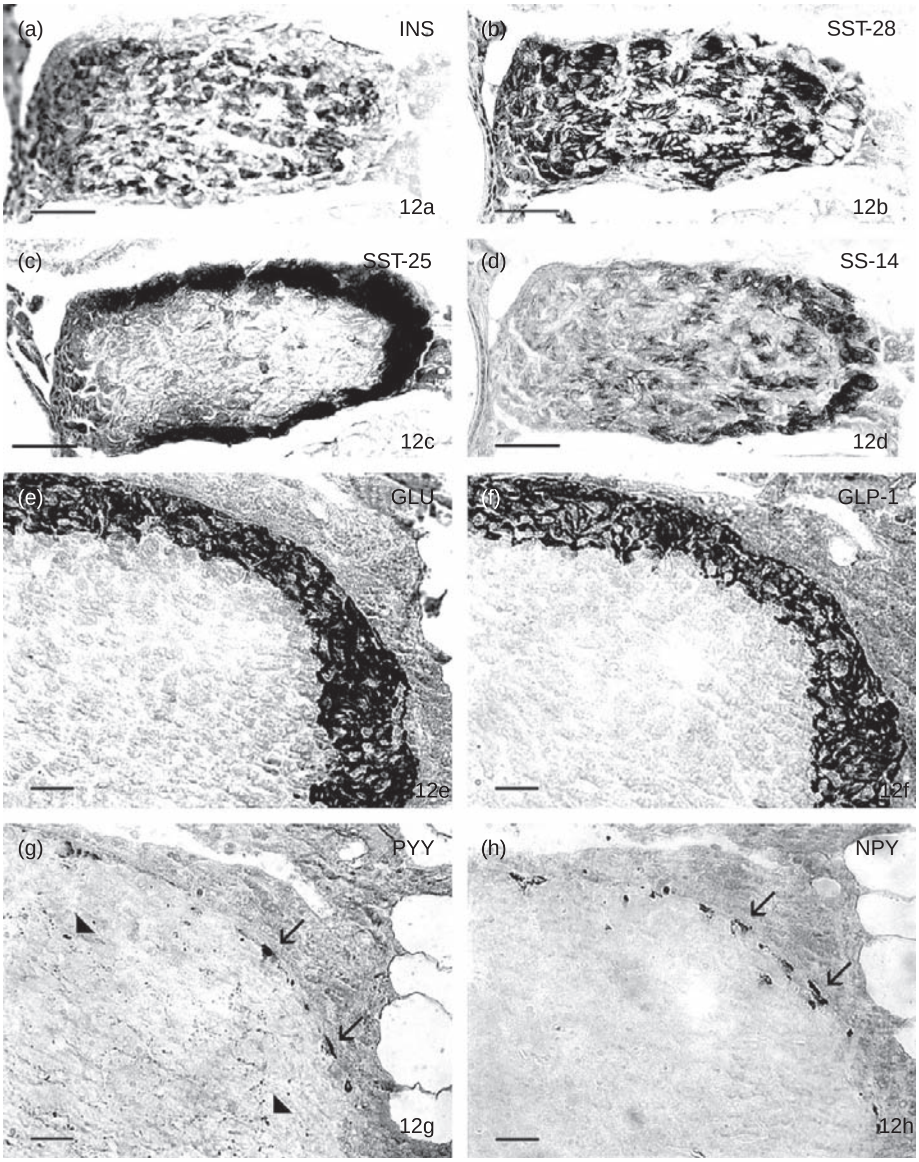

Figure 1 Consecutive longitudinal sections of the principal islet (Brockmann body) of a 51-day-old sea bream (*Sparus aurata*) larva showing (a) insulin-, (b) somatostain (SS)-28 (1–12)-, (c) SS-25-, and (d) SS-14-immunoreactive cells. Detail of the islet periphery shows coexistence of (e) glucagon- and (f) GLP-1-like immunoreactivities or (g) PYY- and (h) NPY-like immunoreactivities. Arrows point out identical cell profiles. Arrowheads in (e) indicate PYY immunoreactive nerve fibers. Scale = 20 μm. Reproduced from Navarro MH, Lozano MT, and Agulleiro B (2006) Ontogeny of the endocrine pancreatic cells of the gilthead sea bream, *Sparus aurata* (teleost). *General and Comparative Endocrinology* 148: 213–226, with permission from Elsevier.

gut and bile duct that consists almost entirely of insulin cells with a relatively low number of somatostatin-secreting cells. Other somatostatin cells are found in the bile duct, whereas glucagon and PYY cells are found in the gut mucosa.

The chondrichthyes are phylogenetically the oldest group of living vertebrates with a combined exocrine–endocrine pancreas. Their islet cells, which have a close relationship with ducts of the exocrine components of the gland, frequently form an outer layer around ductules. The pancreas of chondrichthyes contains only insulin, glucagon, and somatostatin cells; PYY cells are located in the gut.

A well-defined Brockmann body is present in almost all teleosts. The phylogenetic development of islet tissue seems to be toward at least a single, large principal islet or Brockmann body independent or nearly independent of exocrine elements located near the gall bladder or spleen. Phylogenetically, the islet hormones appear long before the emergence of the islet organ. For example, an insulin-like substance occurs in several groups of invertebrates (which lack pancreata), including mollusks and insects. The order of appearance of hormones over the course of animal evolution is insulin, somatostatin, glucagon, and then PYY (**Figure 2**).

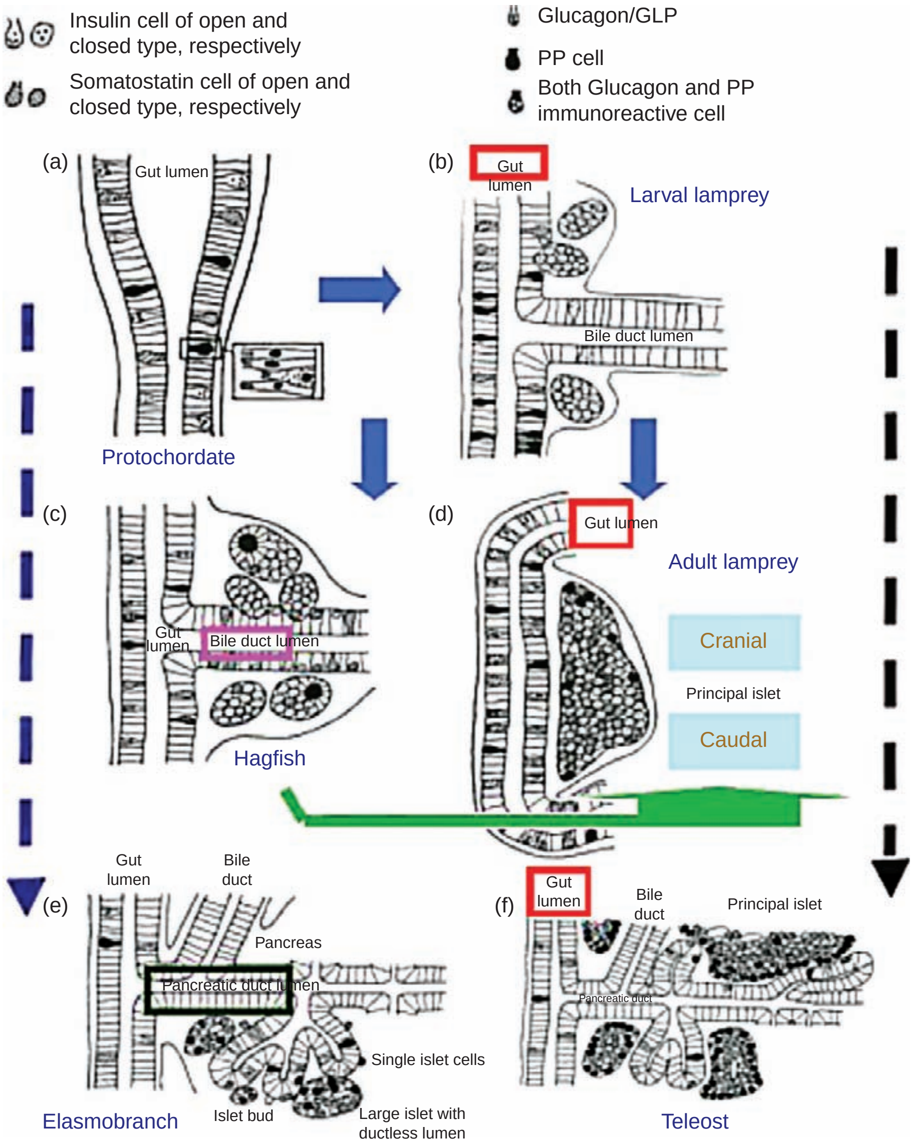

Figure 2 Representation of endocrine cell types in the epithelium of the gut, bile duct, pancreatic ducts, and islet tissue of a protochordate (a) and various groups of fish, including larval (b) and adult (d) lamprey, hagfish (c), elasmobranchs (e), and teleosts (f). Arrows indicate the possible lines of phylogenetic development of islet tissue from protocordates, in which the endocrine cells are confined to the gut, to the larval lamprey or hagfish. The larval lamprey islets give rise to the adult cranial principal islet, whereas the caudal principal islet can arise from the larval bile duct, similar to the situation in hagfish. The islets of elasmobranchs originate from the pancreatic ducts while those of teleosts arise from the gut. It should be noted that glucagon-family peptides are confined to the gut epithelium in hagfish and lamprey, but in elasmobranchs and teleosts, cells producing glucagon-family peptides also are incorporated into islet tissue. Reproduced from Youson JH (2006) Peripheral endocrine glands. I. The gastroenteropancreatic endocrine system and the thyroid gland. In: McKenzie DJ, Farrel AP, and Brauner CJ (eds.) *Fish Physiology, Vol. 26: Primitive Fishes*, pp. 381–455. New York: Academic Press, with permission from Elsevier.

Hormones of the Pancreas

As mentioned above, the four main pancreatic hormones (insulin, somatostatin, glucagon, and PYY) are expressed by separate cells in most adult fish. Additional hormones may co-localize with these in some cell types. The hormones play important roles in metabolism as well as in control of other secretory processes (see **Table 1**).

The relative abundance of each cell type has been estimated, with α cells being 25–40%, β cells 30–50%, δ cells 15–20%, and an undetermined amount of F-cell types. The relative hormone content in coho salmon (*Oncorhynchus kisutch*), from most to least, is insulin, somatostatin (SS)-25, glucagon-like peptide 1 (GLP-1), glucagon, SS-14, and PP. Within the islets of actinopterygians, the β and δ cells usually occupy the central region,

Table 1 Physiological actions of pancreatic hormones produced in fish

Hormone	*Principal action*	*Example*
Insulin	Metabolism	Aids in nutrient uptake (e.g., amino acids) and glycogenesis
	Growth	Promotes anabolism through lipogenesis, myogenesis, and osteogenesis
	Cellular differentiation	Necessary in the formation of the developing pancreas and gut
	Secretotropic	Glucagon-like-peptide (GLP), secretin, cholecystokinin (CCK)
Glucagon	Metabolism	Initiates glycogenolysis in liver and muscle tissue and lipolysis
Somatostatin	Metabolism	Promotes lipolysis and glycogenolysis
	Growth	Inhibits the proliferation of intestinal muscosa and osteogenesis
	Cellular differentiation	Inhibits the differentiation of cartilage and osteocytes
	Secretotropic	Modulation of insulin, glucagon, and exocrine pancreas
	Transport	Modulation of intestinal transport of Na^+ and Cl^-
Peptide YY	Metabolism	Stimulates appetite, gastric emptying
Glucagon-like-peptide 1	Metabolism	Promotes glycogenolysis and gluconeogenesis, promotes satiety

while α cells and F cells occupy the peripheral border (**Figure 1**). Close to the β cells are D2 cells that produce SS-14, whereas the SS-25-producing D1 cells are located in the periphery of the islets near α cells. PYY and neuropeptide Y (NPY) are located in the periphery of the islets. The proximity of the different islet cell types suggests the existence of specific interactions between islet hormones to regulate production/secretion.

Insulin

The first to appear in development is insulin, which is synthesized and secreted from β cells. Insulin, which is mainly involved in nutrient homeostasis and also has cell proliferative (mitogenic) effects. Insulin is synthesized from a large precursor, preproinsulin, that contains a 24-amino-acid signal sequence, followed by a B-chain (30 amino acids), a C-peptide of variable length (~28–42 amino acids), and an A-chain (21 amino acids). Preproinsulin is processed in a stepwise manner by first removing the signal sequence to form proinsulin, and then prohormone convertases cleave the C-peptide to form bioactive insulin. C-peptide and some proinsulin are secreted together with insulin and enter the circulation. Extrapancreatic production of insulin has been suggested for decades, but only recently has evidence been provided that it is synthesized in the brain and adipose tissue of rainbow trout.

Insulin mediates carbohydrate metabolism in fish (e.g., stimulates glucose uptake and glycogen synthesis); however, this role is minimal compared with its action on protein metabolism (e.g., stimulates amino acid uptake and protein synthesis; decreases protein turnover and inhibits gluconeogenesis from amino acids). Amino acids are also more potent secretagogs of insulin than glucose. These observations may reflect the diet of fish, at least that of those species most studied, which is rich in amino acids and poor in carbohydrates.

Insulin also enhances lipogenesis (e.g., stimulates fatty acid uptake, fatty acid synthesis, and triacylglycerol synthesis) and inhibits lipolysis (i.e., hydrolysis of stored triacylglycerol). During periods of fasting, insulin counteracts the reduction of fuel supplies by conserving muscle and adipose tissue. Plasma insulin levels depend on dietary protein level and nutritional state, and display seasonal variation.

Glucagon

Glucagon antagonizes the metabolic actions of insulin. It typically consists of 29 amino acids and is highly conserved among vertebrates. Glucagon is also synthesized from a prohormone, proglucagon, which is expressed in the pancreas and other tissues (e.g., intestine), and, depending on the presence and activity of processing enzymes, glucagon or GLP-1 may be produced. Glucagon and GLP-1 are both produced by α cells in the pancreas and may also co-localize with PYY in this cell type. GLP-1 is produced primarily in the intestine. Glucagon promotes glycogenolysis and gluconeogenesis in liver and muscle, and results in increased plasma glucose. Glucagon also stimulates lipolysis from fat stores and elevated plasma fatty acid levels. Interestingly, GLP-1 and the related hormones such as gastric inhibitory polypeptide (GIP) are secretagogs of insulin, while glucagon inhibits insulin release.

Somatostatin

Somatostatin has many effects on growth, development, and metabolism. Fish possess multiple genes encoding somatostatin, and, depending on the proteolytic processing of the precursors, several hormonal variants may be produced, including SS-14 and SS-25. Somatostatin is produced and secreted from several locations, including the central nervous system, stomach, intestine, and δ cells of the endocrine pancreas. In some cases, it is co-secreted with CCK and NPY. The two subpopulations of δ cells in teleosts, D1 and D2 cells, produce different forms of somatostatins.

Somatostatin is a major player in the regulation of digestion and metabolism because of its inhibitory effects on hormones of the endocrine pancreas (e.g., insulin and glucagon) and intestine, as well as on acid release from the stomach and enzyme secretion from the exocrine pancreas. Somatostatin also has direct effects on metabolism by stimulating lipolysis.

Peptide YY

PYY affects a number of processes associated with feeding and digestion in fish. This family of pancreatic polypeptides also includes NPY and fish pancreatic peptide (PY). All of these peptides display similar characteristics, with a high frequency of conserved amino acids, size, and three-dimensional (3D) structure. PYY has been identified in a number of piscine species, including the lamprey, and is secreted from the pancreas, as well as from the gastrointestinal tract and nervous tissue. It has an orexigenic effect in fish and aids in gastric emptying, whereas NPY is made predominately in nervous tissue, and stimulates food intake when administered to the brain but not when administered peripherally. Unlike NPY, PYY inhibits food intake; however, similar to NPY, PYY inhibits gastric and exocrine pancreatic secretions.

Enzymes of the Pancreas

The exocrine pancreas secretes enzymes, such as proteases, carbohydrases, and lipases, necessary for the digestion of protein, carbohydrate, and fat (**see also Integrated Function and Control of the Gut:** Gut Secretion and Digestion). Pancreatic enzymes in fish are secreted into the intestine through the pancreatic or hepatic ducts and have characteristics similar to those of the corresponding enzymes in other vertebrates (**Table 2**). In particular, trypsin, chymotrypsin, amylase, pancreatic elastase, pancreatic lipase, endothelial lipase, phospholipase, lipoprotein lipase, carboxypeptidase A and B, carboxylesterase, and carboxylic ester hydrolase exist in fish. Considering the evolutionary and life-history patterns of fish, involving highly variable diets and extreme variation in habitat, fish enzymes present certain qualities that complement and distinguish themselves from those of mammals.

Peptidases

Carnivorous fish rely heavily on the intake and assimilation of amino acids; consequently, proteases are a critical component of metabolism and growth. The protein-digesting endopeptidases, trypsin, chymotrypsin, and elastase, all are derived from precursor molecules or proenzymes. This ensures that they are activated only when present in the lumen of the small intestine. Although there exist slight variations in the size of certain peptidases, most share a high percentage of nucleotide identity with enzymes from mammals, However, where variability does exist, it is most likely due to differences specialized for the temperature variances experienced by the many different species of fish. Certain pancreatic proteases (e.g., elastase and trypsin) in some species of fish have higher catalytic efficiencies than the corresponding enzymes in mammals (when measured at the same (cold) temperature).

Lipases

Lipids, a highly diverse group of biomolecules, play important roles in fish. Their metabolism is accomplished

Table 2 Physiological actions of pancreatic enzymes produced in fish

Enzyme	*Principal action*
Trypsin	Hydrolyzes the carboxyl terminal of amino acids lysine and arginine
Chymotrypsin	Hydrolyzes the carboxyl terminal of amino acids tyrosine, tryptophan, and phenylalanine
Pancreatic elastase	Catalyzes the catabolism of elastin, fibrin, hemoglobin, and albumin
Carboxypeptidase	Hydrolyzes the carboxyl terminal of a peptide bond
Carboxylic ester hydrolase	Hydrolyzes carboxylic acid esters, resulting in the formation of an alcohol and a carboxylate
Pancreatic lipase (triacylglycerol lipase)	Hydrolyzes ester linkages of triglycerides
Endothelial lipase	Hydrolyzes SN-1 acyl chain of phospholipids
Phospholipase	Hydrolyzes phospholipids into fatty acids and other lipophilic substances
Lipoprotein lipase	Hydrolyzes very low density lipoproteins (VLDL) into fatty acids and glycerol
Carboxyl ester lipase	Hydrolyzes cholesteryl esters, tri-, di-, and mono-acylglycerols, phospholipids, lysophospholipids, and ceramide
Amylase	Hydrolyzes starch into di- and trisaccharides

by a large number of lipases produced by several organs, including the pancreas, liver, pyloric ceca, and stomach. Pancreatic lipase or colipase-dependent lipase is the primary lipolytic enzyme found in most fish species. Carboxyl ester lipase (CEL), also known as bile-salt-dependent lipase, is a critically important pancreatic lipase because it hydrolyzes several lipid molecules, including triacylglycerols, phospholipids, cholesteryl esters, wax esters, and vitamin esters. This enzyme depends on bile salt for hydrolysis of water-insoluble substrates, whereas soluble substrates may be hydrolyzed in the absence of bile salt.

Homogenates of Atlantic cod (*Gadus morhua*) pancreatic tissue reveal that fish lipases hydrolyze triglycerides containing unsaturated fatty acids at higher rates than those with saturated fatty acids. Certain ester bonds with myristic and palmitic acid are resistant to hydrolysis. Moreover, rapid release of glycerol from the reaction mixture indicates that Atlantic cod lipase is able to hydrolyze bonds in all positions of the triglyceride.

Other enzymes that depend on bile salts and other minerals (e.g., Ca^{2+}) include the phospholipases. Choline and glycerophospolipids are hydrolyzed more efficiently than ethanolamine and inositol phospholipids. Specific activities and substrate specificities are affected differently by calcium and bile-salt concentrations.

Carbohydrases

Amylase activities of pancreatic tissue and intestinal contents show great variation. In several fish species, intestinal amylase activity correlates positively with dietary carbohydrate level and feeding intensity. The ability to adapt amylase secretion to match carbohydrate level in the diet and feed intake is restricted to herbivorous and omnivorous fish.

Regulation of Pancreatic Secretion

The secretion of pancreatic hormones and enzymes is controlled by neural innervation and by hormones and metabolites. Many of the regulating hormones come from neighboring pancreatic or GEP cells. Notably, many of the hormones produced in the pancreas are also produced by the gut (e.g., GIP, glucagon, GLP, NPY, PYY, and somatostatin; **see also Integrated Function and Control of the Gut:** Endocrine Systems of the Gut) and help in coordination of digestion and metabolism. The control of islet hormone release is discussed in **Integrated Function and Control of the Gut**: Gut Secretion and Digestion and Nervous System of the Gut the focus of this section is on the exocrine portion of the pancreas.

Nutrients in the lumen of the gastrointestinal tract stimulate the secretion of pancreatic enzymes. Breakdown products from macronutrient lysis are more potent activators of enzyme secretion than whole feed itself. Most importantly, single amino acid mixtures increase enzyme secretion, whereas intact protein with a similar amino acid composition release little to no enzymes. Studies with rainbow trout indicate that fish regulate their pancreatic enzyme stores according to specific diet composition. Proteolytic activity of pancreatic tissue, measured 24 h after the last meal, increases with increasing levels of dietary protein.

The luminal environment (e.g., nutrients, low pH, and ionic composition) also stimulates the secretion of several GEP hormones that in turn affect the exocrine pancreas and other digestive processes. For example, secretin from the intestine stimulates the release of bicarbonate from the exocrine pancreas that is used to buffer gastric acid emptying from the stomach. In addition, CCK and secretin are released from the gastrointestinal tract to stimulate the release of exocrine pancreatic enzymes (e.g., pancreatic phospholipase) that aid in the digestion of food.

Numerous interactions between and among GEP hormones also exist. Insulin stimulates the release of GLP-1 that acts synergistically on the gastrointestinal tract and other tissues, recruiting the uptake of nutrients (**see also Integrated Function and Control of the Gut**: Intestinal Absorption). Inhibitory regulators from endocrine pancreatic cells, such as somatostatin, PP, and PYY, inhibit the release of secretin and CCK. GLP-1 and PYY also inhibit gastric secretion and motility, while GLP-2 stimulates growth and digestion. Somatostatin also modulates the intestinal active transport of Na^+ and Cl^- ion uptake, aiding in maintaining osmoregulatory homeostasis. Overall, the GEP exhibits a dynamic relationship regulating various physiological processes throughout food intake, digestion, nutrient absorption, and intermediary metabolism (**Table 1**).

Concluding Remarks

The study of fish has provided considerable insight into the structure, function, and evolution of the pancreas. Because of their diversity, fish offer a unique account of the phylogeny of the pancreas. Species differ in the structure of their pancreas, ranging from a discrete organ containing both endocrine and exocrine tissue to a diffuse collection of endocrine and exocrine tissue distributed on/in several internal organs. Enzymes produced by the pancreas help digest food, whereas hormones produced by the pancreas regulate numerous processes associated with growth, development, and metabolism, including control of pancreatic enzyme secretion and other digestive processes.

Glossary

Basement membrane The extracellular component attached to the epithelial layer, consisting of connective tissue made up of a complex of short filamentous proteins, e.g., collagens. Epithelial cells adhere to the extracellular matrix by expressing cell adhesion molecules on their basal surface.

Blastoderm The layer of cells that develops on the surface of the yolk, giving rise to the cells from which the embryo develops.

Ectoderm The germ layer positioned on the outside of the embryo after gastrulation, giving rise to epidermis, neurons, and neural crest.

Endoderm The germ layer positioned on the inside of the embryo after gastrulation, giving rise to the lining of the digestive tube, respiratory tube, and accessory digestive organs such as the liver and pancreas.

Gastrulation The migration and rearrangement of cells after embryo undergoes proliferation to increase cell number (cleavage stage) in order to create three germ layers.

Germ layers The three cell layers created after gastrulation: ectoderm on the outside, mesoderm in the middle, and endoderm most internal.

Lumen The opening in the center of a tubular organ. Within the digestive system, this space is bordered by a single layer of epithelial cells, which create a barrier between outside and inside of the organ.

Mesoderm The germ layer positioned between the endoderm and ectoderm, which gives rise to notochord, dermis, muscle, blood, bone, and kidney.

Patent In this article, patent refers to a continuous open lumen, which occurs once the digestive organs connect with each other.

Primitive gut tube A simple epithelial tube that is closed at both ends. In zebrafish, this only encompasses the intestine, whereas other organs associated with the gut form from separate groups of cells.

Somites The blocks of cells that form at regular intervals from the paraxial mesoderm (tissue on either side of the embryonic midline) in an anterior-to-posterior direction; these go on to form repeating muscles, cartilage, dermis, tendons, and vascular cells.

Specification Taking on characteristics of a particular cell type as determined by gene expression and morphology.

Introduction

Development of the fish digestive system has gained wide attention over the past few decades. Zebrafish (*Danio rerio*) have become the subject of intense study for everything from early patterning to the details of organ development, and will be the model system used in this article to describe formation of the digestive system. While the genetics and development of the zebrafish digestive system are similar to other vertebrates, there are also differences and each step is not representative of all vertebrates. For example, zebrafish do not develop a stomach or pyloric ceca.

Zebrafish embryogenesis is completed in 5 days, after which the digestive system is functional and contains a full complement of tissues and cell types found in other vertebrates. As with other vertebrates, the fish digestive system is formed from all germ layers. Further changes occur in juvenile fish before the adult form is achieved.

The zebrafish digestive system develops in three general phases. The first phase involves specification of the endoderm and mesoderm, which forms the majority of cells within the digestive system. Few endodermal cells are specified; hence, the second phase involves endodermal proliferation to create enough cells to form the digestive tube and associated digestive organs, such as

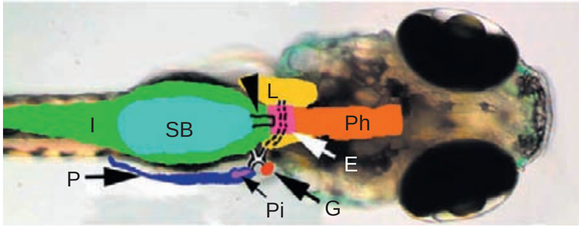

Figure 1 Zebrafish digestive anatomy. The pharynx (Ph) connects to a short muscular esophagus (E) which connects to the intestine (I). The liver (L) straddles the esophagus. The hepato-pancreatic duct enters the anterior intestine connecting the liver, gall bladder (G), and pancreas (P). The pancreas has a single islet (Pi) with the tail containing exocrine tissue. Reproduced from Wallace KN and Pack M (2003) Unique and conserved aspects of gut development in zebra fish. *Developmental Biology* 255: 12.

liver, pancreas, and gall bladder. However, the endoderm does not form a continuous sheet to fold into a primitive gut tube, as with other vertebrates. Instead, the digestive organs form separately and later join to create a patent tract. The third phase involves a dramatic decrease in cell proliferation between the third and fourth day of embryogenesis, and a maturation of cell types within the epithelium and mesenchyme. Differentiation of enteric neurons completes the formation of a functional digestive tract by the end of embryogenesis (**Figure 1**).

Specification of Endoderm

After fertilization, the single cell divides on top of the yolk. As cells become more numerous, they begin to migrate over the yolk cell in a manner that would be akin to pulling a knit cap over one's head. Deep cells form closest to the yolk and a thin enveloping layer develops on the outside. When cells reach the halfway point on the yolk (50% epiboly), gastrulation begins with deep cells separating into the hypoblast layer (endoderm and mesoderm) between the yolk and epiblast cells (ectoderm). Endoderm and mesoderm are specified around the entire margin, followed by migration to the embryonic midline. As migration to the midline proceeds, endoderm and a portion of the mesoderm undergo further specification to form specific digestive organs.

When the embryo reaches 50% epiboly, cells at the blastoderm margin undergo a series of signaling events prior to and during gastrulation to differentiate endodermal from mesendodermal cells. Signaling through the nodal pathway has been shown to be essential for this process. Nodal-related genes, *squint/ndr1* and *cyclops/ndr2*, are expressed in both mesodermal and endodermal progenitors around the blastoderm margin. With the aid of the co-receptor one-eyed pinhead (oep), these nodal-related genes are required for specification of endoderm and mesoderm. The products of *squint/ndr1* and *cyclops/ndr2* are members of the transforming growth factor (TGF)-β superfamily of ligands, which bind to type II TGF-β receptors and allow binding to type I TGF-β receptors, activating the cytoplasmic kinase. Kinase activation leads to phosphorylation of the transcription factors Smad 2 and 3. Smad 2 and 3 then bind Smad 4 and enter the nucleus to repress or activate downstream genes, leading to endoderm specification.

Within the developing endoderm, nodal signaling results in expression of several transcription factors. These transcription factors appear to work in parallel with each other to induce and maintain expression of the transcription factor Sox32/Casanova, which is critical for differentiation of endoderm. Sox32/Casanova in the endoderm is critical for expression of endoderm markers, such as *sox17* and *foxA2/axial*.

Development of the Digestive Tract: Formation of the Pharynx, Esophagus, and Intestine

While zebrafish develop a pharynx, esophagus, and intestine, they (and some other species) do not develop a stomach. However, most species develop a stomach by the hatching period (**see also Gut Anatomy and Morphology**: Gut Anatomy) for more details on anatomy), with gastric glands developing later in the posthatching period.

The Intestine Is First to Begin Organizing

While the pharynx, esophagus, and intestine share a common lumen by the third day of zebrafish embryogenesis, they initially develop as separate organs (**Figure 2**). The intestine first forms a group of radially organized cells in a short anterior region at 21 h postfertilization (hpf) (**Figure 2(a)**). Later, at 26 hpf, a stretch of endoderm at the posterior end of the future intestine becomes radially organized (**Figure 2(b)**. In addition, at 26 hpf, endodermal cells throughout the intestine begin to polarize with basement membranes forming between developing epithelial cells and surrounding mesoderm. At 34 hpf, the entire intestine has formed a continuous tube with an observable lumen (**Figure 2(c)**). This is closed at both ends and has been referred to as a 'primitive gut tube' but, unlike other vertebrates, it only encompasses the intestine rather than the entire digestive tract. At this stage, intestinal epithelial cells have distinct apical and basolateral surfaces, with more pronounced basal laminin as well as apical β-actin and alkaline phosphatase. Cadherin is expressed on the lateral surface, indicating the presence of desmosomal junctions.

In contrast, tight junctions have not yet developed at 34 hpf. As epithelial cells mature into the second day, the tight junction protein ZO-1 develops in irregular patches at

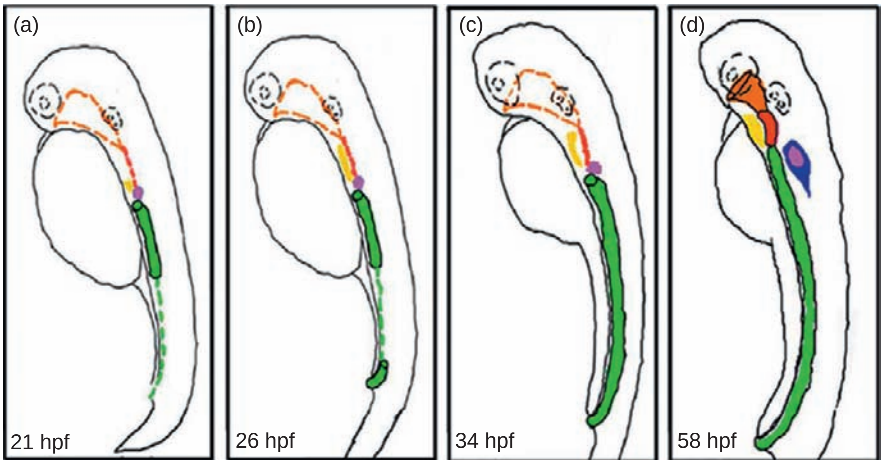

Figure 2 Sequence of digestive organ formation. At 21 hpf, a short anterior region of the intestine develops radial organization (solid green (a)) while both the liver (yellow) and endocrine pancreas (purple) can be identified molecularly. At 26 hpf, a short posterior region of the intestine becomes radially organized (solid green (b)). At 34 hpf, the entire intestine is radially organized, epithelial cells have become polarized and a lumen is observed throughout the intestine (solid green (c)). By 58 hpf, the pharynx (orange) and esophagus (red) have formed and the entire digestive tract is patent (d). Adapted from Wallace KN and Pack M (2003) Unique and conserved aspects of gut development in zebrafish. *Developmental Biology* 255: 12.

the apical–lateral junctions. Expression of ZO-1 matures by 74 hpf when distinct desmosomes and tight junctions are observed by transmission electron microscopy.

Throughout intestinal development, the epithelial layer continues to be comprised of a single layer of cells attached to the basement membrane (**Figures 3(a)** and **3(b)**). The cells, which were cuboidal early on (**Figure 3(a)**), begin developing a more columnar appearance throughout the third day. During the fourth and fifth days, the epithelial layer adopts a folded configuration throughout the length of the intestine (**Figure 3(b)**). At the base of the folds, epithelial cells are cuboidal while being surrounded by columnar neighbors. As shown by electron microscopy, epithelial cells also form a well-developed brush border between 74 and 120 hpf (**Figures 3(c)** and **3(d)**) ((**see also Integrated Function and Control of the Gut:** Barrier Function of the Gut) for more details on the intestinal epithelium).

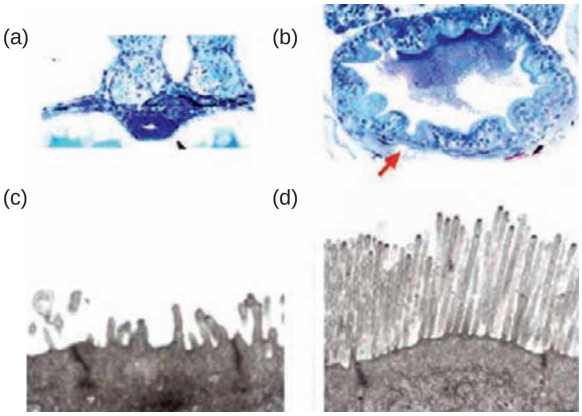

Figure 3 Organization of the intestinal epithelium. At 50 hpf, epithelial cells are cuboidal (a) but by the end of embryogenesis, these cells have a columnar appearance (b). The epithelium becomes folded with cells remaining cubodial at the base of the folds (red arrow in (b)). Between 74 and 120 hpf, the apical surface develops well-differentiated microvilli (c and d). Adapted from Wallace KN, Akhter S, Smith EM, and Pack M (2005) Intestinal growth and differentiation in zebrafish. *Mechanisms of Development* 122: 157–173.

Organization of the Pharynx and Esophagus

The anterior endoderm, giving rise to the pharynx and esophagus, does not organize until after 34 hpf. At this stage, polarization of the epithelium begins with laminin developing in the basement membrane. At 50 hpf, the pharynx develops a bilayer appearance, forming a thin tube spanning the width of the endoderm, with polarized epithelial cells expressing cadherin on the lateral surfaces. Farther posterior, the esophagus and hepatic duct form, with polarized cells expressing laminin at the basement membrane and cadherin on the lateral surfaces.

During the second day, the pharynx becomes rounder and thicker with an obvious lumen and pharyngeal arches develop at the lateral sides to support gills. The esophageal lumen becomes wider during this period, becoming patent with the intestine. At 58 hpf, the posterior end of the pharynx has no apparent lumen before transitioning into the esophagus. A lumen in the posterior pharynx opens by 74 hpf, creating a patent digestive tract up to the posterior end of the intestine, which does not open until 96 hpf.

Intestinal Epithelial Proliferation

Intestinal tube organization involves a period of high cell proliferation. Over 40% of the epithelial cells undergo DNA replication (S-phase of the cell cycle). As junctional complexes mature during the second and third day, proliferation decreases. As epithelial cells differentiate, proliferation decreases to <10% on the fourth day and <5% on the fifth day.

Cell proliferation is evenly distributed throughout the intestinal epithelium from tube formation at 34 hpf to initiation of folding at day 4. During the fifth day, proliferation becomes restricted to the base of the folds, which is a feature of the adult intestine.

Determination of the Anterior-to-Posterior Position of the Liver and Pancreas

After gastrulation, endoderm migrates to the embryonic midline. Endodermal cells are arranged in a flat sheet in two groups on either side of the embryonic midline at 14 hpf. Cells between somites 1 and 3 give rise to liver and pancreas. Duplicate columns of three cells are present on either side of the embryonic midline. Medial cells are opposed to each other at the midline, followed by lateral 1 and lateral 2 cell columns. Medial cells primarily give rise to endocrine pancreas and intestine. Lateral 1 cells give rise to exocrine pancreas, intestine, and some endocrine pancreatic cells; lateral 2 cells give rise to exocrine pancreas, intestine, and liver cells. By 18 hpf, endodermal cells have completed migration to the midline.

As endodermal cells migrate to the midline, regionally expressed signals specify differentiation of individual digestive organs along the anterior-to-posterior axis. One of these is a gradient of retinoic acid (RA) in the mesoderm. The loss of RA prevents pancreas and liver precursors from developing without affecting other endodermal organs. Ectopic RA converts pharyngeal precursors into pancreas. Other factors, such as the transcription factor Cdx4, limit the development of the pancreas. Normally, expression of Cdx4 in an endodermal gradient creates an inhibitory region, providing a posterior limit to the pancreas. Removal of *cdx4* allows pancreas precursors to form at more posterior positions.

Other paracrine factors from the surrounding tissue also initiate signal transduction cascades to promote liver and pancreas differentiation. For example, expression of *wnt 2b*, a ligand for the transmembrane frizzled receptor, in the surrounding lateral plate mesoderm, inhibits degradation of β-catenin. Accumulated β-catenin binds to other transcription factors to alter transcription and promote liver differentiation. Similarly, *bmp2b* promotes pancreas differentiation. Binding of *bmp2b* to type I and II TGF-β receptors results in phosphorylated Smad entering the nucleus, resulting in the absence of *pdx-1* expression in liver progenitors. Cells farther away, still expressing *pdx-1*, become exocrine pancreas and intestine. RA signaling is required between 8 and 13 hpf, *bmp2* at 14 hpf, and *wnt 2b* between 16 and 25 hpf.

Differentiation of Digestive Organs

The teleost gastrointestinal tract forms similar structures to other vertebrates (**Figure 4**). In the zebrafish intestine, there is a single layer of epithelial cells attached to a mucosal layer followed by a layer of circular muscle, enteric neurons, and a longitudinal smooth muscle layer (**see also Integrated Function and Control of the Gut**: Barrier Function of the Gut and **Gut Anatomy and Morphology**: Gut Anatomy).

Intestinal Epithelial Differentiation

The intestinal epithelial layer differentiates into absorptive, goblet and enteroendocrine cells. Specialized cells, which pinocytose molecules from the lumen, also form within a posterior region of the intestine.

The epithelium in zebrafish is organized into folds. There are no villi or crypts. Proliferation of stem cells occurs at the base of the folds. Cells migrate from the base to the top of the folds, differentiating into one of the three main cell types. At the top of the fold, epithelial cells undergo apoptosis.

Beginning at 74 hpf, the majority of epithelial cells differentiates into enterocytes, which express Na^+/K^+ adenosine phosphatase (ATPase) on the basolateral surface and the sodium phosphate co-transporter protein (NaPi) on the apical surface. Expression of both transporters develops in an anterior-to-posterior gradient. Goblet cells differentiate by 74 hpf, growing in size and mucin content throughout the second half of embryogenesis. Enteroendocrine cells differentiate by 96 hpf.

Juxtacrine signaling has been shown to be important in the choice between different intestinal epithelial cell fates. Membrane-bound signals, such as Delta or Jagged ligand, signal to neighboring cells upon binding to the transmembrane receptor, Notch. The conformation of ligand-bound Notch is altered and the cytoplasmic portion is cleaved to act as a transcription factor, thus altering the fate of the receiving cell. Notch signaling between developing epithelial cells is involved in the choice between enterocytes and secretory cells. Expression of DeltaD ligand in enteroendocrine cells appears to laterally inhibit neighboring epithelium from adopting the same fate.

Enteric Neuron and Intestinal Smooth Muscle Differentiation

Enteric neural precursor cells enter the zebrafish digestive system at 32 hpf (**Figure 5**(**a**)). They migrate from the neural crest in two streams into the pharynx, posterior to the ear. They migrate along the edge of the pharynx into the esophagus and intestine, reaching the posterior intestine by 66 hpf (**Figure 5**(**b**)). This is followed by circumferential migration.

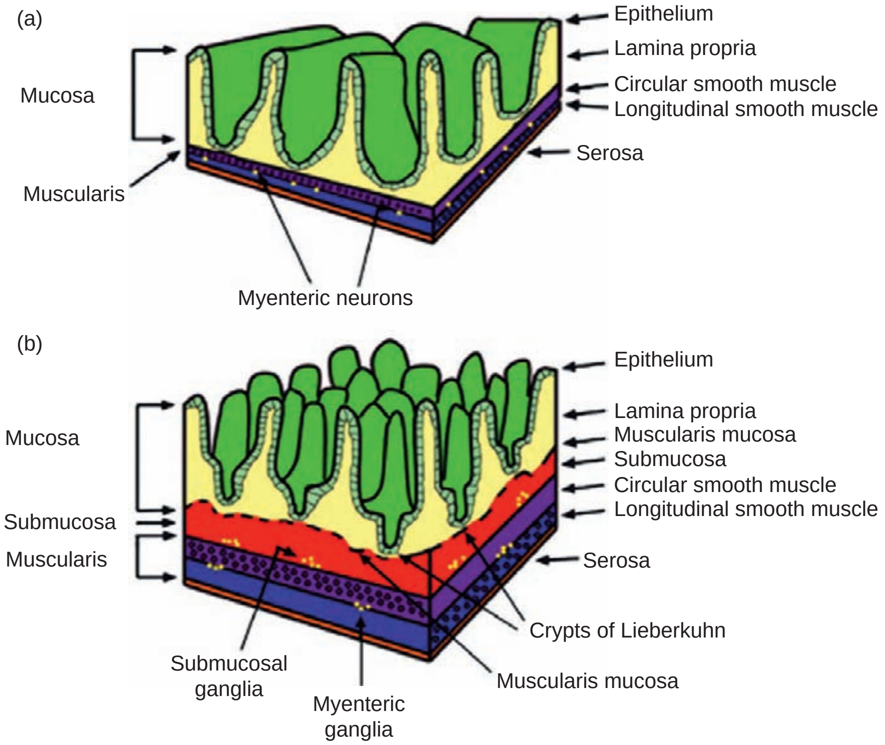

Figure 4 Comparison of teleost intestine to mammalian intestine. The teleost intestine (a) has broad irregular folds rather than individual villi as in mammals (b) and lacks crypts. The teleost has no muscularis mucosa and only a thin layer of connective tissue separates the base of the folds from the circular and smooth muscle layers. Enteric neuronal cell bodies are located between the circular and longitudinal smooth muscle but do not form ganglia as is mammals. Adapted from Wallace KN, Akhter S, Smith EM, and Pack M (2005) Intestinal growth and differentiation in zebrafish. *Mechanisms of Development* 122: 157–173.

During the second day, when migration is a prominent activity, enteric precursors proliferate at high rates (55% of the cells in S-phase at 50 hpf and 44% at 58 hpf). The proliferation rate is lower for anterior enteric precursors, where enteric neurons are differentiating as shown by the general neural marker Hu C/D (**Figure 5(c)**). At 64 hpf, proliferation is equal throughout the intestine (**Figure 5(d)**). During the third day, as more enteric precursors differentiate, the proliferation rate continues to decrease to 18% by 82 hpf.

By 50 hpf, a few enteric neurons are differentiating in the esophagus and anterior intestine. Differentiation of enteric neural precursors continues farther posterior during the second day. During this period, enteric neurons differentiate in two lines along the lateral surface of the intestine. By 74 hpf, enteric neurons begin differentiating around the circumference of the anterior intestine but continue to differentiate in lateral lines in the posterior. Later in the third day, enteric neurons have begun to differentiate around the circumference of both the anterior and the posterior intestine, increasing in numbers until the end of embryogenesis. During enteric neural development, a lower density of neurons develops in the anterior intestine as compared with the posterior.

As circular smooth muscle begins differentiating at 69 hpf, the number of enteric neurons increases dramatically and axons begin to project (**Figure 5(e)**). Later, as longitudinal smooth muscle begins to differentiate (**Figure 5(f)**), there is another dramatic increase in enteric neuron numbers. The largest increase in enteric neurons occurs as the muscle matures between 93 and 98 hpf, resulting in the formation of about one-third of the total neurons.

Neuronal subtypes (**see also Integrated Function and Control of the Gut**: Nervous System of the Gut) form at different times. Neurons expressing neuronal nitric oxide synthase (nNOS) are the first to develop at 60 hpf. As shown by expression of nNOS RNA, these neural precursors have an even distribution throughout the intestine, and the numbers increase relatively evenly throughout development. In contrast, serotonin-expressing neurons are present in low numbers on the third day and only increase during the fourth and fifth day. In addition, serotonin neurons develop in an anterior-to-posterior direction. Each of these neural subtypes develops a lower density in the anterior intestine.

The genetics of enteric development have been conserved. Major known regulators of enteric neuronal precursor migration and proliferation play a role in migration and differentiation of enteric neurons within the zebrafish intestine. Antisense knockdown of transcription,

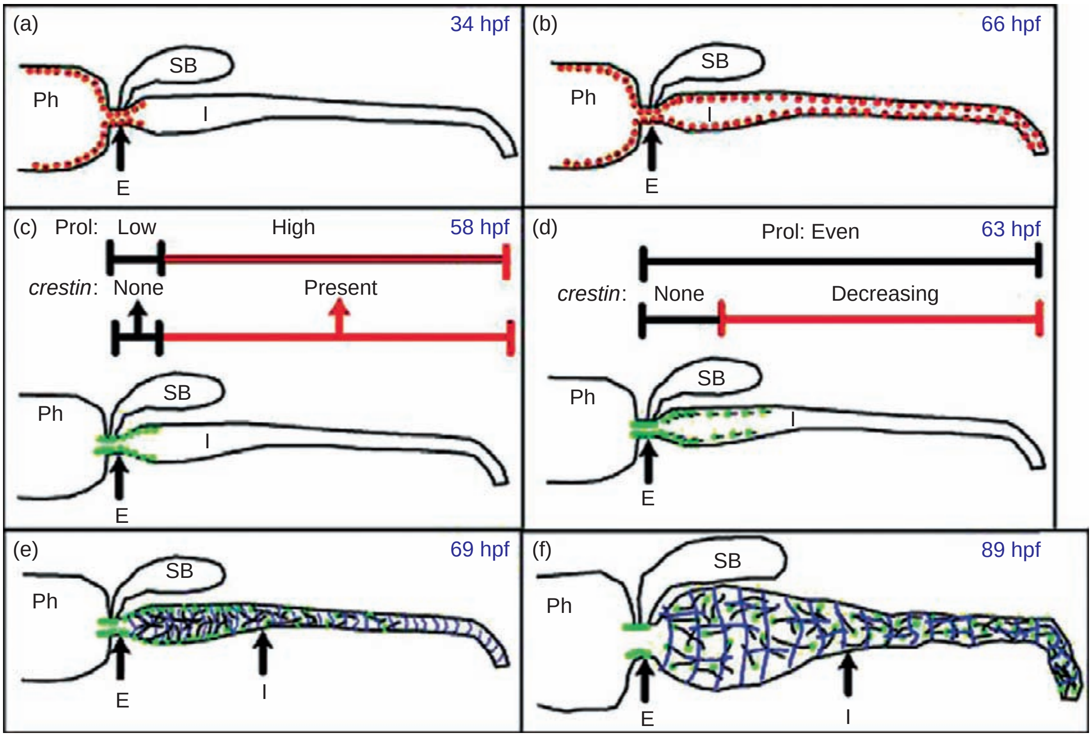

Figure 5 Development of enteric neurons. (a) Enteric neuronal precursors enter the intestine by 34 hpf. (b) Enteric precursors migrate along the lateral sides of the intestine, reaching the posterior by 66 hpf. During the second day of embryogenesis, enteric neurons begin differentiating in the esophagus and anterior intestine (c). This region also shows loss of *crestin* expression (a marker for undifferentiated neural crest) and significantly lower proliferation rates than posterior enteric precursors. At 63 hpf, enteric neurons begin differentiating more posteriorly as *crestin* expression decreases and enteric neuronal precursor proliferation becomes even throughout the intestine. At 69 hpf (e), there is a significant increase in enteric neuron numbers, they begin projecting axons, and there is a coordinated circular smooth muscle development. At 89 hpf (f), longitudinal smooth muscle develops with a second significant increase in enteric neuronal numbers. A third of the enteric neurons differentiate as the longitudinal muscle matures between 93 and 96 hpf. Ph, pharynx; E, esophagus; SB, swimbladder; I, intestine; red dots, enteric neuronal precursors; green dots, enteric neurons; blue lines, differentiating smooth muscle; black lines, axons. Reproduced from Olden T, Akhtar T, Beckman SA, and Wallace KN (2008) Differentiation of the zebrafish enteric nervous system and intestinal smooth muscle. *Genesis* 46: 484–498.

using morpholinos to each of the glial-cell-line-derived neurotrophic factor (GDNF) signaling components, results in lower numbers of enteric neurons, which leads to varying degrees of aganglionosis in the posterior intestine. TGF-β related ligand GDNF activates the RET receptor tyrosine kinase upon binding the growth factor receptor alpha (GFRa)1subunit. The activation of RET is responsible for regulation of enteric nervous system proliferation, differentiation, survival, and migration.

In addition, loss of expression of *sonic hedgehog* (*shh*) in the endoderm or *hand2* in the mesenchyme affects the expression of smooth muscle myosin heavy chain (*myh11*) in the developing smooth muscle, which also results in reduction of enteric neuronal precursor proliferation.

Differentiation of the Pancreas

The pancreas develops both the exocrine and the endocrine tissues. Exocrine cells develop a network of ducts that collect digestive enzymes to drain into the anterior intestine. Among fish, there is diversity in distribution of endocrine tissue. Many teleosts have a diffuse distribution of small islets within exocrine tissue, while other species tend to have principal islets (**see also Gut Anatomy and Morphology:** Pancreas). Like other cyprinids, adult zebrafish have a pancreas comprised of a diffuse network of both endocrine and exocrine tissues surrounding the intestine. The embryonic zebrafish pancreas, however, develops with a single islet at the anterior head surrounded by a body of exocrine tissue, which forms a posterior tail.

At 17 hpf, before the endoderm completes migration to the midline, insulin-expressing cells differentiate in bilateral groups adjacent to the midline. By 18 hpf, they merge to form the majority of the endocrine pancreas. The islet develops in an organization similar to amniotes with central β-cells and α-, δ-, and ε-cells in the periphery.

Later, a second group of endodermal cells differentiate ventral to the developing esophagus, forming the majority of the exocrine pancreas. The two groups join at 48 hpf, forming a single islet surrounded by exocrine cells. At this stage, there is no observable differentiation of ducts or acini and the tissue is considered protodifferentiated. At 60 hpf, ducts and acinar cells can be observed but these isolated cells are not yet organized into distinct glands and ducts. By 72 hpf, exocrine tissue proliferates and grows in the posterior direction, forming a distinct tail from the head of the pancreas, which contains the single islet. Ducts and acini organize from isolated groups of cells rather than the continuous branching that occurs in mammals. By 120 hpf, acinar cells are fully polarized and there is an organized network of ducts that drain individual acini.

Notch signaling is a key regulator of the fate of the pancreatic cells. As with the differentiation of other cell types, activation of Notch signaling plays a role in maintaining cells in an undifferentiated state. During pancreas differentiation, Notch signaling is required at multiple stages to maintain cells in the appropriate precursor state. Several Notch signals (*deltaA*, *jagged2*, and *jagged1b*) are expressed during pancreas development, acting at different times and places within the developing pancreas to permit the differentiation of both endocrine and exocrine cell types.

Differentiation of the Liver

As mentioned above, liver endoderm becomes specified as early as 14 hpf. During the early phase, the liver increases in size, but bile duct formation does not begin until 70 hpf. Biliary cells are first observed between 50 and 60 hpf, and a branching network of biliary ducts is observed by 80 hpf. Formation of the biliary network is not dependent on the presence of vasculature as in mammals.

The zebrafish liver has a tubular organization. Here, small bile ducts reside within hepatocyte tubules, which are surrounded by fenestrated sinusoidal endothelial cells (**Figure 6**(**a**)). In contrast, the mammalian liver is organized around a central vein surrounded by bilayered hepatic plates and radially organized groupings of portal veins, hepatic arteries, and bile ducts (**Figure 6**(**b**)).

Differentiation of hepatoblasts and the biliary tree has been demonstrated to be dependent on Notch signaling, using a combination of ligands and receptors. Genes for the Notch receptors *notch 1a*, *1b*, *2*, *and 5* along with the ligands *jagged 1*, *2*, *and 3* are expressed during bile duct formation at 2 dpf. Morpholino knockdown of *jagged 2 and 3* disrupts intrahepatic biliary development, whereas knockdown of *jagged 1* does not. Compound knockdown of the receptor genes *notch 2* and *5* also affects intrahepatic biliary development. Additional signals (such as *onecut 3* and *hnf*) also play a role in intrahepatic biliary development.

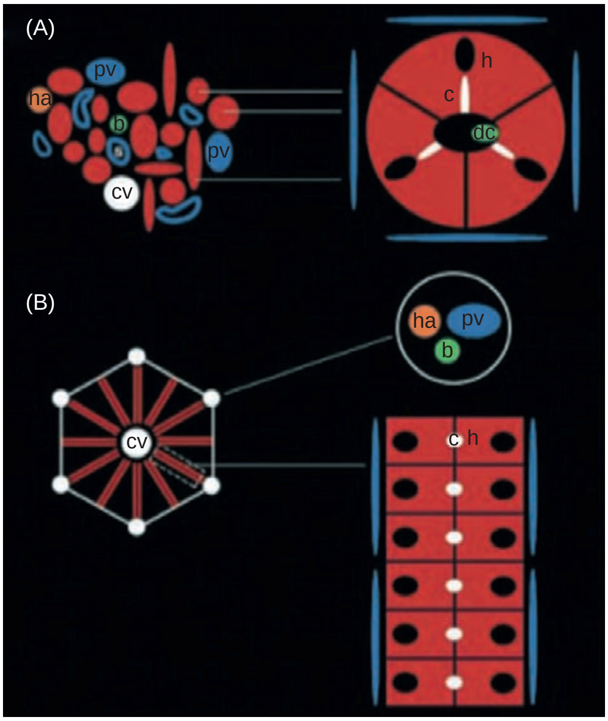

Figure 6 Structure of the teleost liver. The teleost liver (A) has a tubular organization with small bile ducts (dc) residing in the center of hepatocytes and anastomoses with three unicellular hepatocyte canaliculi (c). Hepatocytes are surrounded by fenestrated endothelia (blue). The portal vein (pv), hepatic artery (ha), and bile ducts (b) are not grouped around the bilayered hepatocytes (h) and central vein (cv) as in mammals (B). Organization of the teleost liver is not as apparent in cross section due to longitudinal, transverse, and oblique sections of tubular structures (A). Adapted from Lorent K, Yeo SY, Oda T, *et al*. (2004) Inhibition of Jagged-mediated Notch signaling disrupts zebrafish biliary development and generates multi-organ defects compatible with an Alagille syndrome phenocopy. *Development* 131: 5753–5766.

Concluding Remarks

There are differences between development of zebrafish and other vertebrate digestive systems. However, there are also many striking similarities, in both structure and genetic pathways, between the digestive systems of many vertebrates. This suggests that even though species are separated by wide evolutionary distances, a common pathway for digestive development may emerge for vertebrates.

Glossary

Chyme Partly digested food particles mixed with digestive secretions expelled by the stomach into the intestine.

Enteric nervous system The part of the autonomic nervous system contained within the gastrointestinal wall.

Peristalsis Propagating movements of gut contents by contraction of gut muscle.

Postprandial Period after ingesting a meal.

Propagating contractions Directional contraction waves in the gut in fasted and feed animals.

Slow waves Periodic depolarizations and repolarizations in gut muscle cell membranes which do not always result in an action potential.

Standing contractions Local nonpropagating contractions involved in mixing of the gut contents.

What Is Gut Motility?

The concept gut motility includes mixing and propulsive activity that is achieved by contraction and relaxation of smooth muscle in the gut wall. Gut motility plays an essential role in the breakdown and transport of food in the gastrointestinal tract, and occurs also in fasted states, when no food is present in the gastrointestinal tract. To facilitate digestion, the ingested food is mixed so that enzymes and acid can gain access to all food particles. Likewise, food needs to be transported from the mouth, where digestion starts, along the stomach and intestine where it is further digested before nutrients are eventually absorbed.

To ensure optimized processing of the food, all these different activities need tight control and coordination. The control systems are complex and we know only a fraction of the pathways involved. In this article, we review the fragmented literature available on gut motility in fish.

Different Motility Patterns Are Present in the Gut

The type of motility depends on the feeding status of the animal as well as the region of the gut. There are few *in vivo* studies of gastrointestinal motility in fish, limiting our knowledge of what patterns exist and when they occur.

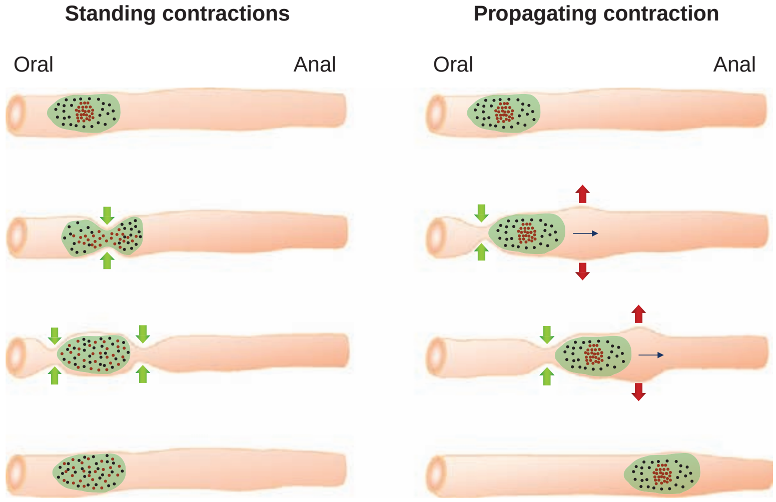

Figure 1 Different motility patterns of the gut. Local standing contractions mix the gut contents while propagating contractions move gut contents in an oral-to-anal direction. Green arrows indicate contractions, red arrows relaxation.

In most vertebrates, food intake induces propagating contractions of varying frequency and amplitude (**Figure 1**). In addition, local standing contractions mix the food. Propagating contractions also are seen in the fasted state but their appearance often differs from the postprandial (after food intake) patterns. Motility patterns also include the relaxation that may occur in response to distension of the gut wall (accommodation) or by anticipation of food (receptive relaxation).

So far, in fish, most studies on gut motility are *in vitro* recordings of muscle contractions, focusing more on specific control mechanisms than trying to reveal normally occurring motility patterns under natural situations. When using isolated muscle strip preparations, it is impossible to tell if a contraction is local or propagating. Some resolution can be achieved by using longer gut segments or intact organs, but still the situation is far from what occurs *in vivo* because the gut is detached from many of its control systems (see below). To accurately distinguish between propagating and nonpropagating contractions and to make comparisons with mammalian motility patterns, *in vivo* studies are needed in fish. These may include several different methods from pressure balloons inserted into the gut lumen or force transducers attached to the serosa to X-ray monitoring or video recordings.

Propagating Contractions

Propagating contractions in fish have been observed *in vivo* mainly in larvae. The transparent larvae are well suited for noninvasive studies of gut physiology and pharmacology in living fish. Using video-microscopy on zebrafish (*Danio rerio*) larvae, contractions are seen traversing the intestine in an oral-to-anal direction at a frequency of approximately one contraction-wave per minute and a speed of 0.1–0.5 cm min^{-1} (**Figure 2**; **Video Clip 1**).

Other studies involve *in vitro* or *in situ* experiments. In the late 1950s, G. Burnstock performed a series of experiments on brown trout (*Salmo trutta*) identifying different contraction patterns in isolated intestine and stomach. Propagating contractions were observed visually, moving at ~2 cm min^{-1}. Judging from his figures, the contraction frequency was approximately one per 5–6 min. The contraction waves were most prominent in fish that were fed prior to the experiments. Similarly, balloon distension and/or transmural electrical stimulation of rainbow trout (*Oncorhynchus mykiss*) and Atlantic cod (*Gadus morhua*) intestine *in vitro* trigger contraction waves traveling at approximately 3.5 cm min^{-1}. The contraction frequency in both stomach and intestine of unfed fish usually is about one every 2 min.

Postprandial propagating contractions (often simply referred to as peristalsis) are characteristically fine-tuned interactions between the muscles immediately anal and oral to the food bolus. Moreover, in fish, stimulation at one point causes oral contractions and a simultaneous anal relaxation, but the exact roles of the circular and longitudinal muscle layers are not known.

In fasted/unfed mammals, propagating contractions are often referred to as migrating motor complexes (MMCs). MMCs consist of three distinct phases, with only one phase containing regular (migrating) contractions. These contractions differ from the postprandial propagating contractions by running for longer distances and at a lower speed. They may play an important housekeeping function, cleaning the gut from unwanted debris and bacteria when normal peristaltic movements are absent. In continuous feeders such as sheep and guinea pig, the distinction between MMCs and postprandial movements is less obvious. Propagating contractions observed in unfed fish, including young zebrafish larvae, are possibly the equivalent to mammalian MMCs. As different feeding strategies exist among fish, it is likely that motility patterns vary accordingly.

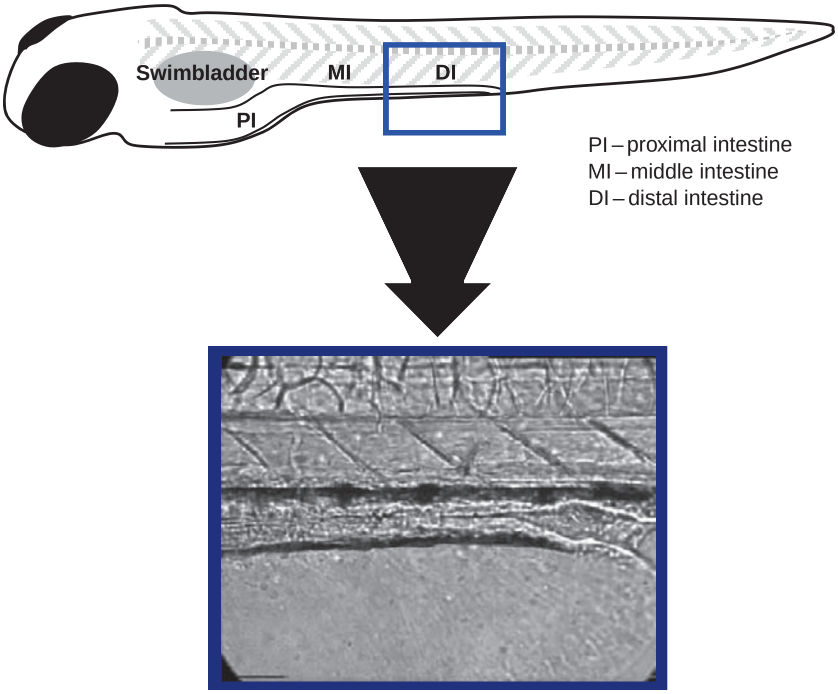

Figure 2 Propagating contractions in the distal intestine from a zebrafish (*Danio rerio*) larva at 7 days postfertilization (dpf). (see **Video Clip 1**; please note the events in the video are sped up, the time velocity is around 20 μms^{-1}. **Video Clip** courtesy of Dr. Anna Holmberg).

Although the propagating contractions normally run in the oral-to-anal direction, it is not uncommon to see retrograde (anal-to-oral) contractions. Zebrafish and Atlantic halibut (*Hippoglossus hippoglossus*) larvae have regular retrograde contractions, mainly in the proximal gut. The purpose of these movements is not fully understood but perhaps they mix gut contents and fill the pyloric ceca. Retroperistalsis is also seen in lesser-spotted dogfish (*Scyliorhinus canicula*) and has been suggested that it may contribute to vomiting.

Local Contractions

Transport of food (chyme) in the gut is a discontinuous process. To improve digestion, the chyme needs to be mixed with enzymes. To facilitate absorption, chyme has to be in close contact with the epithelial cells. Hence, propagating movements are interrupted by local, standing contractions in the postprandial state.

The propulsion rate varies along the gut, with muscular sphincters function acting as dividers between different regions (**see also Gut Anatomy and Morphology**: Gut Anatomy). Both propulsion rate and the state of the sphincters are controlled by an orchestra of subconscious signals. The sphincters are normally tonically contracted, keeping them closed, and open in the presence of an appropriate stimulus. For example, gastric emptying (the process where stomach contents are released into the intestine) normally occurs in smaller portions at a rate adjusted so that the food can be handled by the small intestine. The rate is ultimately determined by the state of the pyloric sphincter situated between the distal part of the stomach and the proximal intestine. If the sphincter is contracted, very little chyme is released while relaxation of the muscle results in opening of the sphincter.

Cellular Mechanisms behind Motility

Gut motility occurs when the smooth muscle in the gut wall contracts and relaxes in a reasonably well-coordinated fashion. The smooth muscle cells are connected to each other via gap junctions, allowing adjacent cells to contract in synchrony. The muscle layer generally has a basal tone of activity.

Muscle cells contract when the depolarization reaches a threshold, resulting in an action potential. Contraction may also occur if intracellular calcium levels increase without a change in membrane potential. Relaxation, on the other hand, occurs when the cell is hyperpolarized or if calcium levels decrease. So far, few, if any, studies on fish have examined the electrophysiological events in gut muscle cells and little is known about the ion channels involved. However, extracellular recordings of enteric electrical activity are a useful way of recording contractile activity *in vivo* in fish as in mammals (**Figure 3**).

In mammals, gut smooth muscle cells depolarize and repolarize in a rhythmic fashion, without any external stimuli. This spontaneous slow-wave activity, however, does not originate in the muscle cells but in the so-called interstitial cells of Cajal (ICCs) from which the electrical activity spreads to muscle cells via gap junctions. Muscular

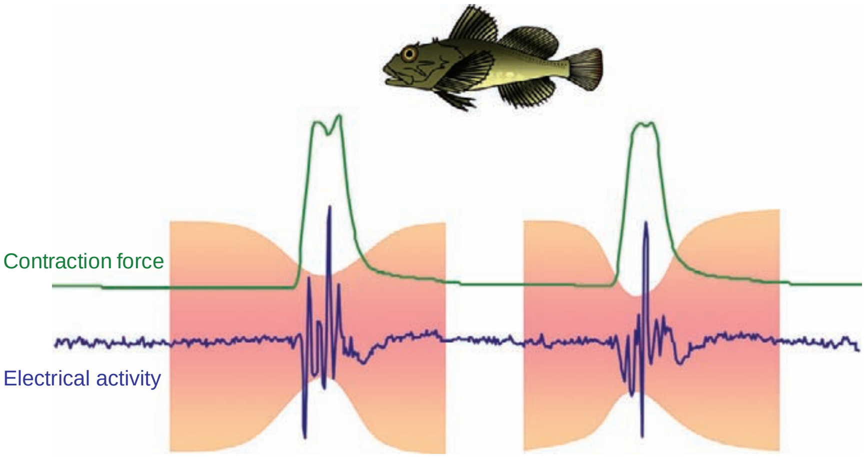

Figure 3 Correlation between electrical activity and mechanical contractions in the gut smooth muscle of shorthorn sculpin (*Myoxocephalus scorpius*).

slow waves often need additional stimuli from nerves or hormones to effect contractions. ICCs are present in fish and we hypothesize that they play a similar role in initiation of gut motility, although this has not been tested.

Gut Motility Is Tightly Controlled

The complex motility patterns of the gut depend on factors including the intrinsic properties of the smooth muscles as well as intrinsic and extrinsic nerves and hormones (**Figure 4**). In addition, environmental factors, such as temperature and pH, play an important role in the control, for example, by affecting the contractility of smooth muscles. Many fish species encounter large variations in the environment and are adapted to handle them. The impact of seasonal changes on gut motility is, however, poorly understood and should be further investigated. Furthermore, the type of food ingested changes motility.

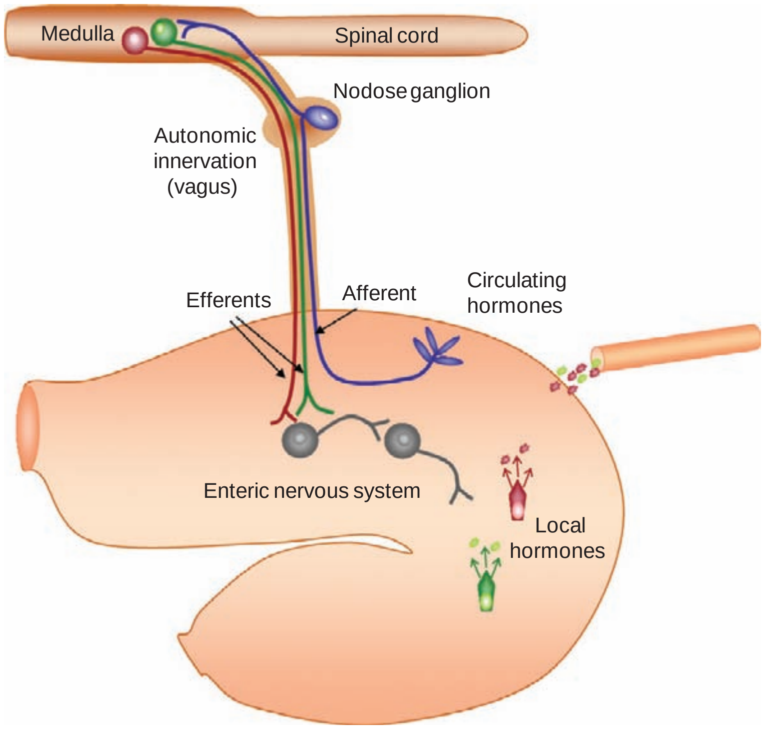

Figure 4 Schematic drawing of nervous and hormonal control of gut motility. Afferent extrinsic neurons (blue) respond to chemical and mechanical stimuli in the stomach, stimulating efferent autonomic pathways (illustrated by the vagal innervation). The efferent nerves may then stimulate (green) or inhibit (red) the enteric nervous system (gray). Inhibitory (red) and excitatory hormones (green) may be released from local endocrine cells or reach the gut via the circulation.

The main player in the control of gut motility is the enteric part of the autonomic nervous system. The enteric nervous system comprises all nerve cells intrinsic to the gut, that is, they have their cell bodies within the gut wall and one of its functions is to contract or relax gut muscle. An important characteristic of the enteric nervous system is its ability to work independently of central input, which means it contains the components to make up entire reflexes (**see also Integrated Function and Control of the Gut**: Nervous System of the Gut). This does not exclude extrinsic input as an important part of the control system, especially for modification and coordination of gut motility between different regions.

In addition to neuronal control, local endocrine cells release hormones that affect muscle activity. The effect can be direct or indirect, either via neighboring cells in a paracrine fashion or by release to the general circulation. Likewise, circulating hormones released elsewhere in the body may affect the gut.

The relative importance of the different control pathways varies among the different motility patterns and situations. Experimental setups seldom allow an integrated estimation of all possible influences. For example, *in vitro* preparations of isolated organs and muscle strips essentially exclude the involvement of circulating hormones and extrinsic innervation. The rhythmic contractions observed under basal conditions in such setups are often called spontaneous because they occur in untreated preparations. However, strictly speaking, this is not correct because they usually depend on some stimulus external to the muscle cell. Application of the sodium-channel blocker tetrodotoxin (TTX) may reduce or completely abolish the activity, indicating that it is nerve dependent.

In mammals, postprandial activity is affected by both intrinsic and extrinsic nerves, as well as by hormones. The extrinsic innervation seems to be less important for basal activity like MMCs. In either case, it is the underlying slow-wave activity that determines the maximal contraction frequency. TTX greatly reduces contraction frequency in intact zebrafish larvae, indicating the involvement of nerves in the initiation and/or maintenance of propagating motility. However, TTX affects both intrinsic and extrinsic neuronal pathways and it cannot be deduced which is its primary effect. On the other hand, TTX also reduces propagating contractions in, for example, isolated Atlantic cod intestine, suggesting that enteric nerves play an important role. Likewise, zebrafish mutants that lack or have reduced numbers of enteric neurons show reduced propagating activity.

Nervous Reflexes within the Gut

Intrinsic and extrinsic reflexes, as well as release of hormones, are initiated by the presence of food in the gut. The actual stimuli may be either chemical or mechanical, activating different types of sensory cells. In fish, few studies have looked at the types of stimuli involved in reflexes. Balloon distension is one way of mimicking mechanical stimulation. Electrical stimulation has also been used in some studies but this is a very artificial stimulus that does not accurately correspond to the normal postprandial distension. To study chemical stimulation, different breakdown products of the food (e.g., fat, proteins, or low pH) may be introduced in the gut *in vitro* or *in vivo*. Using a three-compartment bath, Karila and Holmgren showed that stimulation of the Atlantic cod intestine in one region resulted in contractions anally and relaxation orally, indicating that one stimulus affects both ascending and descending enteric nerves at the same time (**Figure 5**).

The role of the extrinsic innervation of the fish gut is poorly investigated and may vary between species. In mammals, extrinsic reflexes control gastric receptive relaxation and accommodation. In contrast, in teleosts, accommodation of the stomach takes place in the absence of vagal input, indicating that the enteric neurons perform at least some of the tasks that are under extrinsic control in mammals. Electrical stimulation of the vagus revealed mainly inhibitory fibers in salmonids and primarily excitatory fibers in Atlantic cod and plaice (*Pleuronectes platessa*) stomach. In some species, a combination of inhibitory and excitatory vagal fibers has been suggested. Similarly, excitatory effects exist in elasmobranchs but most studies support an inhibitory vagal effect. The splanchnic nerve(s) similarly have excitatory and inhibitory functions in both teleosts and elasmobranchs with species-specific variations.

Pharmacological Studies of Gut Motility

The fish gut has been studied extensively for the presence of signaling substances. Many of these substances occur in both nerves and endocrine cells, but this speaks little to function. An appropriate receptor is also needed for an effect. Although many transmitters are purely inhibitory or excitatory, others depend on the target receptor. For excitatory effects on gut motility, they may be manifested as an initiation of a muscle contraction or as an enhancement of the amplitude and/or frequency of rhythmic contractions. The opposite is true for inhibition.

Pharmacological studies, mostly with isolated gastrointestinal preparations, have discovered much about the effects of different signaling substances. The lack of fish-specific agonists and antagonist, however, has slowed progress. Some signaling molecules, such as acetylcholine, catecholamines, and nitric oxide, are identical across species, while peptides can vary appreciably. Today, the

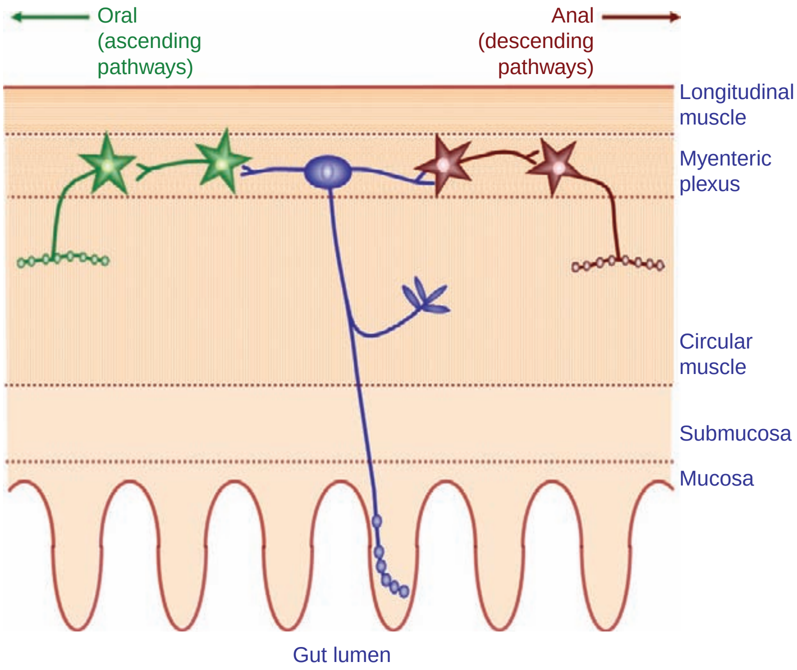

Figure 5 Schematic drawing of ascending (green) and descending pathways (red) in the peristaltic reflex, triggered by a common sensory neuron (blue) that may respond to chemical (luminal content, or hormones released from mucosal endocrine cells) or mechanical (stretching of the muscle layer) stimuli.

sequences of several fish peptides are known but still very few peptide receptor antagonists have worked in fish.

Rainbow trout and Atlantic cod are well studied in this regard. Some control mechanisms are similar throughout vertebrates, but with fish being such a large and diverse group, differences do occur among species and different parts of the gut. For a summary of the effects of different neurotransmitters and hormones in different fish species, see supplementary material (**Appendix A** (pp. 1232–1267)).

Excitatory and Inhibitory Signals in the Gut

Perhaps the most important neurotransmitter controlling gut motility is acetylcholine. In most teleosts and elasmobranchs, acetylcholine has an excitatory effect on the gut. Acetylcholine (or the more stable analog carbachol) may increase contraction amplitude, frequency or basal tone, or cause a combination of these effects in isolated muscle strips. This effect is likely achieved by a direct effect of ascending enteric motoneurons acting via muscarinic receptors because the response is often reduced by atropine but not affected by TTX. Acetylcholine is also involved in distension-induced reflex contractions in Atlantic cod and rainbow trout stomach.

Cholinergic innervation also includes ascending and descending interneurons as well as extrinsic (vagal) fibers. The contribution of these nerves to the overall cholinergic response is less well studied. In addition, little is known about the cholinergic control of fish gut motility *in vivo*.

Another important group of excitatory transmitters present in motoneurons is the tachykinins. Both substance P and neurokinin A (NKA) induce or enhance contractions in muscle strips from thorny skate (*Amblyraja radiata*), South American lungfish (*Lepidosiren paradoxa*), gray bichir (*Polypterus senegalus*), and rainbow trout, while they have no effect in Atlantic hagfish (*Myxine glutinosa*) or lamprey (*Lampetra fluviatilis*). The route of action of the tachykinins varies between species (see **Figure 6**) and may be direct on the smooth muscle or indirect via cholinergic or serotonergic neurons. So far, there are no reports of the effects on gut motility of scyliorhinins, two tachykinins first discovered in elasmobranchs.

The most widely examined inhibitory substances in fish and other vertebrates are members of the vasoactive intestinal polypeptide (VIP) family and nitric oxide. The effect of VIP, its relative pituitary adenylate cyclase activating polypeptide (PACAP), and nitric oxide on isolated gut preparations is mainly a reduction of rhythmic contractions. However, species and regional differences exist. In Atlantic cod, all three transmitters coexist to a large extent in enteric neurons and they may be released in response to slightly different stimuli. While PACAP reduces intestinal contractions in isolated muscle strips, neither mammalian nor cod VIP have any effect. In contrast, VIP reduces gastric contractions. However, VIP does not affect the response to distension in the Atlantic

Figure 6 Effects of tachykinins on gut motility in various species of fish. The tachykinins may be released from enteric neurons or local endocrine cells and may either have direct effect on the smooth muscle, or via release of acetylcholine or serotonin from other enteric neurons. Modified from Jensen J and Holmgren S (1994) The gastrointestinal canal. In: Nilsson S and Holmgren S (eds.) *Comparative Physiology and Evolution of the Autonomic Nervous System*, pp. 119–167. Chur, Switzerland: Harwood.

cod stomach, but causes relaxation in similar experiments in rainbow trout. Furthermore, VIP does not affect motility in any gut region of skate (*Raja* sp.), while inhibition is seen in the lesser-spotted dogfish rectum.

Exogenous nitric oxide lowers basal tension and abolishes rhythmic contractions in muscle strips from several species and regions. In addition, there is usually a nitrergic tone because blocking the synthesis of nitric oxide with L-arginine analogs increases contraction amplitude and basal tension. Nitrergic innervation mainly involves descending motoneurons (and possibly interneurons).

As the effects of inhibitory substances are most easily observed on rhythmically contracting preparations and those contractions would be decreased or abolished by TTX, few studies have managed to reveal where in a reflex VIP/PACAP and nitric oxide are released. If one would make parallels to the mammalian control systems, the most likely suggestion would be descending motoneurons. In the study on rainbow trout stomach mentioned above, it also was suggested that VIP might act via inhibition of excitatory (serotonergic) motoneurons. Judging from the distribution of VIP and PACAP, it also may be released from extrinsic neurons as well as from local endocrine cells.

Another important gut transmitter is serotonin (5-hydroxytryptamine, 5-HT). It is present in a large proportion of enteric neurons in many fish species, and may also be released from mucosal endocrine cells. Serotonin causes contractions of the gut in teleosts. In elasmobranchs, the response is less clear-cut and large variations occur both within and between different regions of the gut (**Appendix A** (pp. 1232–1267)). The route of action is far from clear with both direct and indirect effects reported depending on species. In rainbow trout, for example, serotonin is not blocked by atropine or TTX, indicating a direct effect on the smooth muscle. In Atlantic cod and several other species, an indirect pathway is suggested because the effect is at least partly reduced by TTX. In mammals, serotonin is released from endocrine cells, in response to chemical stimuli in the lumen, and acts as a stimulus for intrinsic sensory neurons. Whether it plays the same role in fish is not established but the serotonergic neurons may, to some extent, include a sensory population. They may also be excitatory descending interneurons.

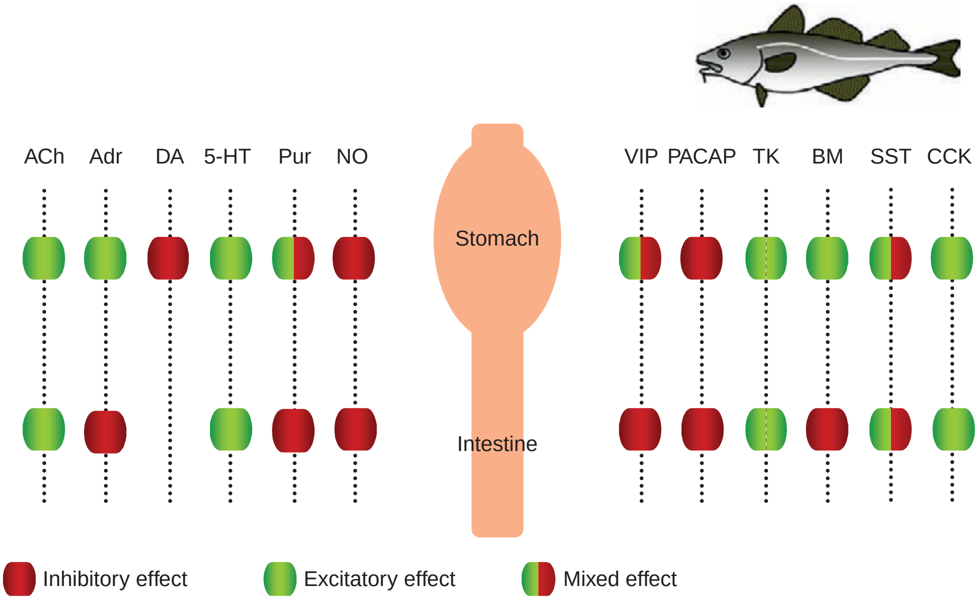

Figure 7 Summary of the effects of individual signaling substances in Atlantic cod (*Gadus morhua*). 5-HT, serotonin (5-hydroxytryptamine); ACh, acetylcholine; Adr, adrenaline; BM, bombesin; CCK, cholecystokinin; DA, dopamine; NO, nitric oxide; PACAP, pituitary adenylate cyclase-activating polypeptide; Pur, purines; SST, somatostatin; TK, tachykinins; VIP, vasoactive intestinal polypeptide.

The effect of catecholamines, like adrenaline and noradrenaline, is mainly extrinsic, via the sympathetic innervation, but electric stimulation of the splanchnic nerves gives variable results depending on species and region. In elasmobranchs, adrenaline usually contracts the stomach and intestine, but relaxes the rectum. In teleosts, splanchnic nerve stimulation and/or application of adrenaline/noradrenaline generally cause contraction of the stomach and relaxation of the intestine in species such as rainbow trout, brown trout, and European eel (*Anguilla anguilla*). However, in Atlantic cod and anglerfish (*Lophius piscatorius*), mixed responses or relaxation occur after adrenergic stimulation. In isolated Atlantic hagfish intestine, adrenaline gives weak and inconsistent effect.

Other signaling substances have been tested including neurotransmitters such as gastrin-releasing peptide (GRP), bombesin, calcitonin gene-related peptide (CGRP) and adenosine, as well as hormones such as cholecystokinin (CCK), somatostatin, histamine, and ghrelin. Results are often less than clear-cut. **Figure 7** summarizes the effects of the signaling substances discussed above on the gut of Atlantic cod, which is probably the best-studied fish species (**Appendix A** (pp. 1232–1267)).

Development of Gut Motility and Control

Young fish larvae mainly depend on internal sources of nutrients (the yolk) and different species start to feed (external feeding) at different stages. Zebrafish larvae have emerged as a model organism for developmental studies on gut motility, not only in fish but also as a more general model for vertebrate development (**see also Gut Anatomy and Morphology**: Development of Fish Gut). Under standard conditions, the larvae usually start to feed at 5–6 days postfertilization (dpf). Gut contractions start at 3 dpf as uncoordinated contractions that soon develop into more rhythmic patterns. At the same time, neuronal control mechanisms apparently begin to be functional with acetyl-choline and nitric oxide being the first to occur and to be involved in the control of contraction frequency. Other transmitters (e.g., various peptides) soon follow.

Integrated Effects on Gut Motility

The coordination of contractions and relaxation in the entire gut depends on the integration of many diverse signals. While the *in vitro* effects of individual neurotransmitters and hormones are relatively well understood, information about the interactions between them and their participation in complex reflex pathways is still limited. Translation to the *in vivo* situation must be done with great caution.

Gastric Emptying Rate

One of the best-studied integrated mechanisms *in vivo* is gastric emptying. In fish this has usually been done by postmortem examinations of the residual gut content, but also more sophisticated methods such as X-ray analysis have been used. The rate of gastric emptying is affected by numerous factors, including extrinsic factors such as meal size, feeding frequency, food composition, and temperature. In Atlantic salmon, larger meal-particle size delays gastric emptying. In rainbow trout, the half-emptying time is approximately 1 day but the lag phase before emptying depends on the dryness of the food. Gut blood flow responses in rainbow trout also depend on the composition of food injected directly into the intestine. As there is a correlation between gut blood flow and intestinal contraction frequency, one can speculate that gut motility is also affected by food composition.

Water temperature also affects gastric emptying rate. When the ambient temperature decreases, appetite, gut motility, digestion rate, and secretion all decrease, thus slowing down the gastric emptying rate. Different species acclimated to different temperatures may, however, show similar gastric emptying rates. Sea bass (*Dicentrarchus labrax*) acclimated to 16 °C, rainbow trout acclimated to 10 °C, and the Antarctic species bald notothen (*Pagothenia borchgrevinki*) living in −1.8 °C all have a half-emptying time of about 24 h. The physiological mechanisms adjusting for this somewhat surprising similarity are unknown.

The gastric emptying rate in fish also greatly varies between individuals and between species. For example, in juvenile lemon shark (*Negaprion brevirostris*), the stomach is emptied after 24 h. Intraspecies variations not only depend largely on food composition but also depend on factors such as position in the hierarchy with dominant individuals showing longer gastric emptying time compared with subordinate individuals.

The intestinal brake is a feedback mechanism that slows down gastric emptying rate even when there is food present in the stomach. This includes contraction of the pyloric sphincter and reduced contraction frequency in the stomach. The trigger of the brake is the amount and composition of food entering the intestine that in turn stimulates endocrine and nervous responses. One of the most important signals in mammals seems to be the release of CCK from endocrine cells in the proximal intestine in response to fat and acid in the proximal intestine. Moreover, in rainbow trout, CCK prolongs gastric emptying time. Other neurotransmitters and hormones have been suggested as potential factors involved in the intestinal brake, with gastrin and serotonin being two strong candidates.

Concluding Remarks

The lack of *in vivo* studies has hampered the knowledge of gut motility patterns in fish, how they are triggered, and propagated. Based on what we know, there are many similarities with mammals. The enteric nervous system is essential for the control of smooth muscle activity but local hormones also play important roles.

Introduction
Secretion
Digestion
Concluding Remarks
Further Reading

Glossary

Chyme Partially digested food particles mixed with digestive secretions.

Digestion The process of solubilization and hydrolysis of ingested nutrients into constituent molecules and elements suitable for transport across the intestinal wall.

Emulsification A process by which lipid and water can be mixed with the aid of emulsifiers, compounds with both lipophilic and hydrophilic areas such as phospholipids and bile acids.

Ligand (*ligare* (Latin): to bind) A molecule that binds to another molecule, such as an enzyme substrate, cofactor or signaling molecule.

Microbiota In this context, the microorganisms that inhabit the gastrointestinal tract, also called microbial flora and microflora.

Secretion The process of releasing compounds from a cell.

Introduction

Digestion is the mechanical and chemical breakdown (enzymatic hydrolysis) of food into smaller components to a form that can be absorbed by the intestinal epithelium. Digestion requires interaction between the dietary nutrients and a range of digestive enzymes and other components, which are secreted from various organs and tissues of the alimentary tract. The components secreted from the stomach, liver (via the gall bladder), and exocrine pancreas are of major importance for enzymatic hydrolysis of complex food polymers, namely proteins, carbohydrates, and fats, into smaller fragments. For proteins and carbohydrates, the final stages of hydrolysis are catalyzed by enzymes located in the brush-border membrane of the enterocytes (**see also Integrated Function and Control of the Gut**: Intestinal Absorption). Vitamins and minerals need to be released from the food matrix and made soluble before they can be absorbed. Any condition impairing interaction between nutrients and digestive components will limit digestion and absorption of the nutrient. Both chemical and physical characteristics of the diet as well as intestinal conditions can influence digestion.

Secretion

Secretion occurs all along the alimentary tract from the mouth to the anus (see **Figure 1**). These secretions are water mixed with mucins and a range of proteins, lipids, and other biologically active compounds. Levels and types of secreted components are specific and optimal for the various regions of the alimentary tract for their various digestive functions. The secreta are also necessary for conveyance and solubilization of nutrients. Mucus aids passage and mixing of chyme, and protects the epithelia against harsh dietary components, including the mucosal surface from its own acid, alkaline, and enzyme secretions. The mucus also protects the entire organism against microbes and chemicals that might be detrimental to its health and well-being. In addition to aiding nutrient digestion and absorption, water and ion secretions are vital for osmoregulation in fish. Mechanical and chemical stimuli derived from the meal induce secretory responses, via humoral and neural signals.

Water and Mucus

Mucus secretions come from mucus-producing cells (**Figure 2**) in the foregut, intestine, liver, and pancreas. Mucus contains water and mucins. Mucins are highly glycated proteins with great water-holding capacity and are produced by specialized epithelial cells located in the mucosal lining all along the alimentary tract (**see also Integrated Function and Control of the Gut**: Barrier Function of the Gut). Fish appear to lack salivary glands and instead have salivary cells dispersed among the epithelial cells. The number of mucin-secreting cells varies between the esophageal, gastric, and intestinal sections and so does

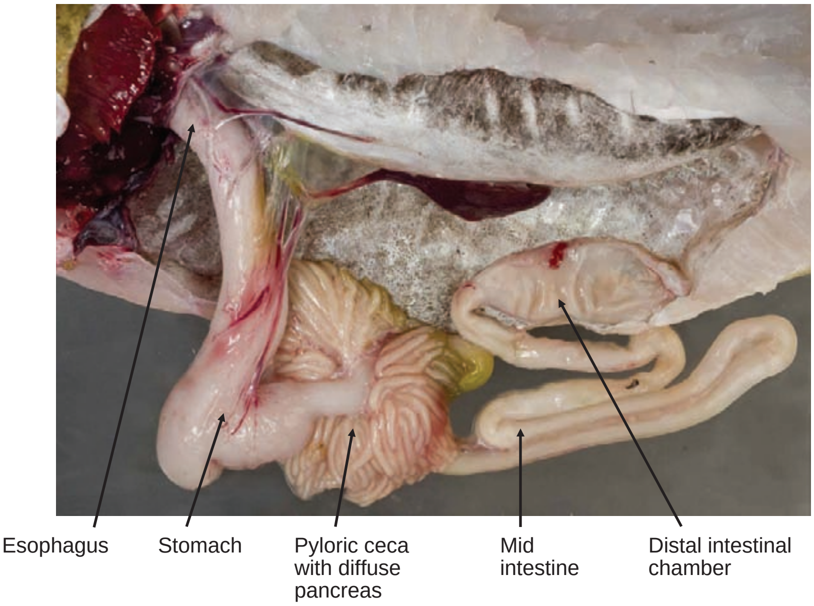

Figure 1 An overview of the gastrointestinal tract of Atlantic cod (*Gadus morhua*) caught in the Oslo fjord. Courtesy of D Griffiths.

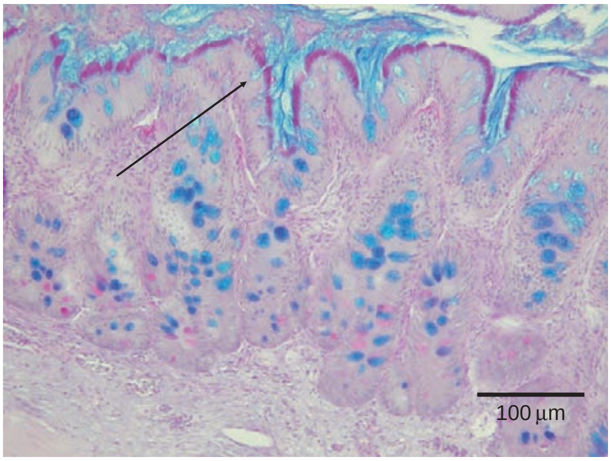

Figure 2 Section from the distal intestine of Atlantic cod stained with alcian blue/periodic acid–Schiff reaction (AB–PAS). The mucin secreted into the lumen and located in the apically situated goblet cells is stained blue, whereas the brush border of the enterocytes and the goblet cells situated deeper in the intestinal folds are stained magenta.

the flow of mucus, from low in the mouth to high in the intestinal regions. The quality of gut mucosubstances can vary with factors such as feeding habits, diet composition, fish species, and developmental stage.

The mucus of the gastrointestinal (GI) tract may also contain immunoglobulins and antimicrobial components such as enzymes and peptides, as well as organic compounds with antioxidative characteristics. Dead cells sloughed off from the surface also add proteins and enzymes to the mucus. The secretion of mucus may be helpful in removing harmful bacterial products by a washout effect. Mucus is kept close to the surface of the intestine by the glycocalyx, which consists of glycoprotein filaments extending from the interior of absorptive cells to the exterior forming a buffering network above the cell surfaces.

Stomach Secretions

In fish species with true stomachs, the central fundic and distal pyloric regions have secretory functions, whereas the most anterior cardiac region does not. Simple and branched gastric glands in the secretory regions are lined with mucus-secreting cells. The so-called oxynticopeptic cells are located at the base of the glands (**Figure 3**) secreting both hydrochloric acid (HCl) and pepsinogen, the precursor of the proteolytic enzyme pepsin. The ultrastructure of the oxynticopeptic cells reflects their dual purpose: apically located tubulovesicular networks secrete HCl, whereas more basally located zymogen granules contain pepsinogen granules. The secreted HCl contributes to the conversion of pepsinogen to pepsin.

Distension of the stomach wall as food enters is the initial stimulus for increased secretion. Following feeding, gastric pH increases rapidly from about 2 to 5 because water and food dilute or buffer the acidic gastric secretions. After feeding, increased gastric acid secretion gradually re-acidifies the stomach contents. The time taken for re-acidification is dependent on meal size. The response of gastric acid secretion to fasting varies among fish species, with most species secreting acid continuously while others periodically cease secretions during fasting. In the latter, stomach pH becomes close to neutral

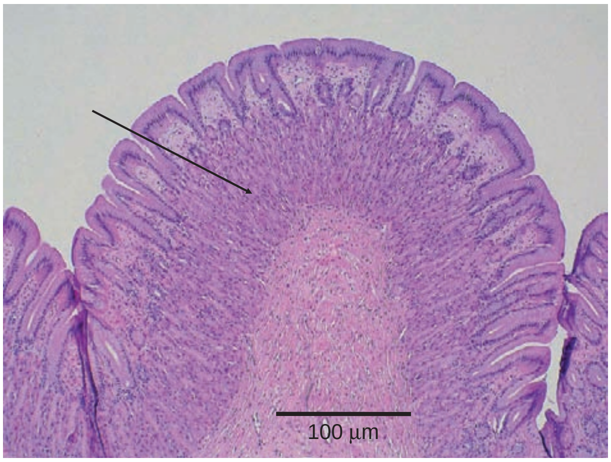

Figure 3 Section (hematoxylin and eosin stained) from the stomach of Atlantic cod. The arrow points to the oxynticopeptic glandular area below the mucosal folds. Courtesy of M Penn.

between meals. Mucus secreted in the stomach has a basic pH creating a thin surface layer protecting the epithelium from acid and proteolysis.

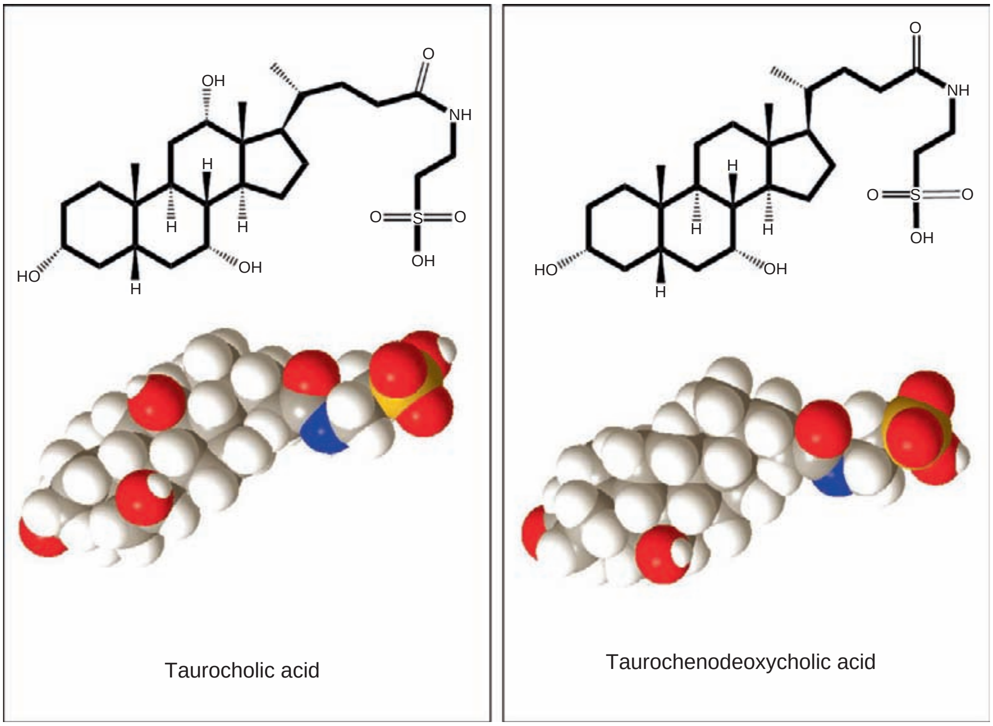
Secretion from the Intestine and Accessory Organs

Chyme enters the intestine and is subsequently mixed with secretions from the intestine and accessory organs, the pancreas and liver/gall bladder. The secretions include electrolytes, especially bicarbonate from the pancreas, liver, and intestine, which are essential to neutralize the acidic pH of the chyme coming from the stomach. This modification of the chemical environment enhances the conditions necessary for the pancreatic and intestinal digestive enzymes to work effectively.

The pH in the intestinal contents of most fishes is in the range from 7.5 to 8.5, which is more alkaline than in mammals. The secreted bicarbonate is also important in osmoregulation in seawater fishes by mediating ion and water absorption in the intestine. The pH may decrease in the distal intestine, most likely due to microbial production of short-chain fatty acids from indigestible carbohydrates.

Bile

Bile is produced by hepatocytes in the liver. It is subsequently released into small liver ducts known as canaliculi that converge and drain into the gall bladder where it is stored. Bile acids are acidic steroids with powerful detergent properties. The primary bile acids, cholic and chenodeoxycholic acids, are formed from cholesterol, and a large proportion of the bile acids are conjugated with taurine to form taurocholic acid and taurochenodeoxycholic acid (**Figure 4**), but some are conjugated with glycine. These primary bile acids may be further modified in the intestinal lumen by bacterial enzymes to form secondary bile acids. The extent and significance of such modifications in fish are largely unknown.



Taurocholic acid

Figure 4 The structure of the bile acid conjugates taurocholic and chenodeoxytaurocholic acid. Courtesy of H Grav.

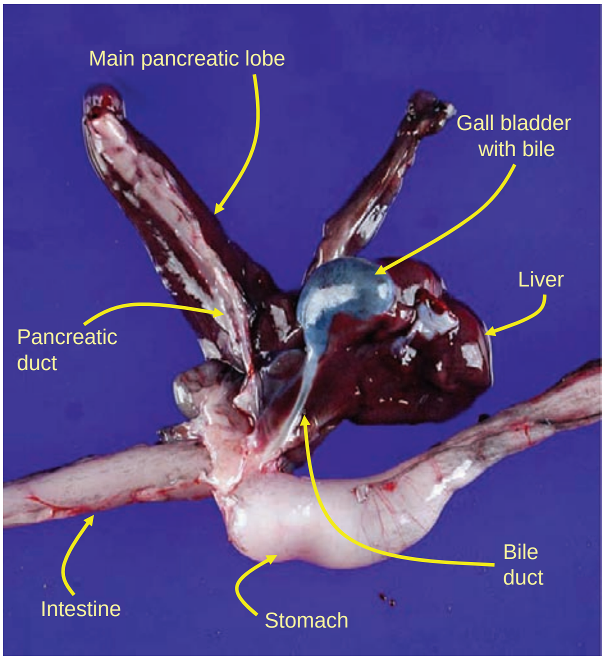

Figure 5 Liver with gall bladder and the main pancreatic lobes in sturgeon. Courtesy of F Dapra.

During fasting, the volume of bile in the gall bladder increases and the bile becomes more concentrated and darker in color (**Figure 5**). After a meal, the gall bladder is typically nearly empty and light in color. The bile acids are presumed mainly to be reabsorbed in the distal regions of the intestine and returned to the liver in the so-called entero-hepatic circulation. Bile acids aid digestion by emulsifying dietary lipids and forming primary micelles, and are necessary for the action of the main lipase in fish. The bile also contains phospholipids and cholesterol, and is a medium for the excretion of many endogenous and toxic waste products that have often been modified and conjugated in the liver to increase their lipid solubility.

Pancreatic juice

Acinar cells of the exocrine pancreas (**see also Gut Anatomy and Morphology**: Pancreas) contain zymogen granules, which store the digestive enzymes produced in the rough endoplasmic reticulum (**Figure 6**). These granules contain proteolytic enzymes: trypsin, chymotrypsin, elastase, and carboxypeptidase A and B; lipases: pancreatic lipase, co-lipase, and phospholipase involved in lipid digestion; carbohydrase: α-amylase for hydrolyzing α1–4 polysaccharides such as glycogen; as well as DNAse and RNAse. Some characteristics of the enzymes are given in **Table 1**. Signals from the gut trigger zymogen granule release into tubules that converge into pancreatic ducts, which are finely structured and numerous in fish such as salmonids with diffusely located pancreatic tissue. These ducts carry the enzymes into the lumen of the pyloric ceca and/or proximal intestine, or into the bile duct(s).

The proteolytic enzymes and co-lipase are stored and secreted as pro-enzymes that need to be activated in the intestinal lumen before they can hydrolyze feed components, whereas the lipases and α-amylase are released in active forms. The cascade of events that leads to activation of the pro-enzymes is initiated by enterokinase secreted from intestinal cells (**Figure 7**). Enterokinase activates trypsinogen to form trypsin, which in turn activates the other pro-proteases.

Pancreatic proteolytic enzymes have been isolated and characterized from several fish species. One enzyme may

Table 1 Characteristics of digestive enzymes secreted by the gastrointestinal tract and its accessory organs

Enzyme	*Species investigated*	*Tissue*	*pH optimum*	*Substrate specificity*
Endopeptidases				
Pepsin	Sea bass (*Dicentrarchus labrax*)	Stomach	3	Tyr, Phe, Leu
Trypsin	Atlantic salmon (*Salmo salar*), capelin (*Mallotus villosus*), Atlantic cod (*Gadus morhua*)	Pancreas	7–10	Arg, Lys
Chymotrypsin	Atlantic salmon	Pancreas	7–9	Tyr, Trp, Phe, Met, Leu,
Elastase 1 and 2	Atlantic salmon, spiny dogfish (*Squalus acanthias*), common carp (*Cyprinus carpio*), channel catfish (*Ictalurus punctatus*)	Pancreas	7–9	Ala, Gly, Ser
Exopeptidases				
Carboxypeptidase A	Atlantic salmon, Atlantic cod	Pancreas	7–10	Val, Leu, Ile, Ala
Carboxypeptidase B	Atlantic salmon, Atlantic cod	Pancreas	7–10	Arg, Lys
Lipases				
Bile-salt-activated triacylglycerol lipase	Atlantic cod, European turbot (*Psetta maxima*)	Pancreas	7–10	Ester bond in triacylglycerides, esp. in the 1- and 3-positions
Co-lipase-activated triacylglycerol lipase				
Phospholipase A	Sea bream (*Sparus aurata*)	Pancreas	8–9	Phospholipids
Amylase	Atlantic salmon, rainbow trout (*Onchorynchus mykiss*), common carp	Pancreas	4–9	α-1,4-bonds in starch

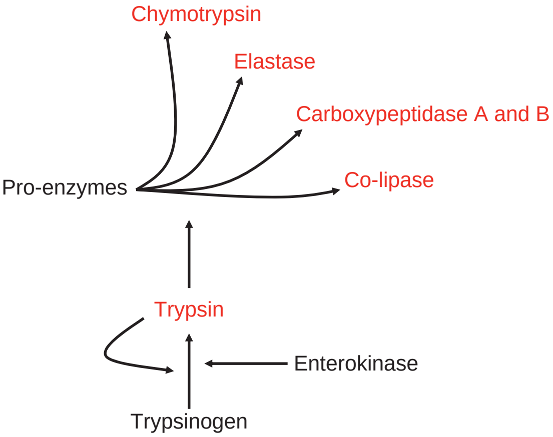

Figure 7 Illustration of activation of pro-enzymes secreted from the pancreas. Enterokinase activates trypsinogen to trypsin, which activates the other pro-enzymes. Trypsin also shows autoactivation.

have several forms in one species, forms that differ in specificity and specific activity. For example, α-amylase has several isoforms in tilapia (*Oreochromis niloticus*). This molecular diversity reflects adaptation to varied but specific feeds and environments. When activities of an enzyme from various species are analyzed at the same temperature, the enzyme from the Antarctic icefish (*Chionodraco hamatus*), for example, is generally more efficient compared to other fishes and endotherms adapted to warmer temperatures. The enzymes act in concert; trypsin, chymotrypsin, and elastase hydrolyze internal peptide bonds in the protein, whereas the carboxypeptidases cut one amino acid at a time from the carboxyterminal end of peptide chains.

The bile-salt-dependent triacylglycerol lipase, with highest specificity for fatty acids in position 1 and 3 of the triacylglyceride molecule, is the dominant lipase in fish. It can also hydrolyze wax esters and phospholipids. Fish also secrete phospholipase A_2, which hydrolyzes cholesterol esters as well as phospholipids, and possibly also the monoglycerides with a fatty acid in the 2 position remaining from the action of the triacylglycerol lipase. Wax-ester hydrolase and cholesterol-ester hydrolase occur in some fish species, but their significance is unknown. The pancreas is the major source of lipases in fish, but the intestinal wall also produces and may release lipases.

The enzyme characteristics differ between species. For example, the pH optimum for α-amylase in six sparid species has been observed to vary between 4 and 9. Atlantic salmon (*Salmo salar* L.) seem to have a defective α-amylase resulting in enzyme activities in the chyme below detection limit when analyzed with starch as substrate. The defect may be related to deletion of a peptide sequence in a substrate-binding site and possibly also an alteration in a sequence important for intracellular protein transport. Chitinase and cellulase activities exist in the GI tract of some fish species, but whether these originate from endogenous sources is debated. However, a chitinase seems to exist in the spiny dogfish (*Squalus acanthias*), suggesting that at least some elasmobranchs can produce chitinase.

Enzymes provided by prey animals may play important roles in nutrient digestion in predatory fish, particularly in larval/juvenile stages. Moreover, microbiota may add to the digestive processes, although microbial activity in fish is lower than in endothermic animals.

Nutrient delivery into the intestine is the most important stimulus of exocrine pancreatic secretion. Diet composition and nutrient digestibility influence secretion of specific enzymes and other factors. For example, the pancreas is stimulated to deliver a juice with higher levels of trypsin by diets containing a high level of protein, protein with low digestibility, and/or components that inhibit proteases, that is, the anti-nutritional factors in some plant feedstuffs known as trypsin inhibitors. A high-fat diet will stimulate higher lipase secretion. The relationship between a high-carbohydrate diet and an α-amylase secretion is more complicated, at least in fish species such as Atlantic salmon.

Digestion

Physical degradation of food can start in the mouth where food is torn apart and crushed by teeth, buccal pads, and/or gill rakers. Ingested food passes quickly to the foregut (**see also Gut Anatomy and Morphology**: Gut Anatomy). In the stomach, muscle contractions secure close contact with enzymes and emulsifiers, which solubilize the main nutrients. Stomach contractions and relaxation of the pyloric sphincter allow chyme to pass into the intestinal tract. Water-soluble components may leave the stomach earlier than fat, and small solid particles leave earlier than larger ones. In stomachless fish, such as common carp (*Cyprinus carpio*), food reaches the intestine before solubilization and emulsification take place to any extent. Some species, such as the gillaro (*Salmo stomachicus*), have a gizzard, a blind muscular sac, which continues the physical breakdown of the food with strong muscular contractions. The proximal intestine and the pyloric ceca, when present, contribute to about two-thirds of total nutrient absorption. However, and in contrast to the situation in mammals and birds, the distal-most and anal regions of fish gut are equipped with enterocytes and brush border, and have absorptive capacity for most nutrients. An overview of nutrient digestion along the digestive tract is given in **Figure 8**.

Newly hatched fish larvae often lack a fully developed GI tract regarding structure and function. They have a simple tube with one loop. All fish may be considered carnivorous and, in the wild, feed on zooplankton until the GI tract is fully differentiated. Maturation progresses at different rates in different species. In some species, such as salmonids and seawolf (*Anarhichas lupus*), the GI tract is well differentiated at hatch, making them capable of eating dry food at first feeding. Most cultivated fish species, however, need

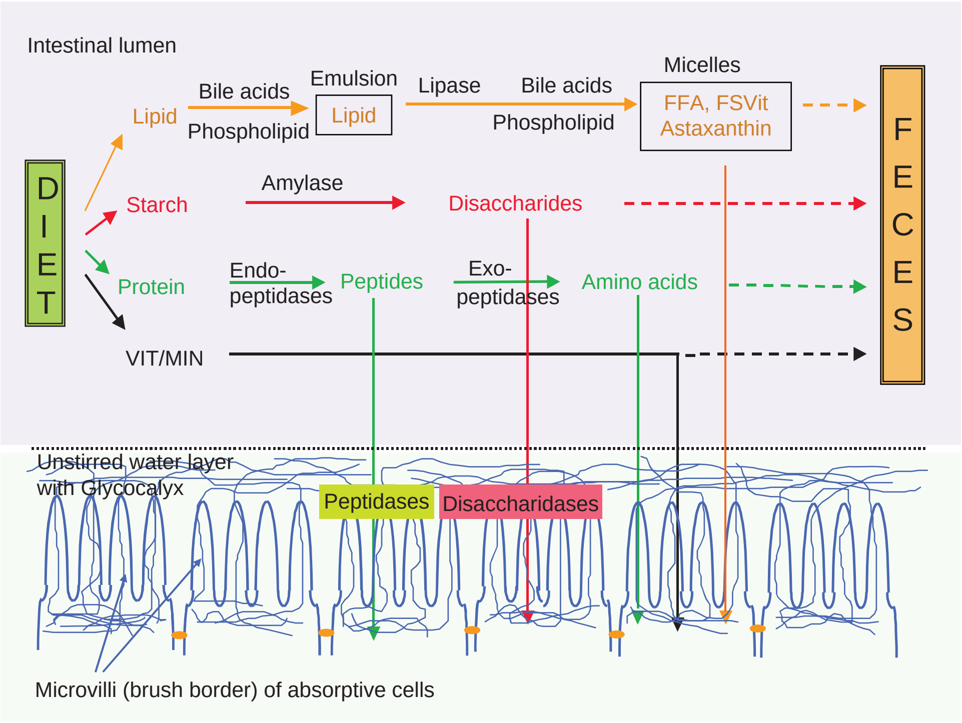

Figure 8 An illustration of digestive processes regarding the main nutrients along the digestive tract of fish. FFA, free fatty acids; FSVit, fat-soluble vitamins (see text for detailed explanation).

live feed the first weeks or months of life. In any case, dietary composition must fulfill the fish's changing nutrient needs and digestive capacity as they develop.

Protein Digestion

Natural prey contain a variety of proteins, as do formulated feeds for fish in cultivation, that vary greatly in aminoacid composition. Their digestibility is influenced by the three-dimensional structure and water solubility. The secretions from the wall of the digestive tract proximal to the intestine and water taken in with the feed moisten the feed to allow initiation of protein digestion. In species with a stomach, proteins are precipitated and hydrolysis is initiated by the action of HCl and pepsin secreted from the stomach wall. Gastric processes yield partially denatured and hydrolyzed protein and peptides in an acid solution, which are emptied into the proximal part of the intestine for further hydrolysis. In stomachless fish, protein digestion is initiated in the proximal intestinal compartment.

The array of proteolytic enzymes present in digestive juices sequentially hydrolyze the proteins and peptides into ever-smaller peptides and free amino acids, until they have molecular sizes suitable for transport across the brush border (see **Figure 8**). The different proteases are characterized according to the position of the peptide bond upon which they act, inside the protein or at the ends, as endo- and exopeptidases, respectively. Enzymes catalyzing the hydrolysis of peptides located at the carboxylic end are called carboxypeptidases, whereas aminopeptidases act on the opposite end. Proteases also show specificity regarding the amino acid at the peptide bond they hydrolyze (see **Table 1**).

Peptides longer than three amino acids are broken down by different classes of peptidases (endopeptidases, aminopeptidases, and carboxypeptidases) localized in the brush-border membrane of enterocytes in the vicinity of the amino acid/peptide transporters of the epithelial cells.

Some proteins entering the intestine either from the food or via the secretions are quite resistant to proteolysis and may be taken up intact by enterocytes by endocytosis in the distal section of the intestine. Intracellularly, they may trigger immune responses that may protect the fish from alien compounds or stimulate hypersensitivity reactions as found in salmonids fed soybean meal. Endogenous proteins are digested later in the digestive processes than food proteins and some, such as enzymes, may be recirculated. The digestive apparatus for protein digestion seems to be regulated according to the protein level of the diet. Protein in most fish food, live prey or formulated, has digestibility in the range of 70–98%. Formulated feeds in general have the lowest values.

Carbohydrate Digestion

Carbohydrates in food for fish in the wild comprise glycogen from the muscle and liver of prey animals, glucose in prey blood, and trehalose and chitin in blood and exoskeleton of crustaceans and insects. Plant sources of carbohydrates, such as phytoplankton, grasses, and algae, ingested by herbivore and omnivore species, may contain some digestible mono- and disaccharides, such as glucose, fructose, and sucrose. However, most carbohydrates in plants eaten by fish are polysaccharides including cellulose, hemicelluloses, alginates, pectins, mucilages, and chitin. Carbohydrates in formulated feeds range from highly digestible mono-, di-, and oligosaccharides to insoluble and indigestible hemicelluloses and cellulose. Starch, in the two forms of amylose and amylopectin, is the main carbohydrate in formulated feed serving both as energy source and as pellet binder. Amylose is a single-stranded molecule with several thousand glucose molecules that form a helix not easily attacked by α-amylase, whereas the amylopectin is highly branched and easily hydrolyzed by the enzyme.

All fish species investigated to date can digest glucose, fructose, sucrose, glycogen, and starch (**Figure 8**). However, most starches are digested in fish only after gelatinization, and amylopectin is more digestible than amylose. Hydrolysis of starch and glycogen is initiated in the proximal intestine by the action of pancreatic α-amylase, producing di- and oligosaccharides. Intestinal α-amylase activity varies greatly among species and is highest in herbivores. Amylase expression has been observed to be regulated according to dietary starch level in some species such as sea bass (*Dicentrarchus labrax*) but not in others (Atlantic salmon and Atlantic cod (*Gadus morhua*)). In many species, the α-amylase activity appears to be the limiting step in starch digestion. Starch digestibilities range from 20% to 99% depending on species, level in the diet, food intake, temperature, etc. Generally, digestibility decreases with increasing starch level, increasing food intake, and decreasing temperature. Herbivorous species digest starch better than omnivores and carnivores, which have lower α-amylase activities and starch digestibilities.

Di- and oligosaccharides are hydrolyzed into their constituent monosaccharides by various brush-border enzymes, such as maltase, sucrase, and trehalase. Brush border maltase activity is often much higher than the other enzymes, 10 times higher in salmonids. Whether expression of these enzymes varies with dietary carbohydrate level of the diet is unclear from the available literature. However, the total capacity can increase by an increase in tissue mass without any change in specific activity or activity per tissue weight. Glucose, galactose, and fructose reach the blood by specific transporters in the brush border and basolateral membrane or by diffusion.

Polysaccharides other than glycogen and starch are not digested by endogenous digestive enzymes. However, some species of the microbiota in the distal intestinal compartments may secrete polysaccharidases that can make some of the energy and the carbon skeleton of undigested plant polysaccharide sources available for the fish. Herbivorous fish species generally show the highest numbers and the greatest species variability of intestinal microbes. However, based on knowledge gained from investigations with grass carp (*Ctenopharyngodon idella*) and other herbivore species, the quantitative importance of plant polysaccharides for growth of fish in the wild is assumed to be low.

Dietary glucose and sucrose are well absorbed by all fish species. However, the capacity for glucose metabolism seems limited in many species. High levels of mono- and disaccharides therefore cause blood glucose and insulin to become elevated and the liver enlarged with glycogen.

Lipid Digestion

The main dietary lipids in fish diets are triglycerides, phospholipids, and wax esters (**Figure 9**). Phospholipids dominate in zooplankton used as larval foods and possibly also in food for herbivorous fish. Wax esters form a heterogeneous group of esters with alcohols other than glycerol and a large range of fatty acids. Waxes may serve as energy storage in prey such as planktonic crustaceans. Triglycerides dominate natural prey of mature carnivorous fish and in most formulated feeds. Fish can hydrolyze and absorb all three categories of lipids. In fish with distinct stomachs, the kneading movements of the stomach muscles, low pH, and solubilization of proteins release lipids from the diet particles. The hydrophobicity of the lipids causes them to aggregate into lipid droplets. Emulsifying compounds, such as phospholipids and certain amphiphilic proteins supplied either from the diet or from fluids secreted from the stomach wall, keep the droplets small and suitable as substrate for lipases present in the intestinal tract. A deficient supply of emulsifiers may cause oil accumulation in the stomach and regurgitation of lipid.

Lingual and gastric lipase are absent in most fish. Hence, in most fish, lipid hydrolysis is initiated when the chyme reaches the proximal intestine and is mixed with bile and pancreatic juice. **Figure 10** illustrates lipid digestion in the intestine. However, in pacu (*Colossoma macropomum*), lipase is present in secretions along the whole length of the GI tract. The bile acids further stabilize the emulsified fat. Free fatty acids, glycerol, and lysophospholipids are the major products of the concerted action of the lipases, although minor amounts of mono- and diglycerides are present in the intestinal

chyme. The long-chain fatty acids that are released are incorporated into primary micelles, which are mixes of bile acids and phospholipids. The micelles absorb the more lipophilic compounds such as fat-soluble vitamins, carotenoids, and cholesterol ester to form secondary micelles. In the vicinity of the brush border, the micelles disintegrate, catalyzed by a descending pH gradient in the glycocalyx causing massive protonation and release of the fatty acids. The short-chain fatty acids, such as C10:0 and C12:0, seem to escape incorporation into micelles and are rapidly absorbed in the proximal part of the intestine. Whether lipase secretion is adjusted to lipid levels of the diet is not clear. Lipid digestibility in fish ranges from 50% to 98% and is highest for marine-based foods.

Vitamins and Carotenoids

Present knowledge on the fate of vitamins along the GI tract in fish is almost nonexistent. However, processes preceding delivery to the intestinal wall for absorption are likely similar to those in mammals. If so, the fat-soluble vitamins A, D, E, and K, as well as carotenoids, follow the emulsified lipid droplets from the foregut to the intestine. As fatty acids are released and incorporated into the micelles to form mixed micelles, these vitamins are picked up by the mixed micelles. As the micelles disintegrate in the unstirred water layer, the vitamins are released close to the brush border. Any condition that interferes with emulsification and micelle formation will interfere with the availability for absorption of fat-soluble vitamins. Chyme conditions such as pH and redox potential affect availability for absorption of water-soluble vitamins.

Minerals

Very little information is available regarding the fate of minerals along the digestive tract in fish, but is likely very similar to that taking place in mammals. Minerals may be present in food in dissociated and solubilized form such as iron in the prey's blood which is bound to a heme molecule. Other minerals are present in the food as solid salts. An example is calcium in the skeleton of prey fish. Formulated feeds are most often supplemented with minerals in solid state. Solubility of mineral salts in digestive juices varies from insoluble to highly soluble depending on the elements involved, crystal structure, and particle size. Solid minerals may become solubilized as a result of the combined action of acid and alkali, digestive enzymes, and intestinal contractions.

Whether an element is absorbed or not also depends on chemical form, valency, and concentration in the chyme. Some elements are inorganic, while others are organically bound and may need to be released from the organic molecule before they can be absorbed. The level in the diet of ligands is very important for mineral availability. Ligands are divalent anions that bind divalent cations such as Ca^{2+}, Fe^{2+}, and Mg^{2+}. Some amino acids bind minerals and make them more available for absorption, whereas other components such as phytate have negative effects on availability for absorption. Antioxidants, for example, vitamin C with the power to reduce the valence state of minerals, affect the availability of minerals for absorption. Vitamin C has positive effects on iron availability but negative for copper. Interactions between minerals in the chyme may also affect availability. For many of the minerals, absorption is regulated according to requirement of the animal by control of carrier-protein production. This is the case for calcium and iron.

Concluding Remarks

Efficient nutrient digestion requires the secretion of a large number of digestive compounds in the right proportions as well as their coordinated conveyance along the digestive tract. Many of the processes and mechanisms are only partially known even for the most-studied fish species. Progress in aquaculture and the need for alternative nutrient sources have created an urgent need for a better understanding of digestive processes in fish.

Glossary

Agastric An organism without a defined stomach.
Amphipathic A molecule with one hydrophilic and one hydrophobic end.
Apical The tip of something, an apex. An apical membrane of an epithelial cell faces the outer world; in the case of the gut, it faces the lumen.
Basolateral The part of a cell or layer of cells lying closest to the blood supply; faces the internal environment.
Divalent A divalent cation has a net charge of +2.
Electrochemical gradient A difference in concentration and charge between two solutions separated by a semi-permeable membrane, including a plasma epithelial membrane, that produces a net movement of an ion by diffusion.
Endocytosis Cellular ingestion of fluid, substances, or particles through the formation of vesicles of the cell membrane.
Enterocyte Columnar adsorptive cell of the intestinal gut epithelium.
Hyperglycemia High blood sugar concentration.
Lipolytic The enzymatic activity that hydrolyzes lipids into smaller breakdown products.
Macronutrient Nutrients needed in large amounts.
Micronutrient Nutrients needed in very small amounts.
Monovalent A monovalent cation has a net charge of +1.

Introduction

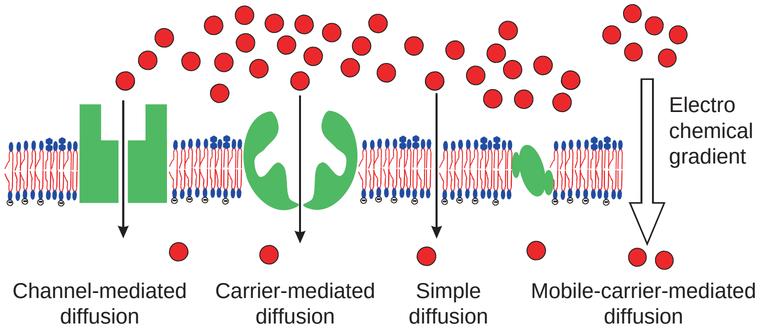
The main function of the fish intestine is to absorb nutrients, ions, and water in order to provide the animal with energy and building blocks for growth and development. For fish in seawater, the important role in fluid absorption results in continuous drinking to ensure a net uptake of water to match water loss across the gills and other epithelia (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). However, in freshwater fishes, this route of fluid absorption is trivial because water is continuously gained across the gills.

The process of absorption means a net transfer of material from the intestinal lumen to the circulation. This is accomplished by the single cell layer of columnar absorptive cells (enterocytes) lining the intestine, the epithelium (**see also Gut Anatomy and Morphology**: Gut Anatomy and **Integrated Function and Control of the Gut**: Barrier Function of the Gut). This article presents the functional morphology and physiology of the intestinal epithelium and its transport mechanisms and further discusses the role of the intestine as a multifunctional transporting epithelium. The article focuses primarily on macronutrient uptake. The specific role of the intestine in ion regulation is further considered in **Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation.

The Intestine as a Transporting Epithelium

Substances move across the intestinal epithelium through simple diffusion, facilitated diffusion, or primary and secondary active transport. When a substance follows its electrochemical gradient, the small, uncharged, lipid-soluble molecules diffuse directly across the lipid bilayer (simple diffusion); the larger, charged, water-soluble molecules pass either between the cells or with the help of carrier or channel proteins in the membrane (facilitated diffusion; **Figure 1**).

If the substance is to be moved against its electrochemical gradient, energy is required. This can be



Electro chemical gradient
Channel-mediated diffusion
Carrier-mediated diffusion
Simple diffusion
Mobile-carrier-mediated diffusion

Figure 1 The main pathways for passive diffusion, that is, movement along an electrochemical gradient, of a substance across a lipid bilayer.

obtained through primary active transport, where a membrane-bound transporting protein is linked to an adenosine triphosphatase (ATPase) or through secondary active transport, which is especially important for nutrient uptake. Secondary active transport utilizes energy stored in an existing electrochemical gradient of another substance. The major primary active transporter of the intestinal epithelium is sodium–potassium ATPase (Na^+/K^+-ATPase), which functions as the primary transporter of Na^+ and K^+ and creates a sodium gradient that drives several secondary transports into the cell. It is also electrogenic.

Enterocytes are polarized, which is a prerequisite for the directed transfer of molecules across the epithelium. Polarization means that the plasma membrane, and thereby the whole enterocyte, is divided into two main regions: apical and basolateral. The apical side, which faces the intestinal lumen, has a brush border. Its surface area is greatly enlarged by the presence of many microvilli (**Figures 2** and **3**). The brush-border membrane is separated from the rest of the plasma membrane by tight junctions that create the main barrier for diffusion and prevent lateral diffusion of the transporters along the plasma membrane. The basolateral membrane faces the

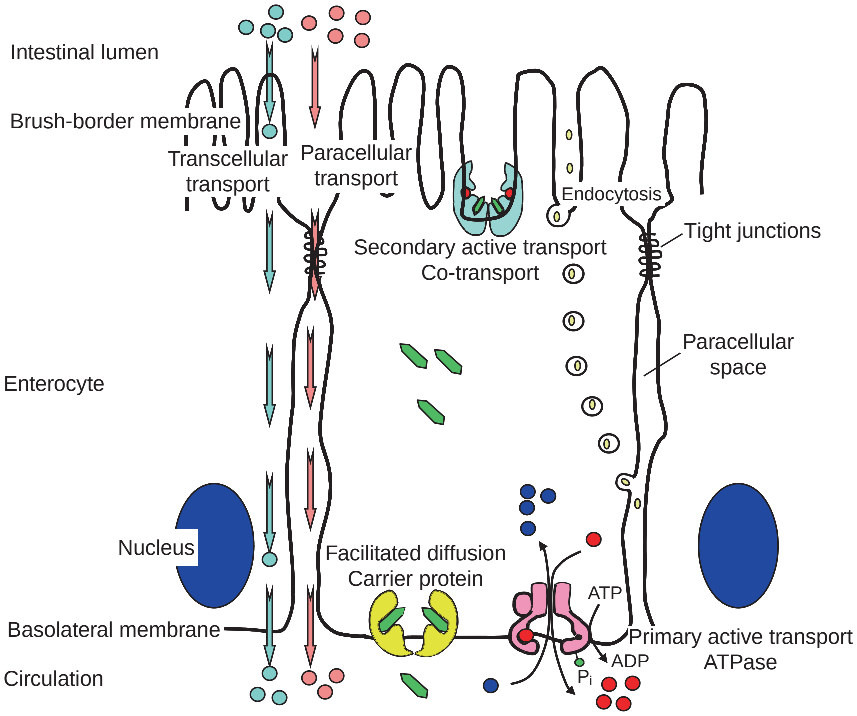

Figure 4 Pathways for absorption across the intestinal epithelium including examples of transporting enzymes inserted in the brush-border and basolateral membranes of the epithelial cells.

neighboring cells and basal membrane, and constitutes the interface to the circulation (**Figures 3** and **4**).

Substances can be taken up via two main pathways: (1) transcellularly through the epithelial cells or, (2) paracellularly, between the epithelial cells passing the tight junctions (**Figure 4**) (**see also Integrated Function and Control of the Gut**: Barrier Function of the Gut). Transcellular transport comprises (1) transport across the brush-border membrane, (2) transfer through the cytosol, and (3) transport across the basolateral membrane. All three steps depend on direction and size of the electrochemical gradients as well as on the presence of specific transporters or the diffusion properties of the lipid bilayer. Together, these properties create a highly efficient and selective transport apparatus (**Figure 4**).

Transepithelial Transport of Macronutrients

Macronutrients are the main nutritional components of food: proteins and their digestion products, peptides and amino acids (AAs); lipids and their degradation products such as diacylglycerides, monoacylglycerides, glycerol, and free fatty acids; and carbohydrates.

Depending on species, developmental stage, habitat, and dietary history, the individual macronutrients differ in their importance. Fish are traditionally regarded as glucose intolerant, and in many species AAs are more insulinotropic (inducing insulin release from the pancreas) than glucose. The low and variable ability to digest and utilize carbohydrates as energy source, as well as the apparent hyperglycemia lasting several hours after a glucose load, strengthens the indications that carbohydrates are less important for fish. Thus, in most fish, proteins are usually regarded as the main limiting factor for growth and lipids as the main source of energy.

However, many omnivores and herbivores can utilize dietary carbohydrates, and glucose is indeed an important energy source for certain fish tissues such as the brain. In herbivores, digestion of carbohydrate-rich food often depends on symbiotic microorganisms in the gut, which use anaerobic fermentation to acquire energy for their own use. The fermentation breakdown products are mainly short-chain and volatile fatty (or carboxyl) acids such as butyric, propionic, and acetic acid, which easily diffuse across the epithelium due to their lipid solubility. Of these, only propionic acid can be converted to glucose in the circulation. This and the observations that several herbivorous fish depend on lipid-rich food sources such as diatoms (unicellular phytoplankton) for growth and reproduction suggest that glucose probably does not meet the total energy requirements throughout the life cycle of herbivorous species.

Protein Absorption

Amino Acid Absorption

The smallest breakdown products of the dietary proteins are AAs. After a meal, the concentration of free AAs in the intestinal lumen increases. AA uptake is mainly transcellular, through Na^+-dependent, secondary active, co-transport. Paracellular diffusion may occur if luminal concentrations are very high.

The AA transporters are a diverse group of membrane proteins that share several properties. They typically exhibit broad substrate specificity, so that several AAs may be transported by one type. More than 20 different dietary AAs can be divided into acidic, basic, neutral, and imino acids; in mammals, each group of AAs seems to have its own specific Na^+-dependent co-transporters. Not much is known about the molecular mechanisms of AA transporters in fish, but the four main groups of Na^+-dependent transporters are present in the brush-border membrane of European eel (*Anguilla anguilla*), rainbow trout (*Oncorhynchus mykiss*), sea bass (*Dicentrarchus labrax*), and the marine bream (*Boops salpa*) (**Figure 3**). Furthermore, sodium-independent AA transporters (i.e., H^+-dependent neutral amino acid brush-border membrane transporters) have been identified in fish and mammals.

Within the absorbing cell, AAs are either metabolized to yield energy for the cell, used in protein synthesis, or transferred unchanged through the enterocyte and into the hepatic portal system for transport to the liver and beyond. Glutamine is a particularly important AA for enterocyte metabolism, serving as a major source of energy for cells in tissues with a high turnover, that is, containing rapidly dividing populations of cells, such as the intestinal epithelium.

AA excretion across the basolateral membrane of the enterocyte occurs through passive diffusion, mainly facilitated by membrane-bound carrier proteins. These require an outwardly directed gradient of AAs from the enterocytes to the circulation. In addition to these Na-independent carrier mechanisms, Na^+-dependent, secondary active transporters (as described above for brush-border membrane) are also found in the basolateral membrane. These transporters carry AA from the circulation into the cell, probably to supply AA to the enterocytes for intracellular energy and protein synthesis between meals and during periods of starvation (**Figure 5**).

Essential AAs generally show a higher uptake rate across fish brush-border membrane than nonessential AAs. Furthermore, the affinities of the Na^+-dependent AA transporters in fish are generally higher than the corresponding mammalian transporter. The higher uptake efficiency of fish is believed to be correlated to their relatively short intestinal length compared with mammals.

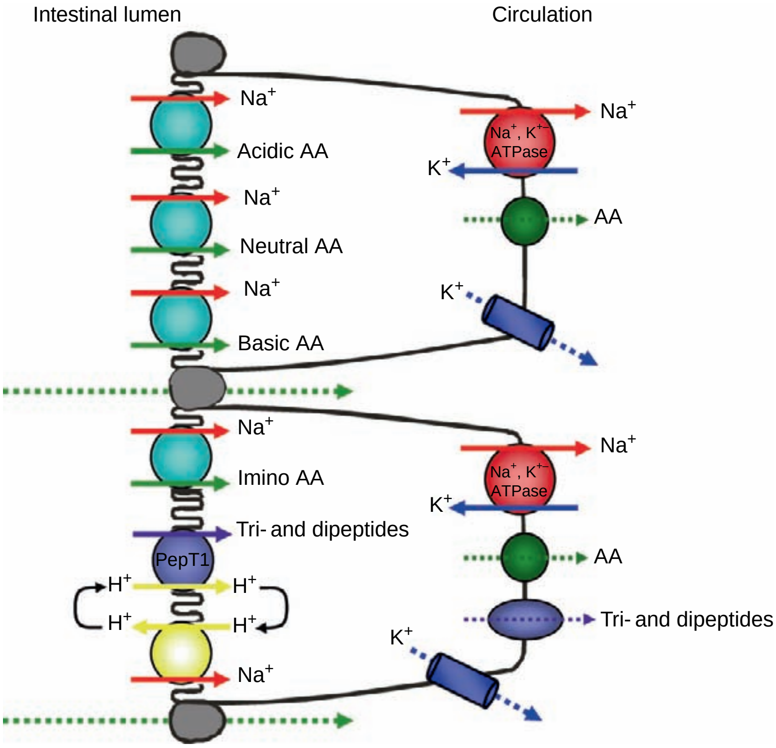

Figure 5 Probable mechanisms for absorption of amino acids and di- and tripeptides across the intestinal epithelium of fish. Pep T1, oligopeptide transporter 1.

Di- and Tripeptide Absorption

Protein digestion into single AAs is not always complete prior to absorption. Recent studies of several vertebrate species suggest that the entry of di- and tripeptides across the apical membrane of the enterocytes is an important route of absorption of digested proteins. Evidence for specific proton-coupled peptide transporters in the brush-border membrane of both mammals and fish is accumulating.

Dietary proteins differ in their AA composition and thus also in the composition and properties of the peptides produced by hydrolysis. The oligopeptide transporter 1 (PepT1) transports di- and tripeptides, and has extremely broad substrate specificity. A detailed analysis of mammalian PepT1 shows that it is a Na^+-independent transport coupled to active proton transport. The mammalian transporter responds to extracellular pH with an optimum of between 4.5 and 6.5, depending on the net charge of the transported substrate. In contrast, the few fish PepT1 characterized to date show increased transport rates with alkaline extracellular pH. After entering the enterocytes, the peptides are normally hydrolyzed to free AAs by cytosol peptidases. However, small peptides that are resistant to hydrolysis may be excreted at the basolateral membrane and enter the systemic circulation (**Figure 5**).

The relative nutritional importance of AA versus di- and tripeptide absorption seems highly variable among fish species with different feeding habits. In salmon, maximal rates of peptide transport, measured *in vitro* (using an everted sleeve method), are low compared with reported transport rates for AAs. At the same time, *in vivo* data suggest that di- and tripeptides are absorbed more rapidly. However, the limiting step for AAs absorption seems to be neither in the AA transporters nor in the di- and tripeptide transporter because the maximal capacity of the transporters is generally higher than the substrate concentrations available in the intestinal lumen.

Absorption of Intact Proteins

Fish enterocytes can also absorb intact proteins by endocytosis (**Figure 4**). This occurs primarily in the posterior intestine, also called the 'hindgut' (**see also Gut Anatomy and Morphology**: Gut Anatomy). The proteins probably bind to a specific receptor at the brush-border membrane that initiates invagination of the membrane, and transport vesicles are formed. Within the enterocytes, the endocytosed vesicles can fuse with lysosomes, whereupon the proteins are degraded by enzymes. The products, peptides and AAs, are released into the cytosol. The vesicles may also be transported through the cytosol, fuse with the basolateral membrane, and secrete the intact proteins into the circulation.

Both larvae and adult fish can absorb intact protein through endocytosis. In larvae of some viviparous fish, the hindgut protrudes and functions as an organ analogous to the mammalian placenta because it can absorb digested nutrients and intact proteins directly from the mother. Absorption of intact proteins in the hindgut may be a general feature in larval fish as it is present in oviparous fish. This mechanism may be related to the lack of a stomach prior to metamorphosis in many fish larvae and therefore absorption and intracellular digestion of intact proteins in the intestine is suggested as an important route that supplies the larvae with AAs. Ultimately, the reported processing rates of proteins in the hindgut are too low to satisfy the high metabolic and anabolic demands for AA of rapidly growing fish larvae, which may in part explain the special nutrient demands of most first-feeding agastric fish larvae. Endocytotic absorption of intact proteins in adult fish has been suggested to be important for recirculation of secreted proteins (e.g., digestive enzymes such as trypsin), absorption of proteins that have not been digested, and, probably most importantly, as a way to present antigens to the mucosal immune system (**see also Integrated Function and Control of the Gut**: Barrier Function of the Gut).

Lipid Absorption

Micelle Formation and Importance

Dietary lipids are emulsified by bile salts and form into droplets containing neutral lipids (mainly triacylglycerol) and an outer layer of polar lipids in a ratio of approximately 30:1 (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion). This facilitates lipolytic action of digestive enzymes by reducing the tension at the oil–water interface, thereby increasing the concentration of lipids at the interface. Lipases, released from the pancreas, hydrolyze triacylglycerides into monoacylglycerides, diacylglycerides, and free fatty acids. The breakdown products, in turn, form smaller vesicles and interact with bile salts to form mixed micelles. In the mixed micelles, the lipid components are surrounded by taurocholate and other bile salts.

In marine fish, in particular, another important lipolytic pathway exists. These fish eat high amounts of dietary wax esters and triacylglycerides containing high proportions of highly unsaturated fatty acids (HUFAs). The typical marine lipids are mostly hydrolyzed by bile-salt-activated lipases, yielding small breakdown products: glycerol, free fatty acids, and long-chain fatty acids (LCFAs), which are also recruited into bile-salt-containing micelles.

The absorption of the lipid breakdown products can be considered simple as lipid-soluble molecules that can easily dissolve in the lipid bilayer of the brush-border

membrane and enter the cell. However, the cell surface is covered by mucus which binds a lot of water and are creating a so-called unstirred water layer (**see also Integrated Function and Control of the Gut**: Barrier Function of the Gut). This layer will constitute a major barrier to lipid absorption. Micelle formation is therefore essential, as it increases the water solubility of the lipids and facilitates the passage through this unstirred water layer (**Figure 6**).

Uptake across the Brush-Border Membrane

Passive diffusion

At the brush-border membrane, the micelles dissociate and the lipid constituents are absorbed into the cell. The dissociation is facilitated by the creation of an acidic environment by Na^+/H^+ exchangers in the brush-border membrane. The subsequent uptake of the lipid components across the brush-border membrane is believed to occur through passive diffusion at high luminal concentrations and via carrier-mediated or active mechanisms at low luminal concentrations. Passive diffusion of fatty acids increases with increasing chain length up to 16 carbon atoms long, as well as with increasing degree of saturation. Thus, LCFAs and HUFAs may depend more on carrier-mediated or active uptake.

Fatty-acid-transporting proteins

In mammals, three main types of facilitating proteins are known for fatty acid absorption: fatty acid translocases, fatty-acid-transporting proteins, and plasma membrane fatty-acid-binding proteins. No fatty-acid-binding or -transporting proteins have been identified to date in the intestinal brush-border membrane of fish, but rainbow trout and Atlantic salmon muscle and liver cells express these proteins. Cytosolic fatty-acid-binding proteins, within the enterocytes, are also of great importance for fatty acid absorption across the intestinal mucosa. The binding proteins will unload the brush-border membrane of fatty acids and thus maintain a high inwardly directed concentration gradient for diffusion of fatty acids into the cell. Similarly, no cytosolic fatty-acid-binding proteins have been demonstrated in fish intestinal cells, although several isoforms exist in muscle, liver, heart, and visceral fat (**Figure 6**).

Intra-enterocytic resynthesis

The mechanism of transfer of lipids and fat products further into the circulation appears to differ in one aspect between mammals and fish. In mammals, the shorter fatty acids (<12 carbon atoms) can be transferred directly across the basolateral membrane into the lymphatic system from which they are eventually emptied into the systemic circulation. However, most studies suggest that fish do not possess a true lymphatic system. Instead, they have a so-called secondary circulation (**see also Design and Physiology of Capillaries and Secondary Circulation**: Secondary Circulation and Lymphatic Anatomy), but this is not present in the intestine. Thus, there seems to be no pathway for a direct transfer of short-chain lipid products into a secondary circulation in fish.

Considering all LCFAs in mammals and possibly all lipid products in fish, a resynthesis of triacylglycerides and polar lipids in the endoplasmic reticulum of the enterocytes is required for lipid absorption. Two main pathways for lipid resynthesis have been described: the 2-monoacylglycerides pathway mainly leads to triacylglyceride reconstitution, while the glycerol-3-phosphate pathway yields both triacylglycerides and phosphatidylcholine. Both pathways are present in fish enterocytes, but the 2-monoacylglyceride pathway appears to be dominant.

Following absorption and resynthesis, triacylglycerides and phosphatidylcholine are mainly incorporated into large particles called ‘chylomicrons’ and/or very low density lipoproteins that contain a core of triacylglycerides surrounded by phosphatidylcholine, cholesterol, and apolipoproteins. Assembly into large, protein-covered particles increases water solubility, thus facilitating blood lipid transport to other target tissues for energy utilization and storage (**Figure 6**).

Carbohydrate Absorption

Dietary carbohydrates are mainly absorbed as monosaccharides. The fish intestine can absorb a range of these monomers, including glucose, fructose, galactose, and the breakdown product of chitin, *N*-acetyl-glucoseamine. In mammals, the monosaccharides glucose and galactose are taken up across the brush-border membrane through secondary active co-transport by the sodium-dependent glucose transporter, SGLT1. Fructose is transported by a member of the facilitative glucose transporter family, GLUT5 (**Figure 7**). In addition, during high carbohydrate loads another protein from this family, GLUT2, is expressed in the brush-border membrane, facilitating entry of monosaccharides into the enterocytes. After transfer through the enterocyte, the monosaccharides cross the basolateral membrane via facilitated diffusion through GLUT2, which is constitutively expressed in this membrane.

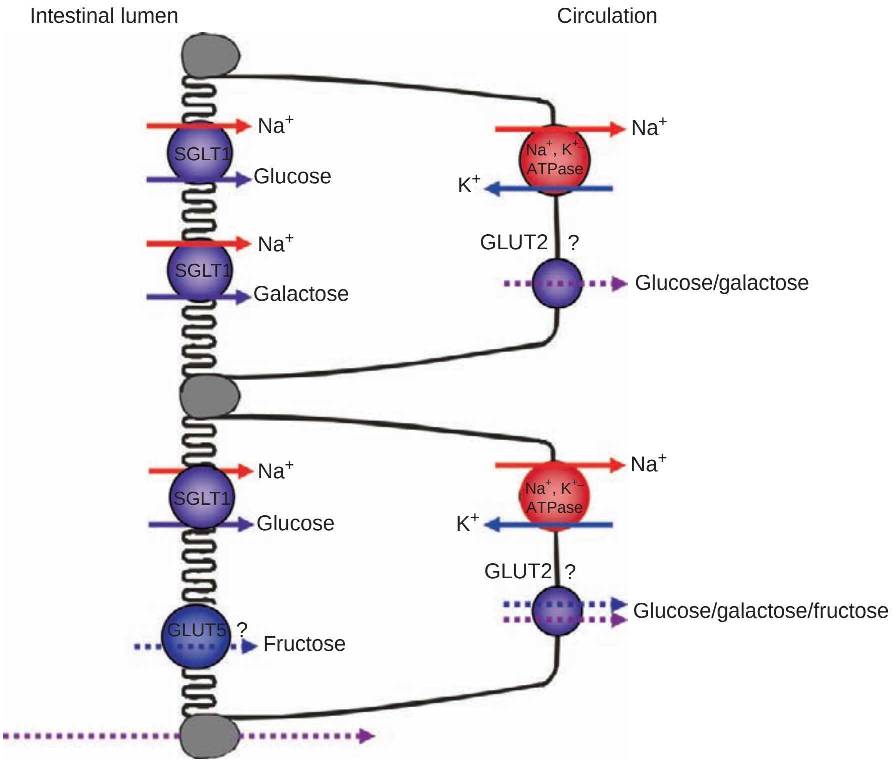

Figure 7 Probable mechanisms for absorption of monosaccharides across the intestinal epithelium of fish. SGLT, sodium-dependent glucose transporting protein; GLUT, glucose transporter.

The entry of glucose and galactose across the brush-border membrane of the fish intestine is SGLT1 driven in all species examined to date. Several members of the GLUT family, including GLUT2 and GLUT5, have been demonstrated in the intestine of several fish species, but their precise location and mechanisms are unknown. However, the mechanisms of carbohydrate absorption are believed to be very similar to those described in mammals (**Figure 7**).

Intestinal Ion and Water Transport

As stated earlier in this article, the gastrointestinal tract is a key organ not only for food digestion and nutrient uptake, but also for regulation of ion and water uptake and maintenance of homeostasis. In seawater, the intestine absorbs ions to create an osmotic gradient that in turn creates an inwardly directed water flux. The main driving force is the same as for the uptake of nutrients, that is, the Na^+ gradient created by Na^+/K^+-ATPases in the basolateral membrane. According to the present model for intestinal ion-coupled water transport, apically located $Na^+/K^+/2Cl^-$ co-transporters drive the uptake of K^+ and Cl^- against their gradients by coupling to the inwardly directed Na^+ gradient. Basolaterally located chloride (cystic fibrosis transmembrane conductance regulator (CFTR)) and potassium channels then permit these ions to flow along their electrochemical gradient into the paracellular spaces between the enterocytes. In combination with the Na^+/K^+-ATPases, which are located in the intestine mainly in the lateral parts of the basolateral membrane, with a higher density toward the tight junction area, creates an osmotic gradient. The highest osmotic concentration in the gradient faces the tight junctions and this osmotic gradient is the driving force for the inwardly directed water flux (**Figure 8**). From this perspective, the presence and possible role of aquaporins, that is, water channels, in the apical and brush-border parts of the enterocyte plasma membrane, are of greatest interest. Indeed, recent research has positively demonstrated the messenger RNA (mRNA) expression of at least four

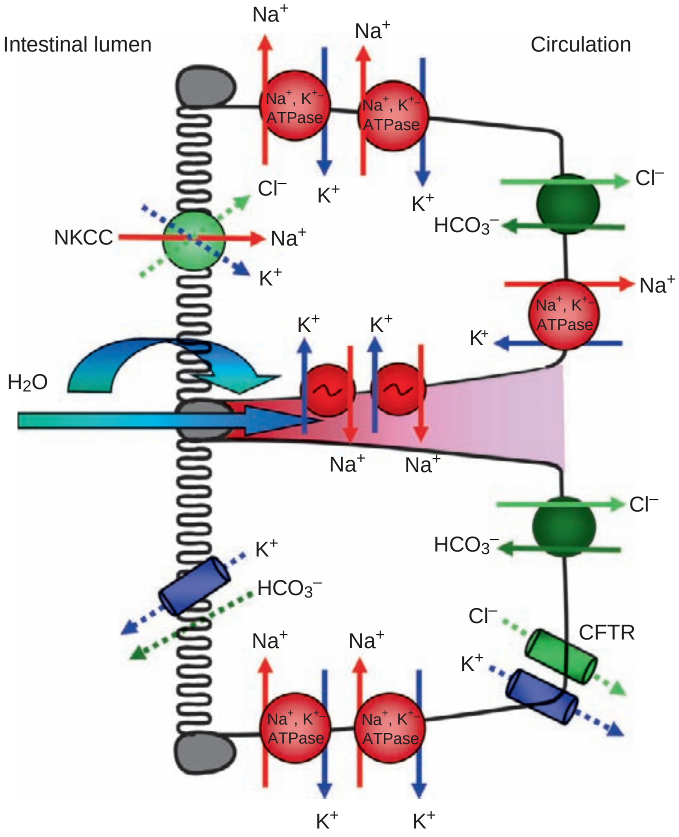

Figure 8 Mechanisms for intestinal fluid uptake. Active transport and passive flow of monovalent ions across the brush-border and basolateral membranes of intestinal cells. The ion transport creates a high salt gradient in the intercellular spaces between the intestinal cells. This gradient passively attracts water that flow across the tight junctions and/or through the cells, creating a flow of water from the intestinal lumen to the circulation. different isoforms of the aquaporin family in enterocyte plasma membranes of Atlantic salmon (*Salmo salar*), Japanese eel (*Anguilla japonica*), European eel (*A. anguilla*), sea bass (*D. labrax*), and the gilthead sea bream (*Sparus aurata*), though the exact role of these water channels in the intestinal water transport remains to be elucidated (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Water Balance and Aquaporin).

Micronutrient Absorption

In addition to monovalent ions, several divalent ions and minerals are of great importance for the physiology and performance of the fish and are thus essential for the organism. These ions are often needed in minuscule amounts, and are called 'micronutrients'. Typical micronutrients such as calcium, phosphorous, zinc, selenium, iron, copper, and iodine, as well as vitamins are necessary for the production of enzymes, hormones, and other substances essential for growth and development. Most micronutrients are absorbed by active mechanisms in the intestine but for Ca^{2+} the gills are also an important tissue with primary active transport through Ca-ATPases present in the chloride cells (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes).

Regionalization of Intestinal Absorption

Intestinal absorption starts immediately after the pyloric sphincter, in the first region of the intestine that also possesses the surface-enlarging pyloric ceca (**see also Gut Anatomy and Morphology**: Gut Anatomy). An absorption gradient is present along the length of the intestine of all fish. Water-soluble nutrients, apart from full-sized proteins, are mostly absorbed in the pyloric ceca and the midgut. Gene expression studies and protein identification methods such as immunohistochemistry have shown that the same types of membrane-bound transporters are present in the pyloric ceca as in the rest of midgut. The pyloric ceca contribute, in a surface-area-dependent way, to the absorption of AAs, di- and tripeptides, as well as monosaccharides. Thus, the more numerous and larger the pyloric ceca are, the larger the surface area and the larger the percentage of nutrient absorption that takes place in these projections. This correlates well in both carnivores and herbivores. In fish with

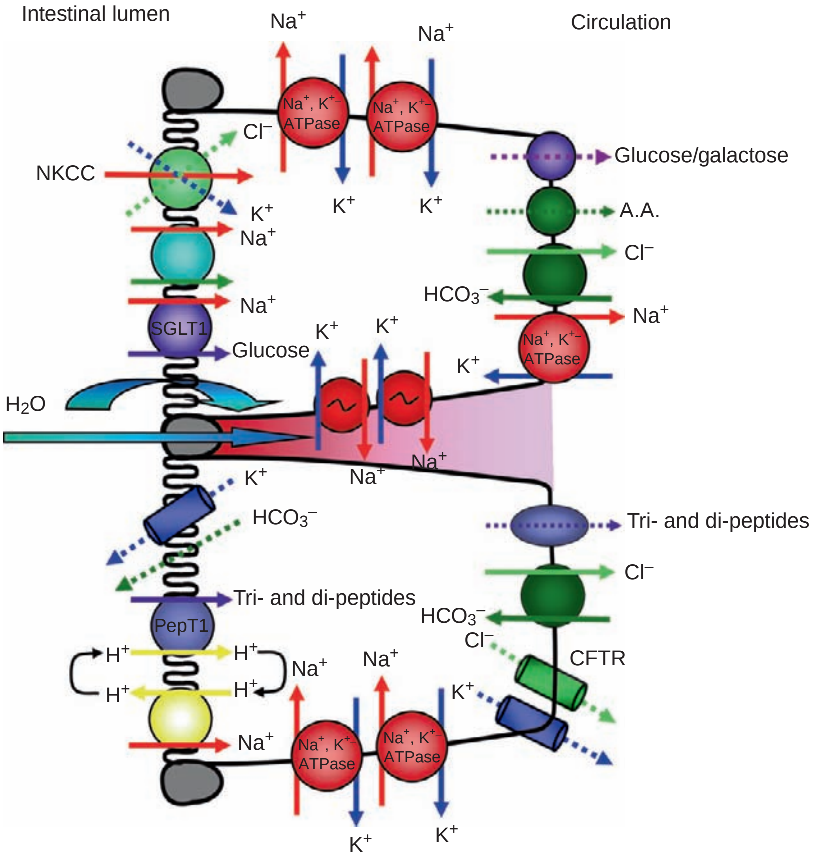

Figure 9 Summary picture describing the ion- and water-soluble nutrient-transporting mechanisms of intestinal cells.

numerous pyloric ceca, such as the salmonids, the absorption of glucose, AAs, and di- and tripeptides in this region can reach 65–80% of total nutrient absorption. Endocytotic transport of intact proteins, on the other hand, mostly occurs in the hindgut.

The absorption of fatty acids partly follows the same regional uptake pattern as water-soluble nutrients. However, there are indications of a regionalization depending on fatty acid chain length; medium-chain fatty acids are mainly absorbed in the pyloric ceca, while LCFAs are absorbed in the midgut. Furthermore, intracellular lipid droplet accumulation, which has been observed in several studies, usually takes place in the pyloric ceca and proximal parts of the intestinal tract.

In many marine species, ion and water absorption along the digestive tract starts in the esophagus. At first, water diffuses from the circulation to the esophageal lumen to dilute the high-salinity seawater, causing a major loss of water from the circulation. The diffusion of water continues to some extent in the stomach and when the ingested water enters the intestine its salinity is reduced to 30–50% of that of the ingested seawater. In other species, such as the European and Japanese eel in particular (but also in the Atlantic cod and several marine flounder species), the esophagus is only slightly permeable to water and instead there is an active uptake of Na^+ and Cl^- in this region of the gut. This reduces the flow of water from the circulation as most desalinization takes place through the active absorption of Na^+ and Cl^-.

In the intestine, Na^+ and Cl^- absorption is active; it creates the osmotic gradient that passively attracts water flux and creates an inwardly directed flow of fluid. This active ion-coupled fluid uptake is higher in the more proximal parts of the intestine. Active and passive uptake of divalent ions also takes place along the length of the intestine, but to a much lower extent than for Na^+ and Cl^-. The concentration of monovalent ions in the lumen thus falls along the intestinal axis, more rapidly at the beginning, while the concentration of several of the divalent ions increases (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation).

Concluding Remarks

The fish intestine is the unique example of the tissue with a constant trade-off between optimal capacity for osmoregulation and nutrient uptake (**Figure 9**). Increased demands for osmoregulation can reduce energy utilization for growth and performance and vice versa. A basic understanding of the physiological mechanisms underlying transport functions and of factors that influence and regulate this balance is of fundamental scientific interest. This is also important in applied aquaculture situations, where it could lead to improved food conversion ratios and energy utilization, resulting in better development, growth, and performance of the fish.

Glossary

Apical The tip of something, an apex; an apical membrane of an epithelial cell faces the outer world; in the case of the gut, it faces the lumen.

Basal The side of the epithelium (or epithelial cells) facing the circulation.

Commensal bacteria The normal nonpathogenic bacterial flora.

Enterocyte Columnar adsorptive cell of the intestinal gut epithelium.

Epithelium Relatively flat tissue (composed of one or a few cells layers) that lines cavities and surfaces in multicellular organisms.

Goblet cell A type of mucus-secreting cell in the epithelium.

Lamina propria A layer of connective tissue, vessels, and immune cells under the gut epithelium.

Microvilli Plasma membrane-bound, cellular extensions that often characterize epithelial cells. Provide for an elaboration of the surface, plasma membrane. Common, for instance, in intestinal cells (enterocytes) that absorb nutrients.

Mucosal fold Surface-enlarging structure of the epithelium, sometimes referred to as villi.

Oral tolerance The ability of the gut immune system to avoid reaction to harmless antigens.

Tight junction Protein complexes that close the space between enterocytes.

Introduction

The gastrointestinal lumen contains microorganisms, some that are pathogenic, and toxins that would kill the fish if allowed to enter the circulation. What the fish needs, therefore, is a protective barrier to keep unwanted agents out, yet minimize the interference with other intestinal epithelial functions, such as nutrient, ion, and water uptake. This article is an overview of how the multiple functional layers of barrier protect the fish and it discusses factors that can affect these functions. Most research has focused on the barrier functions of the intestine and less on the esophagus and stomach. Moreover, the research has focused on a very few teleost species, and even fewer nonteleost fish. We present a consensus view for the teleost intestine, with additional examples from other fish groups when available.

The Epithelium

The epithelium is the cell layer that marks the border between the outside (lumen) and inside (tissue) of the animal (**Figure 1**). The epithelium typically consists of a monolayer of epithelial cells linked at their apical ends by attachment proteins. The cytoskeletons of the epithelial cells are attached to adjacent cells by desmosomes and cadherins. Tight junctions keep the cell membranes of neighboring cells in close contact and reduce diffusion through the paracellular space (**Figure 2**). Despite the physical barrier for diffusion across the epithelium, numerous substances and particles can cross the epithelium. Ions and hydrophilic nutrients are generally actively taken up by membrane-bound transport proteins, while lipophilic substances diffuse passively over cell membranes. Small hydrophilic molecules diffuse across the epithelium via the paracellular route, that is, through tight junctions and the paracellular space. Larger hydrophilic molecules, particles, bacteria, and viruses are mainly transported by active transcytosis (endocytosis at the apical membrane and exocytosis at the basolateral) through epithelial cells (**Figure 2**), because they are too large to pass through tight-junction pores.

The Intestinal Barrier

The intestinal epithelial barrier can be divided into the extrinsic, intrinsic, and immunological barriers.

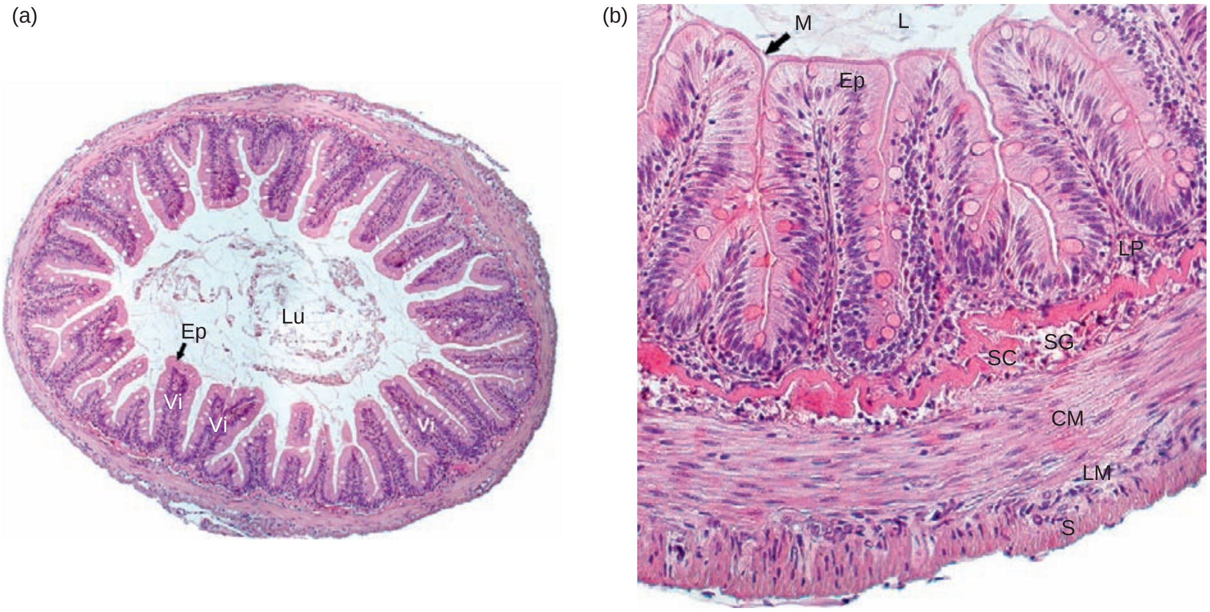

Figure 1 (a, b) Cross section of the proximal intestine in Atlantic salmon (*Salmo salar*) stained with eosin–hematoxylin. Note the numerous mucosal folds (villi) (Vi), lumen with luminal contents (Lu) and the epithelium (Ep) lining the mucosal folds. (b) Mucus (M), stratum compactum (SC), stratum granulosum (SG) with mast cells, circular muscle (CM), longitudinal muscle (LM), and serosa (S). Per Fahlberg and F. Jutfelt.

Extrinsic Barrier

Pathogens entering the gut face a number of obstacles. In the stomach, hydrochloric acid is secreted, killing most microorganisms that enter the gut. In the fish intestinal lumen, commensal bacteria numbering roughly 10^5–10^8 cells ml^{-1} (compared to 10^{12} in mammals) inhabit every ecological niche and reduce the growth of pathogenic bacteria by competing for nutrients and microhabitat resources. Commensals also inhibit the growth of other microorganisms, including pathogens, by secreting bactericidal substances, such as peptide bacteriocins, hydrogen peroxide, and lactic acid. The host tolerates commensal bacteria for their role in protection against pathogens and possible nutritional benefits using regulated interactions with the immune system. However, if the epithelial barriers fail, opportunistic commensal microorganisms infect the host.

The epithelium also has its own secretions to counter pathogens and toxins. Mucus, a viscous fluid containing mucin glycoproteins, is secreted by goblet cells (**Figure 3**). The continuous flow of mucus from the epithelium into the lumen physically removes harmful agents from the epithelium as well as protects the epithelium from mechanical wear. The mucins contain mimics of cell surface receptors to which bacterial adhesion factors attach, after which the bacteria are transported with the flow of mucus away from the epithelium. Viruses, however, are not blocked, but can diffuse through the mucus gel. Antimicrobial factors, such as antimicrobial peptides, reactive oxygen species, and hydrogen peroxide, are secreted into the lumen along with the mucus. Intestinal goblet cells contain antibacterial peptides, at least in some fish species, suggesting that the epithelial surface can be additionally protected by these peptides (**see also The Skin:** Hagfish Slime).

Intrinsic Barrier

The intrinsic barrier is the primary physical barrier between the self and the nonself, keeping the luminal and interstitial fluids separate. The intrinsic barrier consists of epithelial cells and cell junctions (**Figures 4** and **5**). In the esophagus, the epithelium can be mono- or multilayered, depending on the species, while the stomach and intestinal epithelia are monolayered. The epithelium is attached at its basal side to the basement membrane (**Figure 2**), a multilayered collagenous structure that may form a partial barrier for large particles that have crossed the epithelium.

The cells of the intestinal epithelium comprise mainly columnar absorptive cells (enterocytes), as well as goblet cells, endocrine cells and immune cells (e.g., macrophages, neutrophils, lymphocytes, natural killer (NK)-like cells, and rodlet cells) (**Figures 3** and **6**). On the apical membrane, the enterocytes have surface-enlarging microvilli, which are covered in glycocalyx (glycoproteins). In the African lungfish (*Protopterus aethiopicus*), the intestinal epithelium also contains ciliated cells. Intestinal epithelial cilia are absent in most vertebrate groups, and the function of these cells in the lungfish epithelium remains unknown. As an interesting side note, the appearance of intestinal cilia is a pathological condition in humans.

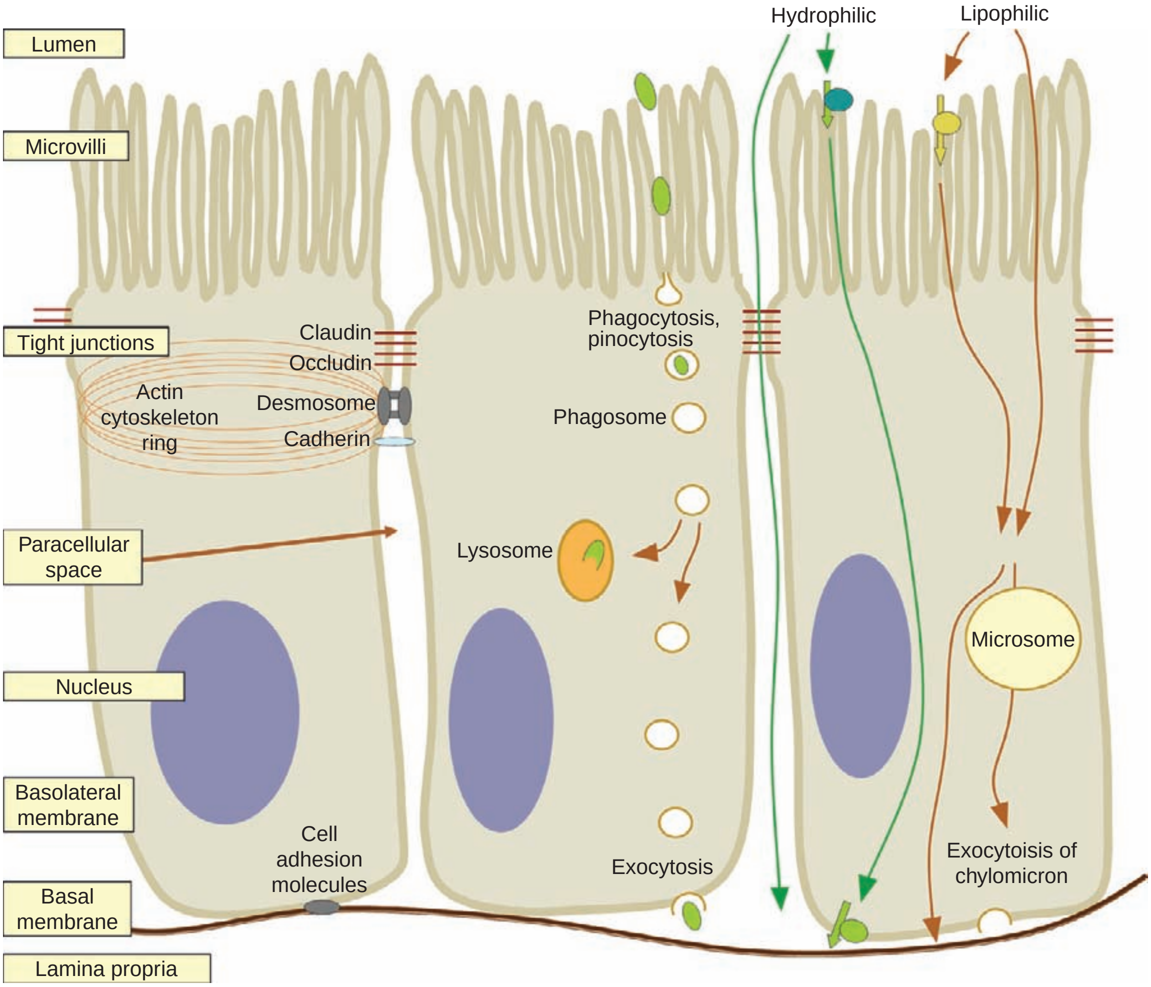

Figure 2 Schematic drawing of three enterocytes. (a) The morphology of an enterocyte, the nomenclature used in the present article, and the attachment protein complexes. (b) Endocytosis and exocytosis of macromolecules/particles and lysosomal digestion in an enterocyte. (c) Routes of transport across the epithelium for lipophilic and hydrophilic substances: the paracellular diffusion, transporter mediated, transcellular transport of both hydro and lipophilic substances, and cross-membrane diffusion of lipophilic molecules. Lipid nutrients can be modified in microsomes before exocytosis. From Jutfelt F (2006) The Intestinal Epithelium of Salmonids: Transepithelial Transport, Barrier Function and Bacterial Interactions. PhD Thesis, University of Gothenburg, Sweden.

The tight-junction protein complexes, where occludin and claudins form the extracellular domains, act as the main diffusion barrier between the epithelial cells (**Figures** 2 and 5). The pore sizes between the protein strands allow only small molecules through and the protein regions exposed to the lumen are negatively charged, leading to cation selectivity. The tight-junction permeability is regulated and is modified according to the current needs of the fish. There are also long-term changes taking place during the development of the fish, such as the tightening of the paracellular barrier when salmonids become smolts in preparation for seawater migration.

Paracellular permeability of the epithelium is often quantified by passive diffusion of small hydrophilic marker molecules through tight junctions, while transcellular permeability is measured by lipophilic molecules diffusing over both the apical and basolateral membranes. Transcellular diffusion of lipophilic substances can be modified by alterations of the membrane lipid composition, such as those seen after a change in diet. Larger hydrophilic molecules, particles, bacteria, and viruses are probably transported through active transcytosis through epithelial cells, as they are too large for tight-junction pores. An epithelium can thus have different permeabilities, depending upon which marker is used. This is often reflected by epithelia with a strong barrier for one molecular size and lower barrier for molecule or particle of another size (**see also Temperature:** Membranes and Temperature: Homeoviscous Adaptation).

Immunological Barrier

Although the extrinsic and intrinsic barriers offer effective protection, the exclusion of harmful agents is never absolute. Therefore, an additional immunological

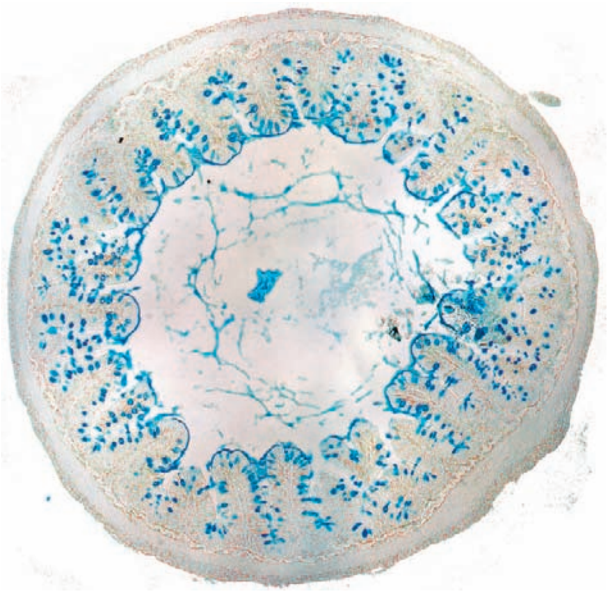

Figure 3 Cross section of the proximal intestine in Atlantic salmon stained for mucus. The mucus (blue) is visible inside goblet cells and as a layer of secreted mucus covering the mucosal folds and filling the spaces between mucosal folds. Per Fahlberg and F. Jutfelt.

barrier is required. Both the innate immune system (e.g., macrophages, neutrophils, and mast-like cells) and the adaptive immune system (the B- and T-cell-like lymphocytes) are present in the intestinal wall. The epithelium and the lamina propria contain phagocytotic cells (e.g., macrophages and neutrophils), which phagocytose and digest harmful agents that have crossed the epithelium (**Figure 6** (**see also Cellular, Molecular, Genomics, and Biomedical Approaches:** Molecular Fish Pathology)).

Enterocytes actively sample luminal contents through endocytosis and release particles and antigens at the basal membrane. Such transcytosis has been demonstrated in several fish classes, including lampreys, sharks and rays, sturgeons, and many teleosts. In teleosts, antigen sampling, processing, and presentation to lymphocytes have speculatively been suggested to occur within the epithelium, lamina propria, and stratum granulosum (**Figure 1**), possibly performed by cells such as macrophages, neutrophils, and/or by the enterocytes themselves. The purpose for this sampling of molecules, particles, and live microorganisms has been suggested to be early detection of pathogens and subsequent production of antibodies (immunoglobulins (Igs)) against the pathogens. The other important role of immune sampling of luminal content is induction of oral tolerance to harmless antigens in order to avoid unnecessary immune stimulation. In other words, this sampling process functions to fine-tune the immune system to the current need.

The intestinal immune system can, after exposure to a luminal antigen, induce a systemic increase in antibodies against the antigen that may confer protection in subsequent exposures. In mammals, antibodies are also secreted into the lumen for protection against microorganisms. Teleost skin mucus contains IgM as a part of the skin barrier function, but the importance of secreted Igs in the intestinal lumen of fish has not been demonstrated conclusively. IgM is present in the intestinal mucosal fold, but has low resistance against proteolytic degradation, which could lead to rapid inactivation if secreted into the intestinal lumen.

Harmful organisms are detected by toll-like receptors (TLRs). When TLRs are stimulated, possibly together with danger signals (other receptors for detecting tissue damage), cytokines mediate an inflammation signal that

activates and attracts cells of the immune system. Such mobilization of neutrophils into the epithelium and mast-like cells into the stratum granulosum has been shown in several teleosts, demonstrating the plasticity of the immunological barrier.

The Barrier Function of Different Intestinal Regions

The gastrointestinal tract is functionally and morphologically divided into distinct regions in most fish groups, and the barrier function varies between the regions. As the uptake function of the esophagus and the stomach is small (European eel, *Anguilla anguilla*, is one exception), the barrier can be strong without interfering with transport. In the absorbing parts of the gut, there are also large differences in barrier function between regions.

In teleosts, the pyloric ceca and anterior intestine are the main nutrient-absorbing regions. They contain similar luminal contents and perform the same nutrient and ion transports, and thus have similar barrier properties (**Figure 7**). The lumen in these regions contains high nutrient concentrations, typically relatively low numbers of bacteria, and high paracellular permeability.

In the posterior intestine, however, bacterial numbers are higher and free nutrient concentrations drop. Here, the diffusion of hydrophilic molecules across the epithelium is low, as measured per cm^2 of the intestinal wall, in the species examined (including salmonids, sea bass, sculpins, and Atlantic cod). This could be caused not only by smaller pore sizes or fewer pores in the tight junctions, but also due to a lower epithelial area because of differences in folding between regions. As the nutrient concentration drops along the intestinal tract and bacteria and bacterial toxins rise in concentration, the need for a tighter barrier increases.

The low tight-junction permeability of the posterior regions could also serve the function of enhancing water extraction by lowering the leakage of Na^+ from the epithelial paracellular space back into the lumen. Particle and macromolecular transport in the posterior region, on the other hand, is high, at least in salmonids. This can be visualized in transmission electron micrographs (TEMs) (**Figure 8**) and in fluorescence micrographs (**Figure 9**).

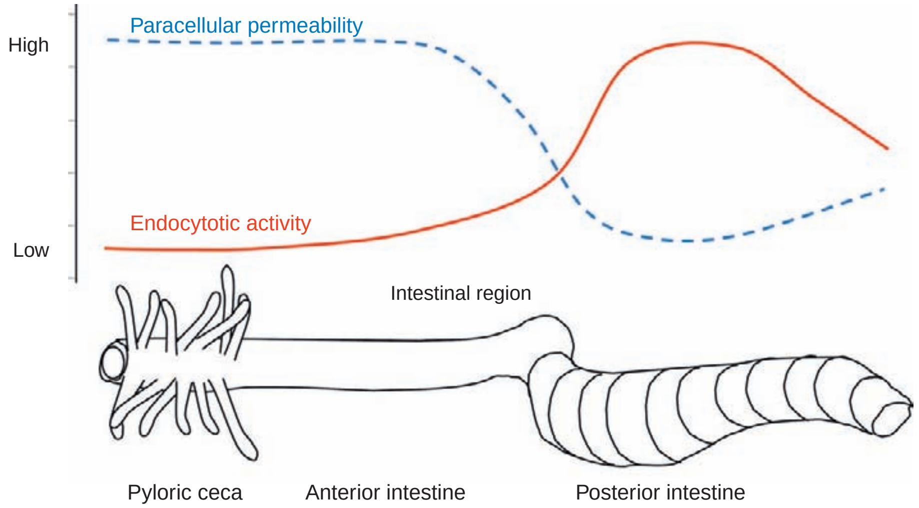

Figure 7 Epithelial barrier function of the regions of the rainbow trout (*Oncorhynchus mykiss*) intestine. The data are from *in vitro* using chamber measurements.

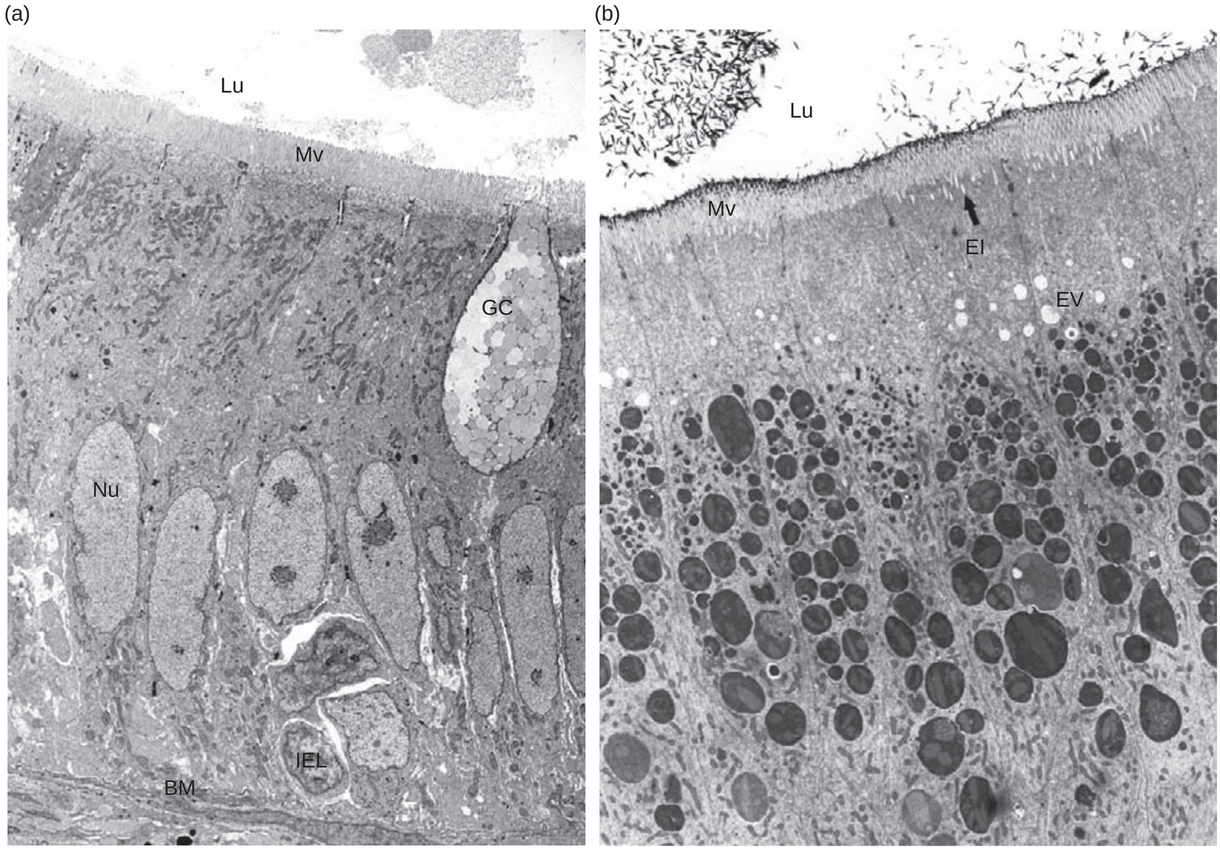

Figure 8 Transmission electron micrograph (TEM) of the epithelium in the anterior (a) and posterior (b) regions of the Atlantic salmon (*Salmo salar*) intestine. (a) Note the intraepithelial lymphocyte (IEL) in close contact with two other intraepithelial cells, possibly neutrophils or macrophages. GC, goblet cell; MV, microvilli; Lu, lumen; BM, basement membrane. Courtesy of Olsen R, Ringø E, and Myklebust R.

In many fish larvae, and probably adults of some species, particle transport is of nutritional importance.

Another suggested reason for high endocytotic activity is the more active sampling of antigen by the immune system in the posterior intestine, both for detection of pathogens and for induction of oral tolerance to harmless antigens. The rectum has low permeability and low active transport.

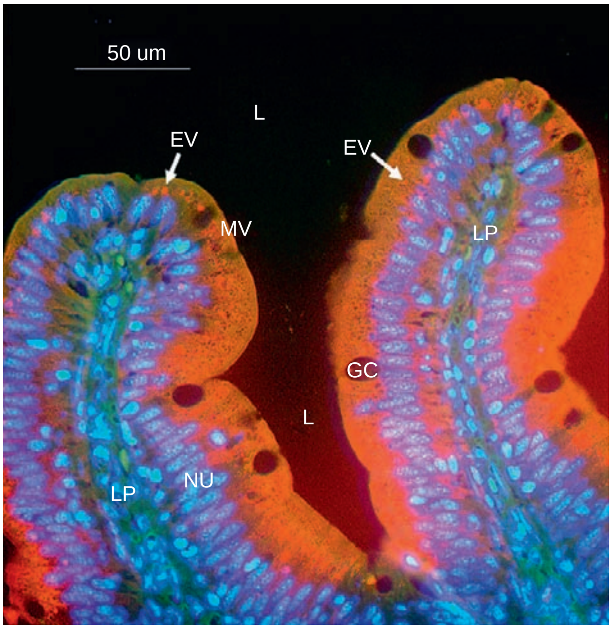

Figure 9 A micrograph showing macromolecular uptake by the intestinal epithelium in brown trout (*Salmo trutta*) parr visualized by the use of Texas-red-labeled albumin using a triple fluorescence filter. The absorbed albumin is seen as red vesicles in the apical half of the enterocytes (arrows), while DAPI-stained cell nuclei are seen in blue and general tissue fluorescence as green. L, lumen; MV, microvilli; NU, nucleus; GC, goblet cell; LP, lamina propria; EV, endocytotic vesicle. Lars Sonesson and F. Jutfelt.

Translocation of Pathogens across the Barriers

An infectious pathogen can enter the fish through the skin, gills, or the gut. The quantitative relevance of these routes has not been measured for any fish pathogen, but both bacteria and viruses can translocate through the intestinal epithelium and infect the host. The pathogen can cross the epithelial barriers in several ways: paracellularly through tight junctions, transcellularly through transcytosis or the cytoplasm (without a vesicle), or through damaged areas of the epithelium. All of these routes are used by different pathogens infecting mammals through the gastrointestinal tract, but less is known for fish pathogens.

Bacteria

Vibrio anguillarium and *Aeromonas salmonicida* are Gram-negative bacteria that can cross the epithelium through transcytosis (**Figures 10** and **11**). Both are pathogenic to several fish species. In addition, both pathogens cause desquamation (shedding of epithelia). This not only could be caused by direct damage from bacterial toxins, but may also be a defense strategy by the fish to expel infected cells. A model for breaching the intestinal barrier by *A. salmonicida* has been proposed (**Figure 11**), where the final result is disruption of the epithelium as well as translocation of the bacteria into the circulation.

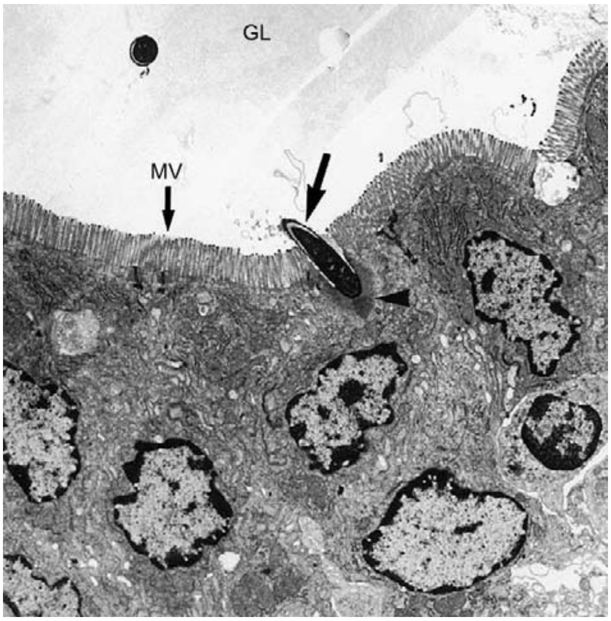

Figure 10 Transmission electron micrograph (TEM) micrograph of the epithelium of a pyloric cecum in Atlantic salmon (*Salmo salar*). The large arrow points at a rod-like cell, partially internalized into an enterocyte. The microorganism was likely a very large bacterial cell. An electron dense area (arrowhead) of the cytoplasm is surrounding the invagination, possibly comprising proteins involved in the internalization process. MV, microvilli. Modified from Ringø E, Olsen RE, Mayhew TM, and Myklebust R (2003) Electron microscopy of the intestinal microflora of fish. *Aquaculture* 227: 395–415.

Virus

Viruses can enter fish through the intestinal route. In Atlantic salmon, the pathogenic infectious pancreatic necrosis (IPN) virus is found in the intestinal epithelium in early stages of infection. IPN virus can cross the intestinal epithelium and enter the circulation *in vitro* with maintained virulence. This demonstrates both the actual crossing of the extrinsic and intrinsic barriers of the epithelium, as well as the failure of the immune system to neutralize translocated virions in the lamina propria. In addition, the epithelial permeability is increased, while the ion-transporting capacity is decreased after 1 h of the virus in the lumen. This implies that the epithelium either is damaged or reacts rapidly to the pathogen.

During IPN-virus infections in Atlantic salmon *in vivo*, the intestinal epithelial barrier function can be severely decreased, leading to increased translocation of bacteria. It is possible that the failure of the intestinal barrier is the main cause of death by IPN virus.

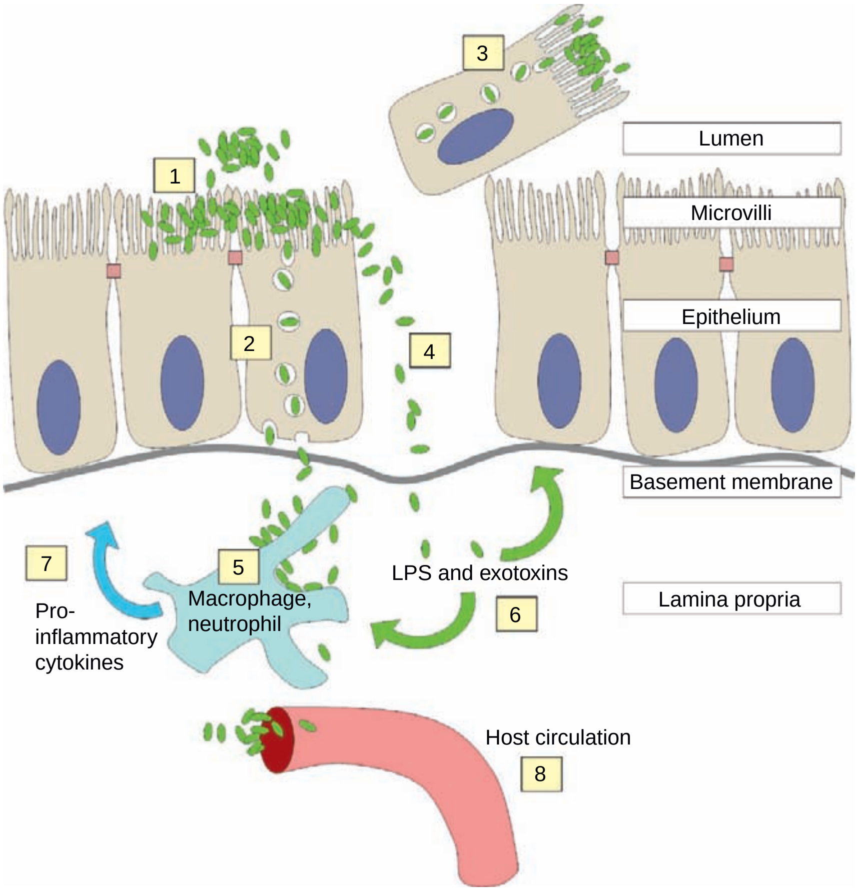

Figure 11 Suggested model for translocation of *A. salmonicida* across the intestinal epithelium in salmonids. (1) Attachment of *A. salmonicida*; secreted exotoxins negatively affect the transepithelial ion fluxes. (2) Transcellular transport. (3) Shedding of enterocytes creates holes in the epithelium. Bacterial extracellular proteases may be involved in the detachment. Apoptotic or necrotic processes may also cause shedding. (4) Entry of bacteria through damaged epithelium. (5) Bacteria have mechanisms for counteracting the innate immune system. (6) Lipopolysaccharides (LPSs) and other bacterial substances are detected by mucosal cells that release cytokines, leading to decreased barrier function. Exotoxins cause tissue damage directly. (7) Cytokines may cause inflammation, increase bacterial translocation, and induce apoptosis. (8) Entry of bacteria into the intestinal vascular system. Extracellular toxins cause host symptoms and death.

The Barrier in Stress and Disease

Disturbances to the general homeostasis of the fish, as with other physiological systems, can affect the intestinal barrier. Many types of stressors weaken the epithelial barrier function. In European eel, the stomach epithelium shows reduced surface area and increased paracellular space in response to social stress. Acute stress also increases the paracellular permeability in salmonids and Atlantic cod. This effect is stronger in fasting fish, demonstrating that the ability of the epithelium to cope during stress is reduced in food-deprived fish. The effect of stress on the epithelium could stem from reduced blood flow to the gut, ultimately resulting in ischemia and tissue damage. However, such serious barrier malfunction would probably cause sepsis and mortality, which usually does not happen. Cortisol, which is released during acute stress, may have a direct effect on the epithelial barrier by increasing tight-junction permeability as well as directly modulating ion transport.

Chronic stress can also lead to a disturbed barrier. Many long-term stressors, including water hyperoxia and hypoxia, suboptimal water temperature, suboptimal diet composition, fasting, starvation, and infection, can impair intestinal barrier functions (**Figure 12**). The reduction in barrier function is significant even in low-intensity long-term stress, when other stress and welfare parameters may fail to detect changes. In fact, the paracellular permeability has been suggested as a new and reliable indicator for chronic stress. Reliable physiological or biochemical indicators for chronic stress have been elusive.

The inclusion of vegetable ingredients in some diets reduces the integrity of the intestinal barrier in carnivorous Atlantic salmon. Vegetable lipids can cause lipid accumulation within the enterocytes to

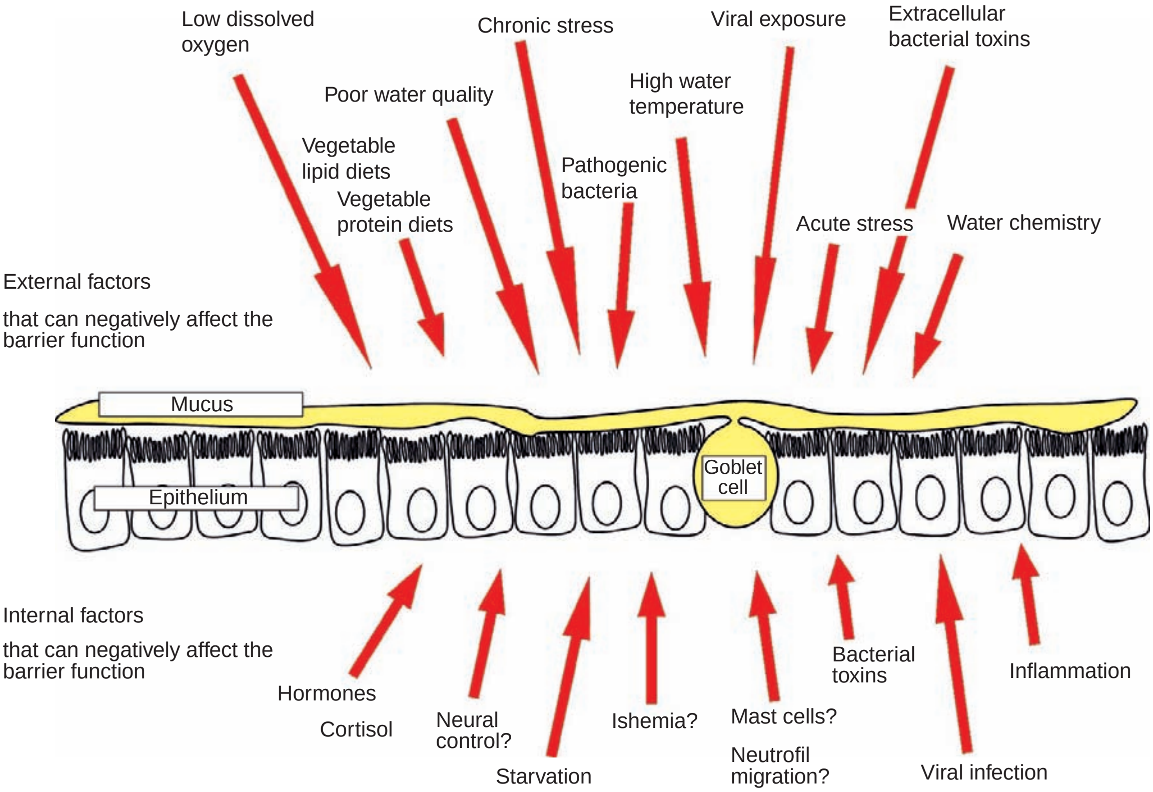

Figure 12 Summary of known and suspected factors that disrupt the integrity of the intestinal epithelium and reduce the barrier function.

such an extent that the cells rupture, causing mild barrier dysfunction. Vegetable proteins in the diet, especially soybean meal, can cause inflammation in the posterior intestine and increase the permeability of the epithelium by a factor of 2–5. The increased permeability is caused by saponins, the amphiphilic-membrane-disturbing molecules in the soybean, increasing the amount of antigens that cross the epithelium, and, in turn, initiate the inflammation. Furthermore, inflammation *per se* can cause even stronger reductions in barrier function, as discussed above.

Does a reduced intestinal epithelial barrier function lead to disease? In mammals, increased epithelial permeability causes many diseases and infections. Similarly, in fish, disease can arise from increased permeability. Soybean-meal-induced barrier dysfunction can cause enteritis, as discussed above, as well as mucosal cancer. There can also be an increased risk of infection by pathogens whenever the barrier function is compromised, regardless of the underlying reason. Fish can be chronic carriers of pathogenic bacteria in the lumen for long periods without showing clinical symptoms, yet, when the fish are subjected to acute stress, the pathogen is able to infect the fish. A plausible explanation is increased translocation through the intestinal epithelium. However, it can also be a change in the immune system that allows the bacteria to survive and proliferate after translocation.

Species Differences

Given the large number of fish species and environments to which they are adapted, the variations in barrier function strategies are probably large. Most research on the intestinal barrier function has been performed on a few species, including salmonids, cod, cyprinids, European eel, sculpins, seabass, and hammerhead shark; hence, the interspecies variation is not well described. As the contents of the intestinal lumen of fish from different environments differ immensely in aspects, such as salinity, pH, temperature, toxins, oxygen concentration, nutrient composition, composition of microorganisms, and exposure to pathogens in the lumen, the barrier strategies used by the different species can potentially provide information on how these factors are handled. They could even be considered as model organisms for research on human medical conditions.

Several aspects of the barrier function in mammals first appeared in fish; allowing us to trace the evolutionary origin of certain mechanisms. For example, mucosal lymphoid nodes, such as Peyer's patches in mammals and bursa of Fabricius in birds, are usually not considered to have appeared before the tetrapods; however, based on histological examinations, the American paddlefish (*Polyodon spathula*) have structures resembling Peyer's patches. However, the physiology of these structures has not been investigated. Sharks can also have lymphoid aggregations in the spiral valve that may have a function in lymphocyte maturation and antigen presentation.

Concluding Remarks

Three functional layers of barriers in the intestine contribute to maintaining homeostasis of the fish by keeping out unwanted substances and organisms. The extrinsic barrier, consisting of luminal secretions and microorganisms, inhibits growth of pathogens as well as their attachment to the epithelium. The intrinsic barrier, consisting of the epithelial cells and the tight junctions, is the main physical barrier that marks the border between the self and the nonself. The immunological barrier is needed to neutralize harmful agents from crossing the aforementioned barriers. In addition, the immune system of the intestine samples the luminal contents for modulation of immune responses.

Most aspects of barrier function are actively controlled. Increase in mucus production and infiltration of immune cells occur when the epithelium senses pathogens or tissue damage. The barrier function is disturbed by factors, such as suboptimal water temperature, hypoxia, low water quality, suboptimal diet, acute and chronic stress, exposure to pathogens, and starvation. This is of great importance for research on health and welfare of fish, disease transmission, vaccination, husbandry conditions in aquaculture, water transport mechanisms, as well as for the general understanding of fish physiology in health and disease.

Glossary

Autonomic nervous system A collection of motor neurons (ganglia) ordered segmentally from cranial to caudal levels. The system controls the inner organs (viscera) through reflexes without conscious control.

Cranial autonomic nerve Autonomic nerve starting in the cranial (head) region of the CNS.

Enteric nerve The nerve that is intrinsic to the gut; the cell body is contained within the gut wall.

Enteric nervous system The part of the autonomic nervous system contained within the gastrointestinal wall.

Extrinsic innervation Innervation that comes from outside the organ. A nerve that is extrinsic to the gut has its cell body outside the gut, but sends its axon to the gut.

Ganglion A collection of nerve cell bodies of similar function. A ganglion is a type of nucleus but often refers to structures in the peripheral nervous system. An exception is the basal ganglia that are nuclei of the telencephalic subpallium.

Glial cells Cells surrounding nerve cells that provide support and nourishment.

Nerve plexus A network of branching nerve fibers in or between tissue layers.

Spinal autonomic nerve Autonomic nerve initiating from the spinal cord region of the CNS.

Autonomic Nerves Innervate the Gut

Nerves control many processes in the gut, such as secretion of digestive juices and mixing and propulsion of food. Gut nerves are part of the involuntary autonomic nervous system (ANS). The innervation of the fish gut is dense and, as in all vertebrates, uses a large number of different neurotransmitters for signaling. Indeed, the nervous system of the gut functions as a small local brain: the nerves form elaborate, interacting reflex pathways, comprising sensory mechanisms, networks of relaying interneurons, and final motor or secreto-motoneurons.

A large division of the innervation of the gut is intrinsic, that is, the nerve cells are located entirely within the gastrointestinal wall. This enteric nervous system (ENS) is, to a large extent, capable of an adequate control of the gut on its own. The gut is also innervated by extrinsic autonomic nerves. These have their nerve cell bodies outside the gut, either in the central nervous system (CNS) or in ganglia (aggregation of cell bodies) along the nerves to the gut, and send their axons to the gut in the extrinsic nerves. The extrinsic innervation plays important roles in coordinating gut activity and relaying information, for example, about hunger and pain to the CNS.

This article outlines the similarities and differences in the anatomy of the gut innervation and the occurrence of different transmitters between different fish groups and in comparison to other vertebrates.

Anatomy of the Gut Nervous System

The general anatomy of the gut nervous system is very similar in all vertebrates, but fish deviate from the general plan in some features, either as a group or as individual species. This mainly is due to differences in general anatomy, such as the lack of a stomach, which is a common feature in many fish families, or the presence of pyloric ceca (**see also Gut Anatomy and Morphology**: Gut Anatomy).

The Gut Nervous System is Well Developed

The vertebrate ENS on average contains similar numbers of nerve cells as the spinal cord, and also contains enteric glial cells, surrounding the enteric neurons. Judging from the few (teleost) fish studies where the number of neurons in the ENS has been calculated, the overall density of nerve cell bodies in the teleost gut is similar to that in small mammals like mice and guinea pig.

In fish, the majority of the enteric nerve cell bodies is located in the myenteric plexus, between the longitudinal

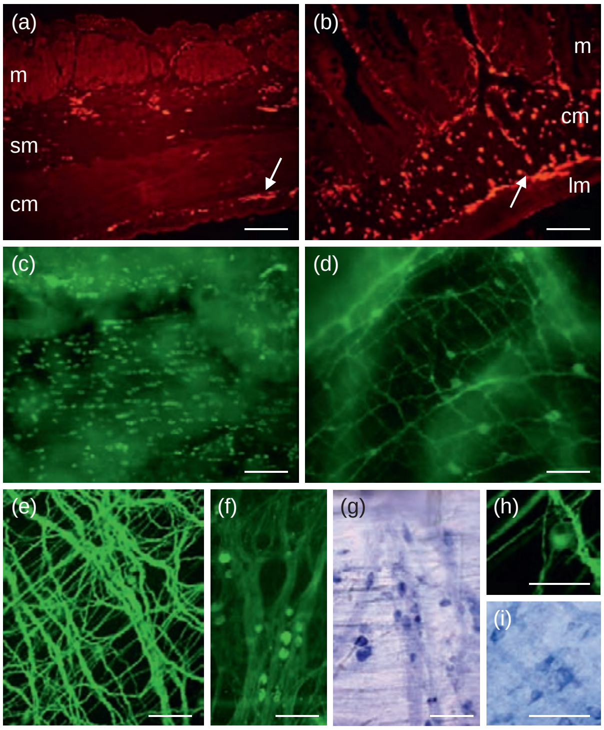

Figure 1 Innervation of the gut wall in shorthorn sculpin (*Myoxocephalus scorpius*) (a,b, e,f, h), zebrafish (*Danio rerio*) (c,d) and Atlantic cod (*Gadus morhua*) (g, i) demonstrated using a mixture of antibodies against human neuronal protein (Hu) and acetylated tubulin (AcT) (a,b, c–f, h), Hu alone (c) or NADH-diaphorase staining (g, b). (a) Nerve fibers in the myenteric plexus (arrow) of the cardiac stomach. (b) Dense innervation of the myenteric plexus (arrow), circular muscle layer and mucosa of the proximal intestine. (c–i) Whole mounts of the intestinal myenteric plexus showing nerve cell bodies and nerve fibers. m, mucosa; sm, submucosa; cm, circular muscle layer; lm, longitudinal muscle layer. Scale = 50 μm (d, h), 100 μm (b, c, e–g, i), 200 μm (a).

and circular muscle layers (**Figures 1(a)** and **1(b)**); (**see also Gut Anatomy and Morphology**: Gut Anatomy). In general, the submucous plexus found in other vertebrates is either missing in fish or limited to a few scattered cell bodies. The enteric nerve cell bodies in fish typically occur singly or as two to three cells together, scattered over the myenteric plexus (**Figures 1(c)–1(g)**), rather than forming ganglia of several cells as in tetrapods. In general, there seem to be more nerve cell bodies per surface area in the intestine than in the stomach.

The size of the enteric nerve cell bodies is also in the same range as for mammals of similar body mass. The diameter of the cell bodies range from 10 to 100 μm in fish such as brown trout (*Salmo trutta*) and Atlantic cod (*Gadus morhua*) with the majority of cells being around 15–20 μm. In smaller species such as zebrafish (*Danio rerio*), the nerve cells are generally smaller (**Figures 1(c)** and **1(d)**). Fish enteric neurons seem to be more uniform than mammalian neurons; the majority of cells have a smooth cell body and most often appear to have only one (long) process (**Figures 1(f)–1(h)**). However, cells similar to the two dominating cell types present in mammals, Dogiel type I (cells with flattened dendrites and one axon) and Dogiel type II (smooth multipolar cells), are found in cyclostomes and some elasmobranch and teleost species. In mammals, the different morphologies correspond to different functions, but this has not been established in fish.

The axons of enteric neurons form a network of smaller and larger nerve bundles, which connect neurons within the myenteric plexus, and innervate muscle, glands, and blood vessels. With the exception of cyclostomes (and in particular, myxinoids), this network is well developed among fish. The axons are predominantly varicose, with the ability to release transmitter substances along their entire length.

Extrinsic Nerves from the CNS Coordinate

Except in cyclostomes, extrinsic nerves reach all parts of the gastrointestinal tract and its associated organs such as the pancreas and gallbladder. The axons form either autonomic nerves transmitting impulses from the CNS to the gut, or sensory nerves transmitting impulses in the other direction, from the gut to CNS. The extrinsic innervation includes both cranial and spinal nerves, but fish generally lack the concentrated outflow of fibers in the sacral/pelvic region that is common in tetrapods (**Figures 2** and **3**).

The cranial autonomic fibers (also called parasympathetic fibers) to the gut run mainly in the visceral branches of the paired vagus nerve. In elasmobranchs, they may also be found in the facial and glossopharyngeal nerves (**Figure 2**). A cranial autonomic pathway has a preganglionic neuron with the cell body in the brainstem. This synapses with a postganglionic neuron either somewhere along the vagus nerve or within the gut wall. In most fish species, the vagal innervation reaches the esophagus, stomach, and proximal intestine. However, in some species, vagal fibers innervate the esophagus only, while in others they may reach far back along the intestine.

The splanchnic nerves to the gut are part of the spinal autonomic system (also called the sympathetic system). Spinal autonomic pathways consist of a preganglionic neuron with its cell body in the spinal cord, connecting to a postganglionic neuron with, in fish, its cell body in the sympathetic chain ganglia just outside the spinal cord. Postganglionic axons run in the splanchnic nerves to the gut.

The number of splanchnic nerves and the distribution of the spinal autonomic innervation vary among fish. In cyclostomes, the innervation mainly reaches the hindgut. In most elasmobranchs, there are several splanchnic nerves to the gut (**Figure 2**). The anterior pair innervates the posterior stomach and anterior intestine. The most anterior outflow of spinal fibers often joins the vagus, forming a vago-sympathetic trunk running to the gut. A varying number of mid- and posterior splanchnic

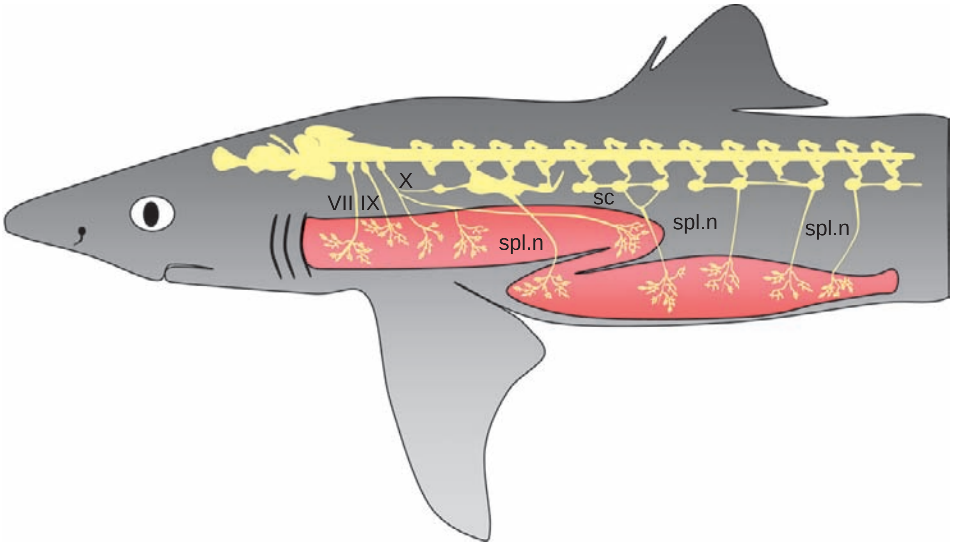

Figure 2 Schematic picture of the extrinsic autonomic innervation of the gut in an elasmobranch. Cranial outflow (parasympathetic nerves) is via cranial nerves X (vagus) and to some extent IX (glossopharyngeal) and VII (facial). Spinal (sympathetic) pathways synapse in ganglia in the sympathetic chain (sc) and then run in a number of splanchnic nerves (spl. n) to the gut. Courtesy of Albin Gräns, redrawn from Nilsson S (1983) *Autonomic Nerve Function in the Vertebrates*. Berlin: Springer.

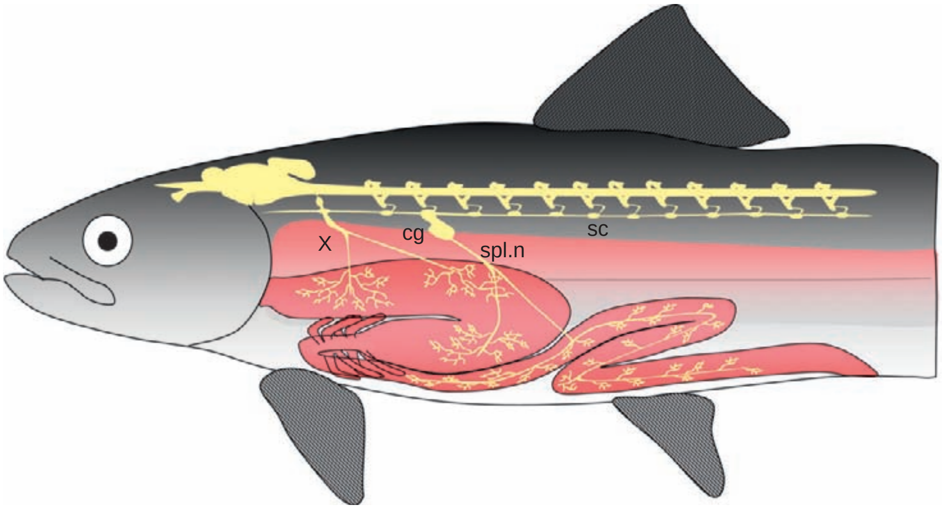

Figure 3 Schematic picture of the extrinsic autonomic innervation of the gut in a teleost. Cranial outflow (parasympathetic nerves) is via cranial nerves X (vagus). Spinal (sympathetic) pathways synapse in the large celiac ganglion (cg) in the sympathetic chain (sc) and then run in the splanchnic nerve (spl. n) to the gut. Courtesy of Albin Gräns, redrawn from Nilsson S (1983) *Autonomic Nerve Function in the Vertebrates*. Berlin: Springer.

nerves innervate the spiral intestine and rectum. In teleosts, the anterior splanchnic nerve divides into several branches, innervating the posterior stomach and most of the intestine (**Figure 3**). In addition, in teleosts, as in elasmobranchs, spinal fibers enter the gut via the vagi.

The vagi and the splanchnic nerves also contain a large number of sensory fibers. Vagal sensory fibers usually have their cell bodies gathered in a nodose ganglion somewhere along the vagus. Splanchnic sensory fibers have their cell bodies in the dorsal root ganglia of the spinal cord.

Neurotransmitters and Their Receptors

The effect of a nerve cell may be either inhibitory or excitatory, depending on the transmitter(s) it releases and the type of receptors and second messenger systems present on/in the target cell. Immunohistochemistry has revealed a large number of neurotransmitters in fish gut nerves. In several cases, the chemical structure of these transmitters is known. It appears that all transmitters present in the mammalian gut are found in a corresponding but not always identical version in fish. In addition, the relative abundance of a transmitter and its distribution along the gut may vary in comparison with mammals, as well as among different groups, families, or species of fish. Distribution and abundance of nerves expressing a certain transmitter, as well as presence of its receptors, are plastic and can change with feeding status, food type, changes in hormone levels, and in the environment. Some studies show that infections and inflammation can alter gut innervation in fish.

The most investigated signal substances that affect the performance of the gut, and their receptors are presented in the following. **Figure 4** shows the distribution of some of the best-studied transmitters in the gastrointestinal tract of shorthorn sculpin (*Myoxocephalus scorpius)* (**Appendix A** (pp. 1232–1267)).

Acetylcholine

Pharmacological and physiological studies suggest that acetylcholine dominates the control of gut functions in fish, like in mammals. However, histochemical evidence of its presence is so far only indirect. For example, the synthesizing enzyme, choline acetyl transferase (ChAT), and the transporter that moves acetylcholine into vesicles in the nerve terminal, vesicular acetylcholine transporter (VAChT), have been demonstrated in the intestine of zebrafish and Atlantic cod. Acetylcholine is proposed to be released from enteric motor- and interneurons. A large population of vagal fibers is cholinergic in most teleosts, but elasmobranchs and some teleosts appear to lack a vagal cholinergic innervation of the gut; in these species, cholinergic nerves are exclusively enteric.

Acetylcholine acts via nicotinic or muscarinic receptors. Several teleost subtypes and subunits have been sequenced, and a muscarinic M3-like subtype appears to be important in the control of gut motility in rainbow trout (*Oncorhynchus mykiss).*

Amines

Amines constitute a group of several signaling substances, including catecholamines (adrenaline, noradrenaline, and dopamine), serotonin (5-hydroxytryptamine; 5-HT), and histamine. Catecholamines and serotonin act as neurotransmitters in the fish gut.

Catecholamine-containing nerves have been demonstrated in the gut by the presence of the synthesizing enzymes, tyrosine hydroxylase (TH) or phenylethanolamine-N-methyl transferase (PNMT), or by making the catecholamines fluoresce. Fibers surround nerve cell bodies in the myenteric plexus and innervate blood vessels in the submucosa as well as major vessels to the gut. In some species, fibers are observed in the muscle layers. As in mammals, adrenergic nerve fibers are believed to be

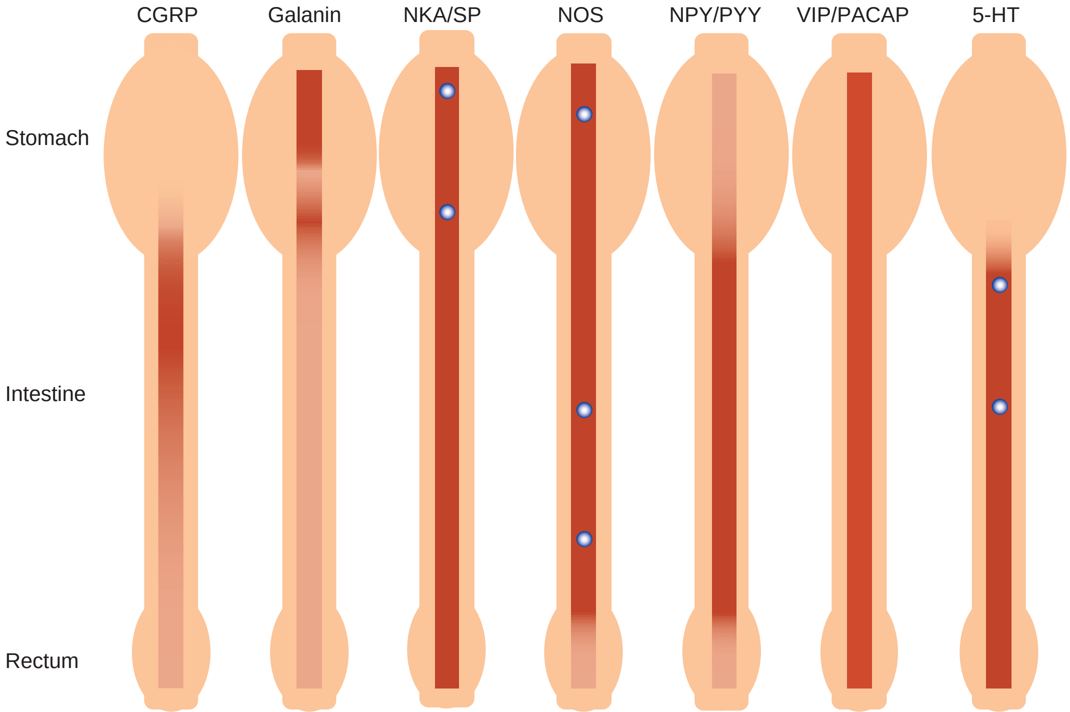

Figure 4 Schematic representation of the presence of immunoreactive material in different nerve fibers (vertical bars) and nerve cell bodies (circles) in gastrointestinal tract of a teleost, the shorthorn sculpin (*Myoxocephalus scorpius*. Based on immunohistochemical data from Holmgren S and Olsson C (2009) The neuronal and endocrine regulation of gut function. In: Bernier NJ, Van Der Kraak G, Farrell AP, and Brauner CJ (eds.) *Fish Physiology*, *Vol. 28: Fish Neuroendocrinology*, pp. 467–512. Burlington: Academic Press.

mainly extrinsic (spinal autonomic), but TH-expressing nerve cell bodies were recently found in the gut of several teleost species, suggesting an enteric subpopulation of the catecholamine nerves.

In most vertebrates, including elasmobranchs, noradrenaline is the dominant catecholamine in adrenergic neurons. However, adrenaline dominates in teleosts and holosteans. Dopamine levels are usually lower, and the release of dopamine from gut nerves in fish, although implicated in both lamprey and some teleosts, is poorly investigated.

Pharmacological experiments suggest the presence of alpha- and beta-adrenoceptor subtypes both in stomach and intestine, and an alpha-2-like receptor is found in the intestine of the Japanese eel (*Anguilla japonica*). The pharmacological properties of these fish receptors appear to differ considerably from those of corresponding mammalian receptors.

Serotonin is expressed in gut neurons or in endocrine cells of the mucosa, with strikingly different proportions between the two populations in different species. In cyclostomes, serotonin is only neuronal. In elasmobranch species, it is rarely found in nerves but commonly in endocrine cells. In sturgeons (*Chondrostei*), serotonin is found in both endocrine and nerve cells. Teleosts show large interspecies variation, from an entirely neuronal presence in some cyprinid fish, through mixed populations, to a presence in endocrine cells only in the European eel (*Anguilla anguilla*). When present, nerve cell bodies are located in the myenteric plexus, sending fibers within the plexus and to the muscle layers. At least seven classes of serotonin receptors exist and members of most of the classes have been isolated from different fish species although little is known about their distribution in the gut.

Neuropeptides

Neuropeptides are small- to medium-sized peptides, consisting of from a few to up to 40 amino acids. Like most true transmitters, they are stored in vesicles in the nerve terminals. They also act as modulators of the action of other transmitters and typically coexist with other transmitters in the terminals. Many neuropeptides are found in gut endocrine cells as well (**see also Integrated Function and Control of the Gut**: Intestinal Absorption). Neuropeptides of the same evolutionary origin are said to form families. Gene duplications and subsequent mutations leading to amino acid substitutions, have led to these groups of neuropeptides of similar structure and overlapping functions.

Calcitonin gene-related peptide (CGRP). It is a 37-amino acid peptide, with at least two isoforms (CGRP1 and CGRP2) in teleosts (**Figure 5**). CGRP nerves are found in teleosts, lamprey, and lungfish. Fibers in the anterior parts of the gut (stomach and proximal intestine) are often extrinsic, reaching the gut via the vagus. Enteric nerve cell bodies, and hence an intrinsic innervation, are present more posteriorly. In Atlantic cod, there is a dense innervation of the myenteric plexus, the circular muscle layer, and the mucosa. Few fibers only innervate vessels in the gut wall. A CGRP-receptor has been cloned from the bastard halibut (*Paralichthys olivaceus*).

Galanin. It is a highly conserved 29-amino acid peptide that has been isolated from ancient fish groups as well as teleosts and elasmobranchs (**Figure 6**). Galanin usually occurs only in nerve cells and fibers but not in endocrine cells. Most nerve cells are found in the myenteric plexus with some present also in the vagus nerve, projecting their axon either toward the CNS or toward

the gut. Most fibers run in the mucosa and submucosa; however, some also occur in muscle layers, indicating effects on both secretion and motility. The density of innervation often decreases from stomach to rectum (**Figure 4**). Galanin fibers innervating gut blood vessels are reported in elasmobranch species and in the Australian lungfish (*Neoceratodus forsterii*).

Peptides of the *GRP (gastrin releasing peptide)/bombesin* family all share the same seven C-terminal amino acids (**Figure 7**). GRP has been sequenced from elasmobranch and teleost species, for example, lesser-spotted dogfish (*Scyliorhinus canicula*), zebrafish, and goldfish (*Carassius auratus*). GRP/bombesin-immunoreactive gut nerves are found in all major fish groups, including lampreys, elasmobranchs, teleosts, and lungfish. The fibers are present along the whole gut, and cell bodies are found in the myenteric plexus of spiny dogfish (*Squalus acanthias)* and shorthorn sculpin, indicating that the nerves may be enteric in many species. In some species, like lungfish and bowfin (*Amia calva*), only a few fibers are found, while others, like spiny dogfish, have a dense innervation. In several elasmobranchs, gut perivascular nerve fibers express a GRP-like peptide.

The closely related peptides *NPY (neuropeptide Y) and peptide PYY (peptide tyrosine tyrosine)* evolved early from an ancestral NPY (**Figure 8**). Evolution has led to two forms of each peptide: NPYa and NPYb, and PYYa and PYYb (formerly pancreatic polypeptide, PP). It has recently been established that NPY is primarily present in the CNS, while PYY is expressed in gut nerves. However, histochemical studies rarely conclusively distinguish between these peptides. Gut nerves containing NPY/PYY-like material are commonly found in elasmobranch and teleost species (**Figure 4**), but not in cyclostomes. The absence of enteric nerve cell bodies in various species studied to date suggests the nerves might be exclusively extrinsic. Nerve fibers are present in the plexa and the muscle layer and some surround blood vessels. At least seven types of NPY/PYY-receptors are present in vertebrates, but the expression in fish gut is little investigated.

Tachykinins form a large group of neuropeptides. The best studied are *substance P* and *neurokinin A* (NKA), which come from the same gene, via different splicing. Several unique fish peptides have also been isolated, for example, the *scyliorhinins* that were first found in the elasmobranch *Scyliorhinus* (**Figure 9**).

Figure 9 The amino acid sequences of different tachykinins from some fish species and mammals. Dash denotes the same amino acid in this position as in rainbow trout substance P. Note the C-terminal, where four out of five amino acids are common, which is characteristic for tachykinins.

Numerous substance P/NKA-immunoreactive neurons are present in the gut of representatives of all fish groups except cyclostomes. Enteric nerve cell bodies are usually common, indicating an intrinsic origin, although some tachykinin-immunoreactive fibers may well be extrinsic (**Figure 4**). Fibers are particularly dense in the myenteric plexus in all gut regions, suggesting a presence in local sensory neurons and/or interneurons, but are also seen in other gut layers and around gut vessels.

The three known tachykinin receptor types, neurokinin (NK) 1–3, have all been found in fish genomes. The type(s) expressed in the gut have not been conclusively established, but functional data suggest the presence of at least NK1-receptors. In general, NK1-receptors are most sensitive to substance P while NK2-receptors prefer NKA.

VIP (vasoactive intestinal polypeptide) and PACAP (pituitary adenylate cyclase activating peptide) are two peptides of the secretin-glucagon superfamily, which often exist together in gut neurons. VIP contains 28 amino acids, while PACAP can exist in two forms, a full-length peptide containing 38 amino acids and a C-terminally truncated 27-amino-acid version. Both VIP and PACAP have been sequenced from several teleost and elasmobranch species (**Figure 10**).

VIP and PACAP exist in gut nerves of most fish species examined, except cyclostomes where it is only present in endocrine cells. However, VIP was discovered first and is the better studied of the two. VIP fibers innervate all layers of the gut wall and, more sparsely, vessels running on and in the gut tissues. Few VIP-immunoreactive nerve cell bodies are usually observed.

VIP and PACAP show 100% co-localization in enteric neurons in Atlantic cod, rainbow trout, and spiny dogfish and generally interact with the same receptors (VPAC1, VPAC2, and/or PAC1). There are species differences in the distribution of receptor types: while pufferfish species express VPAC2 and PAC1 in the gut, only VPAC1 is found in the goldfish and one PAC1 isoform in zebrafish intestine.

Other neuropeptides. Some peptides are more common in mucosal endocrine cells, but occur also in small populations of nerves in fish. Among these is cholecystokinin (CCK), which is found in nerves of the dogfish rectum and in the lungfish foregut. The single type of receptor (CCK-X) demonstrated in fish may be the common ancestral form of the mammalian CCK-A and CCK-B receptors. Similarly, somatostatin, commonly present in

endocrine cells, is found in nerve populations in the spiny dogfish rectum, in the nursehound (*Scyliorhinus stellaris*) stomach and in the intestine of the teleost *Barbus conchonius* (rosy barb).

Nitric Oxide

Nitric oxide is synthesized in nerves by neuronal nitric oxide synthase (nNOS), and may be one of the most common neurotransmitters. The sequence of nNOS has been determined in several fish species, including zebrafish, rainbow trout, and fugu (*Takifugu rubripes*). The presence of NOS is the most commonly used marker for NO-producing (nitrergic) nerves. In several teleosts and in spiny dogfish, NOS is common in the myenteric plexus throughout the gut, often present in over 50% of the nerve cell bodies. Fibers reach all layers, with the highest density in the circular muscle layer. No nitrergic neurons are found in hagfish.

Other Transmitters

Some substances, like amino acids and purines, are transmitters in mammals, but are so far little investigated in fish. Amino acids like glutamate and γ-amino butyric acid (GABA) are the most common transmitters in the brain, but so far there are only a few reports of their findings in the fish gut. The purines adenosine and adenosine triphosphate (ATP), commonly used in the general metabolism of all cells, is concentrated by specific transporters into secretory vesicles in certain nerves, and subsequently released to act as transmitters in the gut. They act through two main types of receptors, P1-receptors stimulated by adenosine, or P2-receptors interacting with ATP and other nucleotides. Both P1- and P2-receptors are found in fish gut.

Coexistence and Chemical Coding

Nerve cells normally express a combination of different transmitters, and the combination of transmitters sometimes gives an indication of the function. However, little is known about the patterns of coexistence in nerves innervating the fish gut, and whether these change with changing circumstances, such as during long periods of fasting. This lack of information may at least in part depend on a lack of specific antisera produced in different hosts, which is needed for simultaneous staining for different markers.

CGRP in combination with substance P often indicates extrinsic sensory neurons in mammals, and this combination also is found in about 20% of the substance P-immunoreactive nerve fibers in the gut of the Australian lungfish. In contrast, few or no fibers co-express the two peptides in investigated teleosts or elasmobranchs. In Arctic lamprey (*Lampetra japonica*), CGRP coexists with serotonin in mucosal nerve cells and fibers.

Cells containing VIP and PACAP often co-express NOS. For example, in Atlantic cod and spiny dogfish, around 50% of the VIP-immunoreactive neurons contain NOS. In other species, some VIP neurons co-express galanin, and most galanin-immunoreactive nerves are also ChAT-immunoreactive, that is, they synthesize acetylcholine.

Concluding Remarks

Large and fundamental similarities exist between fish and other vertebrates in the general anatomy of the gut innervation, although there are several minor variations found. Similarly, most neurotransmitters occur in an identical or similar version in fish as in all vertebrates, but the abundance of nerves expressing a certain transmitter may vary substantially between regions of the gut and between species. Details on receptor types and their molecular identity in fish are very limited so far. In fact, in terms of the distribution and types of nerves innervating the fish gut, it is presently still difficult to determine what constitutes an evolutionary trend and what constitutes a species-specific adaptation to lifestyle and habitat.

Anorexigenic Inhibiting appetite.

Closed-type endocrine cell Intraepithelial endocrine cell without luminal contact.

Enteroendocrine cell Endocrine cell in the epithelium of the gut mucosa.

Open-type endocrine cell Intraepithelial endocrine cell with luminal contact.

Orthologs Genes, or peptides expressed by genes, in different species that have evolved from a common ancestral gene.

Paracrine effect When a hormone from an endocrine cell affects neighboring cells.

Postprandial Period after ingesting a meal.

Proximal intestine First part of the intestine, equivalent to duodenum in mammals.

Vagal afferents Sensory nerves, for example, from the gut, running in the vagus nerve.

Vagal innervation Nerve fibers reaching the gut via vagus nerves.

Introduction

The endocrine cells of the gut are an important source of hormones involved in the control of appetite, digestive processes, and metabolism. They are mainly present in two locations, either scattered in the gut mucosal epithelium or in more concentrated clusters, islets, in the pancreas. The mucosal cells, also called intraepithelial endocrine or enteroendocrine cells, are usually of the open type. These cells have a cone-like appearance, with a broader part containing the nucleus near the basal membrane, and a tapering process toward the lumen (apical side) (**Figure 1**). Closed-type endocrine cells, without the apical process, are less common. The endocrine cells are found all along the gut mucosa, with the highest concentrations in the stomach and proximal intestine. However, when single signal substances are considered, populations may vary from an even distribution all along the gut for some, to populations concentrated to a specific part of the gut such as the cardiac stomach, proximal intestine, or the most distal part of the intestine for others.

The endocrine cells produce a large number of different signal substances. The signal substances are released into the blood circulation, and are thus hormones by definition, but local paracrine effects are also important. Release of hormone from an endocrine cell may be initiated, increased, or inhibited by a large number of factors including food components, mechanical distortion, other hormones or paracrines, and nerves innervating the mucosa. Many gut hormones, such as cholecystokinin (CCK), serotonin, tachykinins, and vasoactive intestinal polypeptide (VIP), are identical in molecular structure or at least closely related to neurotransmitters in the same species. In contrast, others such as gastrin, glucagon, and insulin are more common or exclusive to endocrine cells. For a detailed summary of the occurrence of signal substances in endocrine cells and/or nerves in the gut of different fish species, see **Appendix A** (pp. 1232–1267).

This article presents the hormones of the enteroendocrine cells in a functional (physiological) context, while the pancreatic endocrine system is described in Pancreas **Gut Anatomy and Morphology**: Pancreas. All of the hormones synthesized and produced in the pancreas, that is, insulin, glucagon, somatostatin (SST), and pancreatic polypeptide, also exist in populations of endocrine cells in the gut wall. These may be remnants of a more primitive stage when a separate pancreas was not present.

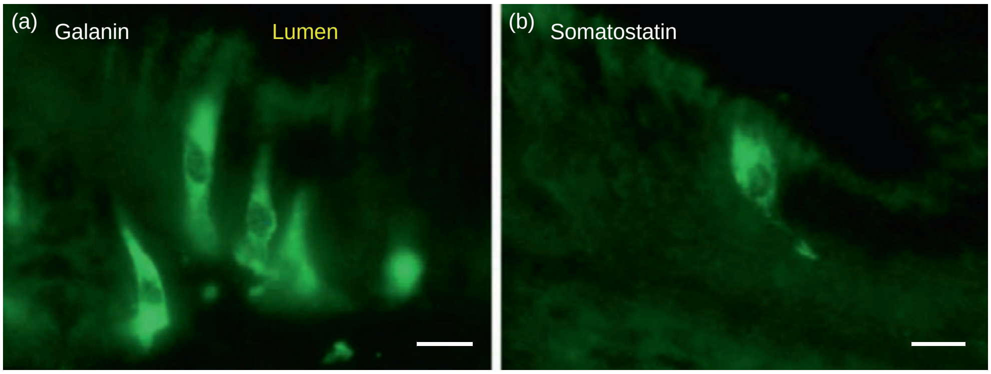

Figure 1 Immunohistochemistry is the primary tool to illustrate the presence of hormones in enteroendocrine cells of the gut, here exemplified by (a) galanin immunoreactive cells in the intestinal mucosa and (b) a somatostatin (SST) immunoreactive cell in the gastric mucosa of shorthorn sculpin (*Myoxocephalus scorpius*). Notice also the cone-shaped structure of the four open-type endocrine cells in (a), with a broad base toward the basal membrane and an apex protruding toward the gut lumen. Photographs courtesy of Mrs. Christina Hagström.

With the exception of SST, they are not further discussed here.

In addition to the slightly better investigated endocrine systems described below, there are more or less occasional findings of, for example, bombesin/gastrin-releasing peptide (GRP)-, calcitonin gene-related peptide (CGRP)-, enkephalin-, FRMRFamide-, galanin- (**Figure 1**), gastric inhibitory peptide (GIP)-, neurotensin-, and VIP/pituitary adenylate cyclase-activating peptide (PACAP)-like peptides in enteroendocrine cells of different fish species (see **Appendix A** (pp. 1232–1267)).

Gastrin, Histamine, and Somatostatin Interact in the Control of Gastric Acid Secretion

Enteroendocrine cells in the stomach mucosa interact with each other and with autonomic enteric nerves, in the control of gastric acid secretion. Among the released hormones (or paracrines), gastrin, histamine, and SST take a prominent position, and their involvement in acid secretion in fish is outlined below.

Gastrin

Gastrins are a group of peptides that belong to a large family of signal peptides also including several cholecystokinins (CCKs). The two peptide groups are very closely related with four amino acids common in the C-terminal end. Unfortunately, most studies in vertebrates investigating the presence of gastrin have used immunocytochemical methods with antibodies that cannot distinguish between gastrins and CCKs, because they are directed toward the common C-terminal. These studies report endocrine cells containing gastrin/CCK-like material in both stomach and intestine in many fish (see **Appendix A** (pp. 1232–1267)). However, judging from the general vertebrate situation, it is most likely that gastric cells contain gastrin, while intestinal endocrine cells and gut nerves contain CCKs.

Histamine

Histamine is an amine formed from the amino acid histidine. In fish, histamine is present in mucosal endocrine cells of the stomach, often called enterochromaffin-like (ECL) cells, due to their staining reaction. Similar cells are found in all vertebrates. In contrast, the presence of histamine-containing mast cells (common in reptiles, birds, and mammals) in the fish gut wall appears more unusual – so far mast cells are found only in the most advanced teleosts, for example, in perch-like fish, and in lungfish. Histamine from mast cells is believed to be involved in inflammatory responses. In rainbow trout (*Oncorhynchus mykiss*), histamine also can produce irregular contractions of preparations of intestinal smooth muscle, possibly mimicking effects of histamine released from infectious bacteria in the live fish.

Somatostatin

Several different SSTs occur in fish (**Figure 2**). They are usually either 14 or about 28 amino acids long. One of the short forms, SST-14-(I), is highly conserved among vertebrates, and is identical in, for example, hagfish (*Myxine glutinosa*), lungfish (*Protopterus annectens*), rainbow trout, and mammals. Other forms vary between species, and there are even those that are found only in fish.

SST is well recognized as a pancreatic hormone in fish as in other vertebrates (**see also Gut Anatomy and Morphology**: Pancreas), but it is also found in endocrine cells of the gut mucosa of most fish species. Typically, SST inhibits the release of gastrointestinal hormones

from other endocrine cells, and also decreases smooth muscle contractions in the gut (**see also Integrated Function and Control of the Gut**: Gut Motility), which may lead to a reduced rate of gastric emptying.

Gastric Acid Secretion

In most fish species, as in many other nonmammalian vertebrates, gastric acid is secreted from so-called oxynticopeptic cells. The cells are usually gathered in gastric glands in the stomach mucosa, and they secrete both gastric acid and pepsinogen. They have a basal secretory activity when the stomach is empty of food, and the secretion increases dramatically after food intake. An important stimulus for this is the distension of the gut wall caused by the presence of food, which in turn triggers endocrine cells in the stomach mucosa to release their hormones, but several nervous reflexes are also involved. Thus, the hormones gastrin, histamine, and SST play central roles in the control of acid secretion (**Figure 3**) together with the neurotransmitter acetylcholine, in fish as in mammals.

Histamine and acetylcholine stimulate acid secretion in several elasmobranch and teleost species, but the most comprehensive studies have been performed in Atlantic cod (*Gadus morhua*) and rainbow trout. Acetylcholine is released from vagal (and probably enteric) nerve fibers and acts via muscarinic receptors, which appear to be present both on the oxynticopeptic cells and on the histamine cells, stimulating the release of histamine. The effect of histamine is mediated via receptors of the H2-type. Histamine-induced acid secretion is inhibited by SST and the neuropeptide VIP in the Atlantic cod.

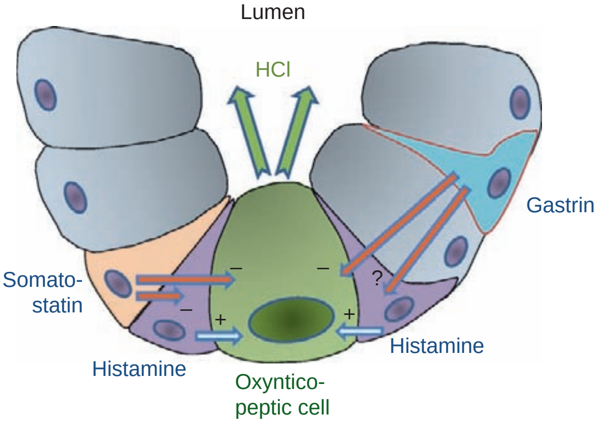

Figure 3 The hormones gastrin, histamine, and somatostatin exert important local control of gastric-acid secretion in fish. In addition (not shown), hormones from other parts of the gut, such as cholecystokinin and serotonin, and transmitters, such as acetylcholine and vasoactive intestinal polypeptide (VIP) released from neurons, are essential in regulating acid synthesis and release.

The role of gastrin in fish is not so clear. It has an unusual effect in Atlantic cod, where it inhibits acid secretion, but stimulates secretion in the common stingray (*Dasyatis pastinaca*), like in mammals. There are too few studies in fish, involving very few species, to show whether these differences are due to evolutionary trends, species differences, or methodological problems caused by using mammalian gastrins.

In addition, hormones released from the intestinal mucosa that reach the stomach via the circulation may affect acid secretion. In Atlantic cod, for example, CCK inhibits secretion. Serotonin, on the other hand, shows a dose dependency: low doses stimulate secretion, while high doses inhibit secretion.

CCK Affects Appetite and Digestion

CCK-like material is found in endocrine cells of the fish intestine in representatives of all fish groups except lungfish (see **Appendix A** (pp. 1232–1267)). As mentioned above, CCKs are closely related to gastrins, but it is likely that the material present in endocrine cells in the mucosa of the proximal intestine is predominantly CCK related. CCK, either hormonal or from enteric nerves, affects many gastrointestinal functions. For example, it controls gut motility and gastric emptying (**see also Integrated Function and Control of the Gut**: Gut Motility), and release of pancreatic hormones (**see also Gut Anatomy and Morphology**: Pancreas). It also affects appetite and gallbladder emptying. A CCK/gastrin receptor, named CCK-X, has been found in fish, and it is suggested that this represents an ancestral common form that has evolved into CCK-A and CCK-B receptors in mammals.

CCK and Gallbladder Contraction

The very first established effect of CCK is emptying of the gallbladder (**Figure 4**). Arrival of acid, fat, and amino acids in the proximal intestine of fish presumably releases CCK from local endocrine cells; CCK in turn contracts the gallbladder. The ability of food components such as fats and certain amino acids and/or CCK to contract the gallbladder has been shown in teleost, elasmobranch, and holostean species.

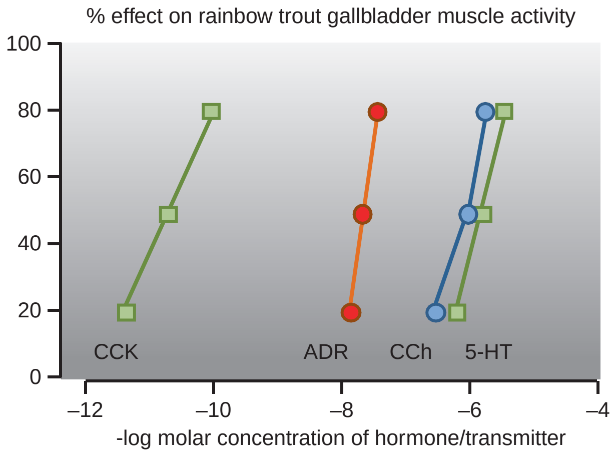

Figure 4 The potency of some hormones and neurotransmitters that affect motility of the gallbladder. The more potent a substance is, the less is needed to cause an effect and the more to the left the curve lies in the diagram. Note how much more effective CCK is than the other hormones and transmitters. ADR, adrenaline, mainly neuronal, inhibitory; CCh, carbachol, enzyme-resistant cholinergic drug, mimics neuronal acetylcholine, stimulatory; CCK, cholecystokinin, mainly hormonal, stimulatory; 5-HT, 5-hydroxytryptamine = serotonin, mainly hormonal. Modified from Aldman G and Holmgren S (1987) Control of gallbladder motility in the rainbow trout, *Salmo gairdneri*. *Fish Physiology and Biochemistry* 4: 143–155.

CCK and Appetite Regulation

CCK is also a classical so-called satiety factor and the first to be defined as such in 1973. This means that as the stomach becomes filled with food during a meal, intestinal CCK is released and signals to the brain to reduce further food consumption. One of the most extreme examples of this is the Burmese python (*Python molurus*), where CCK levels in plasma can increase 25-fold after a meal. The anorexigenic function of CCK is evolutionarily well conserved and has been confirmed across vertebrates including different teleosts such as goldfish (*Carassius auratus*), sea bass (*Dicentrarcus labrax*), rainbow trout, and coho salmon (*Oncorhynchus kisutch*). It is believed that gut-derived CCK induces the sensation of satiety mainly by stimulating CCK receptors on vagal sensory nerves, which then transmit the signal to the brain.

Due to difficulties in measuring CCK in fish plasma, it is still not established exactly which nutrients in the food regulate the endocrine release of CCK from the gut, but a recent study on rainbow trout showed that it was influenced by the dietary protein-to-lipid ratio. The postprandial increase in plasma CCK in rainbow trout was less pronounced and slower than in mammals.

Another approach is to measure mRNA levels. In the yellowtail (*Seriola quinqueradiata*), CCK mRNA levels increased after a meal. In line with this, in the more long term, CCK mRNA expression was lower during fasting in yellowtail and winter flounder (*Pseudopleuronectes americanus*), when the gut is empty of food. But different species react differently; for example, gut CCK mRNA expression increases in coho salmon during winter when appetite is suppressed, although the stomach is empty. In the elasmobranch winter skate (*Leucoraja* (*Raja*) *ocellata*), CCK mRNA levels also increase during fasting, whereas they remain unchanged in fasted Atlantic salmon (*Salmo salar*).

Serotonin – Hormone or Transmitter?

Many of the gut hormones are also expressed in an identical or very similar form in gut nerves. This often occurs in the same species (see **Appendix A** (pp. 1232–1267)), but in some cases a substance is expressed exclusively in endocrine cells in some species or groups, and in nerves only in others. Serotonin (5-hydroxytryptamine, 5-HT) represents an interesting case in this context, with different distributions in nerves and/or endocrine cells, sometimes even between closely related species (**see also Integrated Function and Control of the Gut**: Nervous System of the Gut). Based on this, a theory has been put forward that endocrine cells express serotonin only when there is no serotonergic innervation of the mucosa. Pharmacological experiments in fish demonstrate that serotonin may stimulate pepsinogen secretion from oxynticopeptic cells and increase gut and gallbladder (**Figure 4**) contractions.

Glucagon-Like Peptide-1 Has a Deviant Effect in Fish

In addition to glucagon, the intestinal proglucagon gene generates two other peptides through alternative splicing, glucagon-like peptide-1 (GLP-1) and glucagon-like peptide-2 (GLP-2). These hormones have been described across vertebrate species. In teleosts, GLP-1 is produced both in the intestine and in the pancreas (**see also Gut Anatomy and Morphology**: Pancreas), whereas GLP-2 is produced only in the intestine. So far, a function for GLP-2 is only known for mammals.

GLP-1 is important for the maintenance of glucose levels in the blood, but interestingly it has opposite effects in mammals and fish. This may be related to differences between these vertebrate groups in the importance of glucose as a nutrient and how they regulate a glucose load. In mammals, GLP-1 is released from the intestine during feeding even before blood glucose levels are elevated. It inhibits gastric emptying and thus slows down nutrient absorption. At the same time, GLP-1 stimulates insulin release (this is called the incretin effect), which in turn lowers blood glucose levels. In fish, on the other hand, GLP-1 has glucagon-like effects; it increases blood glucose levels through the stimulation of liver glycogenolysis and gluconeogenesis. GLP-1 also increases the capacity of enterocytes from black bullhead catfish (*Ictalurus melas*) to transport glucose *in vitro*. This indicates that GLP-1 is involved in the not-so-well-known local hormonal regulation of intestinal nutrient absorption in fish.

Ghrelin Influences Appetite and Growth-Hormone Secretion

Ghrelin is produced in all vertebrates, predominantly in endocrine cells in the stomach epithelium. An exception in stomach-less species, such as goldfish, where ghrelin-expressing cells are especially abundant at the base of the mucosal folds in the proximal intestine (intestinal bulb) (see **Appendix A** (pp. 1232–1267)). Ghrelin is a 12–26-amino-acid-long peptide in fish, and varies between 25 and 28 amino acids in other vertebrates (**Figure 5**).

In mammals, most ghrelin is produced in the acid-secreting mucosa in the so-called X/A-like cells, now often referred to as ghrelin cells. Similar to this, the ghrelin immunoreactive or mRNA-expressing cells are located in the gastric glands or stomach mucosal folds in, for example, Japanese eel (*Anguilla japonica*), summer flounder (*Paralichtys dentatus*), Atlantic halibut (*Hippoglossus hippoglossus*), sea bass, and rainbow trout. At least in rainbow trout and Atlantic halibut, these cells are both of open- and closed-type. Ghrelin also is present in a species-specific manner in several other tissues, for example, in endocrine cells in the intestine, pancreas, and lungs, as well as in the brain and heart.

Ghrelin was discovered as an endogenous stimulator of growth hormone (GH) release, acting through the GH-secretagogue receptor (GHS-R) in the pituitary. One by one, the list of ghrelin's physiological functions has expanded, and perhaps the most well known is its instrumental role in appetite control. In mammals, ghrelin stimulates hunger, increases food consumption, and the deposition of fat. In birds, on the other hand, the effect of ghrelin on appetite depends on dose and site of administration. The detailed roles of ghrelin in fish are not clear-cut, but a generalized overview is given in **Figure 6**. Ghrelin increases food intake in tilapia (*Oreochromis mossambicus*) and goldfish, but decreases or has no effect on food intake in rainbow trout. In goldfish, ghrelin stimulates appetite by acting on vagal afferents, similar to its mechanism of action in rats. Plasma ghrelin levels as well as gut ghrelin mRNA expression fluctuate with feeding status in fish, but again the patterns vary between studies and species. The detailed nutritional regulation of ghrelin release/production is little explored in fish. One study on tilapia, however, showed that glucose increased stomach ghrelin mRNA expression, which is in contrast to what occurs in mammals.

In line with the original description of ghrelin's function in mammals, it also has direct *in vitro* and *in vivo*

Dash denotes the same amino acid in this position as in ghrelin from zebrafish (*Danio rerio*); dots denote presumed amino-acid deletions in the peptide sequence during evolution. Note the large differences between teleost, elasmobranch, and mammalian sequences.

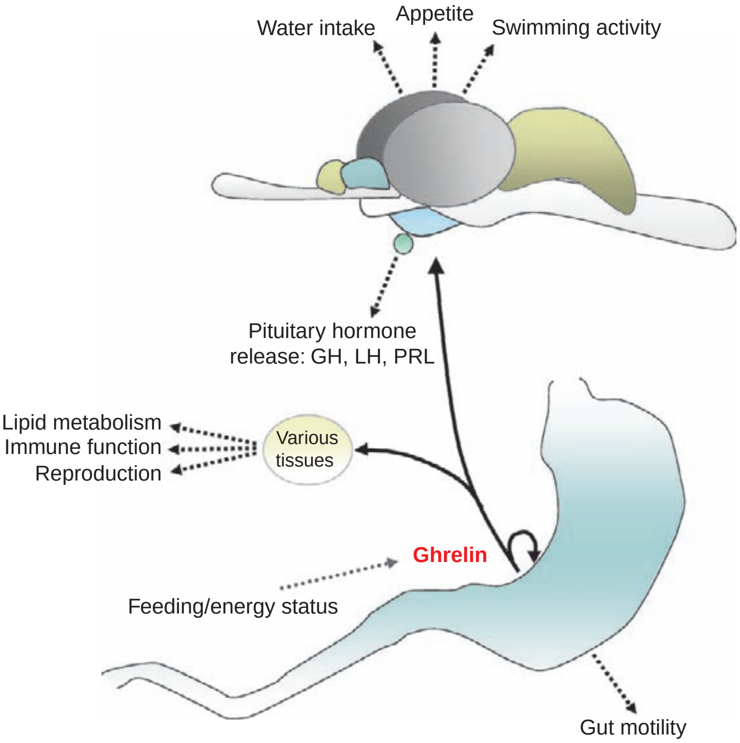

Figure 6 Overview of the effects of ghrelin (hatched black arrows) in fish. Ghrelin released into the circulation potentially acts on various target tissues (black solid lines). The functions of ghrelin as a growth-hormone secretagog and a modulator of food intake are so far the most well studied, but ghrelin may also play a role in several other processes. Both short- and long-term energy status influence plasma ghrelin levels and gut ghrelin mRNA expression (dotted gray arrow).

systemic effects on pituitary GH release in fish. In some fish species, ghrelin also stimulates prolactin and luteinizing-hormone (LH) secretion. Less is known about the effects of ghrelin on metabolism in fish but, as in humans and rodents, it inhibits the breakdown of fat and stimulates lipogenesis in tilapia. It also stimulates intestinal motility in zebrafish. This is consistent with the distribution of ghrelin receptor-like immunoreactivity in the gut muscle layers and with results from other vertebrates. Ghrelin also is implicated having a role in many other processes in fish such as in the control of immune function, reproduction, and water intake.

Des-acyl ghrelin, ghrelin without the fatty acid modification of the third amino acid (**Figure 5**), also is present in the circulation of mammals and has some biological actions. Des-acyl ghrelin has not been characterized in fish but inhibits ghrelin-induced food intake in goldfish.

In 2005, a new putative hormone obestatin, encoded by the ghrelin gene, was found in rat. An ortholog of the mammalian obestatin gene exists in sea bream, but the obestatin protein has not yet been isolated in a nonmammalian vertebrate. Ghrelin also has structural resemblance to motilin, another gastric peptide, and these two hormones may have evolved from a common ancestral peptide. Although motilin stimulates gastrointestinal motility in zebrafish, only a few motilin-immunoreactive cells are present in the gut (**see also Hormonal Responses to Stress**: Stress Effect on Growth and Metabolism).

Leptin's Role in the Gut Is Not Yet Known in Fish

It was not until 2005, more than ten years after its discovery in obese mice, that leptin was characterized in a fish species, the pufferfish (*Takifugu rupripes*). Leptin plays a key appetite-inhibiting role in the control of food intake, but it is also involved in the regulation of gut proliferation, nutrient absorption, and gut motility in mammals.

Leptin is primarily produced by adipocytes in mammals, and in minor amounts in other tissues. The primary source of circulating leptin in fish is not clarified, and it is likely that it differs from mammals since fish store lipids to a larger extent in several tissues, but its presence in gut endocrine cells has been reported in representatives from all vertebrate groups. Leptin release is affected by nutritional status and CCK. One problem in fish studies is that, generally, antisera raised against mammalian leptin have been used to detect fish leptin. In light of the fact that the amino-acid-sequence similarity between human and different teleost leptin is only 16–25%, the presence of leptin-immunoreactive cells in different tissues should be verified using species-specific antibodies. Leptin mRNA expression has been demonstrated in the gut of zebrafish and pufferfish, but attempts to detect it in rainbow trout gut have so far failed. What type of gut cells in addition to endocrine cells express leptin remains to be clarified, together with its gastrointestinal functions in fish, which are still virtually unknown.

Concluding Remarks

There is a rich diversity of gut hormones, often with profound systemic effects in the whole fish as well as having important roles in local control of gastrointestinal functions. Often the identity, function, and distribution of the gut hormones are conserved among vertebrates, but comparative research also highlights that there are differences between fish and especially mammals, and also among fish. For example, gastrin stimulates gastric-acid secretion in most investigated vertebrates, but in Atlantic cod, gastrin inhibits acid secretion. Similarly, GLP-1 has opposite effects on blood glucose levels in fish and mammals. Ghrelin stimulates appetite in goldfish and tilapia, but suppresses appetite in rainbow trout, and it has species-dependent effects on the release of various pituitary hormones. Furthermore, both ghrelin and CCK levels show variable species-dependent responses to food deprivation. This reflects the great diversity in this vertebrate group and the complex interactions between environmental/seasonal, nutritional, and hormonal factors.

Glossary

Diffusion Net movement of a solute from an area of higher concentration to an area of lower concentration.

Glomerulus Tuft of capillaries surrounded by the Bowman's capsule of the vertebrate kidney where blood is filtered to produce urine in the proximal tubule.

Hyperosmotic Containing a greater concentration of solutes than another solution. If the solutions are separated by a permeable membrane (such as gill epithelium), solute will diffuse from a hyperosmotic to a hyposmotic solution and water will move from the hyposmotic to hyperosmotic solution.

Hyposmotic Containing a lesser concentration of solutes than another solution.

Isosmotic Containing the same total solute concentration as another solution. If the solutions are separated by a permeable membrane, there will be no net movement of either solute or water from one solution to the other.

Osmoregulation The maintenance of consistent cellular or organismal fluid composition and volume.

Osmosis Essentially diffusion for water molecules. As with diffusion for dissolved solutes, water moves due to random thermal oscillations, in a net sense, from where there is a higher water concentration (amount per unit volume) to where there is a lower water concentration. This is generally inversely related to the situation for dissolved solutes, as higher levels of these occupy space leaving less space for water and reducing its concentration. Water therefore (again in a net sense) moves from where the osmolality is lower to where it is higher (the opposite of what occurs for the diffusion of solutes).

Introduction

Osmoregulation is a fundamental process of living systems, equivalent in importance to respiration, digestion, or reproduction. Osmoregulatory processes are those that enable a fish to maintain its cellular fluid composition and volume. This is of critical importance because the protein-based processes of cells are sensitive to cytoplasmic ionic concentrations, and cell membranes tolerate relatively small deviations in cell volume (they will either collapse or explode). While terrestrial organisms are continually faced with the problem of dehydration, fishes are surrounded by water, and the water can tend to either dehydrate (in seawater, SW) or hydrate them (in freshwater, FW).

The differences in the ionic and total osmotic concentrations of the water and those of the fish body fluids determine the magnitude and the direction of ion (diffusion) and water (osmosis) movements across the fish gill epithelium. Fishes can limit ion and water exchanges by creating barriers at the skin surface (e.g., scales and mucus layers) that limit permeability. However, they still possess gills that are specialized for gas exchange (large surface area, thin, highly vascularized), which remains an excellent site for osmotic movement of ions and water. In fact, when oxygen and carbon dioxide diffusion across the gills increases during activity, ion and water diffusion increases too. This creates a problem for a fish called the osmorespiratory compromise (**see also Role of the Gills**: The Osmorespiratory Compromise). Therefore, post-exercise fish not only have to rectify the depletion of oxygen stores, but they must also deal with ions and water they may have lost or gained as a result of breathing more! When terrestrial animals exercise, they only lose water via their respiratory surface.

With the exception of the hagfishes, the ionic concentrations of all fish plasma are intermediate between SW and FW levels (**Table 1**). Consequently, excluding hagfishes, all fishes must osmoregulate because they usually live in either FW (hyposmotic to fish plasma) or SW (hyperosmotic to fish plasma). Hagfishes are exceptional because their plasma has similar ionic and osmotic concentrations as the SW environment (termed isosmotic), and osmoregulation is not necessary. Animals that maintain their blood plasma isosmotic with the environment are able to save metabolic energy, because life in nonisosmotic solutions requires compensatory transport of solutes and water by cell membranes, epithelial tissues, or specific organs and these processes are energy demanding (variously estimated at 2–8% of resting metabolic rate).

The differences in the ionic (and total osmotic) concentrations between SW and FW are extreme (1000 times in most cases), by comparison with the difference in plasma ionic concentrations among fish (only ~3 times). Most fishes are adapted to either FW or SW, not both. Fishes that are only able to osmoregulate over a very narrow range of salinities are termed ‘stenohaline’, those that can tolerate a wide range of salinities (e.g., both FW and SW) are termed ‘euryhaline’. Freshwater fishes can often tolerate salinities up to isosmolarity and marine species can often tolerate salinities down to isosmolarity. Euryhaline species can osmoregulate on both sides of the isosmolarity point. Estuarine environments provide a full range of salinities in which many fish live; isosmolar habitats may exist here too. Very few fish species are adapted to hypersaline conditions. (**see also Intertidal Fishes**: Intertidal Habitats).

Table 1 Ionic compositions of plasma in fishes in SW and FW

Modified from Evans DH and Claiborne JB (2009) Osmotic and ionic regulation in fishes. In: Evans DH (ed.) Osmotic and Ionic Regulation: *Cells and Animals*, pp. 295–366. Boca Raton, FL: CRC Press.

Over 95% of the total solute concentration (32–35 parts per thousand, ‰) of SW is due to the salts listed in **Table 1**, but over 80 other elements and ions are present in measurable quantities. The same elements predominate in FW but at much lower concentrations and more variable compositions because of differences in input from the terrestrial substrates (**Table 1**). One of the more important variables in FW is the calcium concentration, which, although lower than that in SW, may affect the permeabilities (salt and water) of biological membranes, thereby indirectly influencing osmoregulation (see below).

Paleoecology of Fishes

Much can be learned about the possible evolutionary course of osmoregulatory strategies and mechanisms by comparing the plasma ionic compositions and habitats among the major phylogenetic fish groups. The finding that the plasma ionic concentration of all fishes (except for the hagfishes) is 30–40% that of SW has intrigued physiologists for over a century. Based upon the fossil record and the fact that the most primitive bony fishes (sturgeons, gar and bowfin, and bichirs) are FW fishes, and the fact that euryhaline marine species reduce their plasma salt concentrations as they enter lower salinities, it is generally agreed that ancestral fish species entered FW over 500 million year ago from a marine origin. Subsequent evolution of modern marine fishes (both bony and cartilaginous), as well as tetrapods (amphibians, reptiles, birds, and mammals), took place after this FW invasion. Extant lampreys, which are either FW or euryhaline migrants (FW to SW to FW) as they mature and reproduce (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development and **Toxicology**: The Effects of Toxicants on Olfaction in Fishes), are probably modern descendents of these ancestral fish species. The stenohaline, marine hagfishes are thought to be remnants of the ancestral, marine pre-vertebrates, largely because, like marine invertebrates and unlike any other chordates, they are ionically isosmotic to SW.

Osmoregulation in Marine Fishes

Hagfishes

Although hagfish plasma is isosmotic to SW, there are ionic differences, most notably greater Na$^+$ but lesser Cl$^-$, Mg^{2+}, and SO$_4{}^{2-}$ concentrations (**Table 1**). The mechanisms maintaining these ionic gradients are largely unknown, although the copious slime production by hagfishes may be an excretory pathway for at least the divalent ions (**see also Hagfishes and Lamprey**: Hagfish and Hagfish Slime). The slightly greater plasma Na$^+$, and lesser Cl$^-$ concentration may be secondary to the presence of gill Na$^+$/H$^+$ and Cl$^-$/HCO$_3^-$ exchangers used in net acid secretion for acid–base regulation or because of the charge distribution secondary to plasma organics or excretion of unwanted divalent ions (e.g., Ca^{2+} or Mg^{2+}), but these propositions are largely untested.

Teleosts

Marine teleosts face dehydration and net ionic loading because they are hyposmotic to SW (**Table 1**). In the 1930s, two pioneers in fish osmoregulation (Homer Smith and Ancel Keys) demonstrated that teleosts ingest SW to offset the osmotic loss of water and excrete the excess NaCl, using the gills, rather than the kidneys (as mammals and birds do). Specialized 'chloride' cells (now termed mitochondrion-rich cells, MRCs) were described in the marine fish gill by Keys, and substantial evidence now exists that MRCs are the site of NaCl extrusion by the marine teleost gill epithelium (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). The ingested divalent ions (Ca^{2+}, Mg^{2+}, and SO$_4{}^{2-}$) are excreted by the intestine and kidneys (**Figure 1**). In fact, the ingested

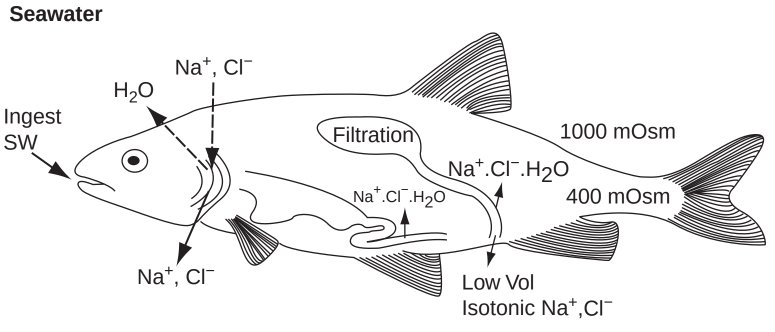

Figure 1 General pattern for SW teleost osmoregulation. From Evans DH (2008) Teleost fish osmoregulation: What have we learned since August Krogh, Homer Smith, and Ancel Keys? *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 295: R704–R713.

Ca^{2+} is precipitated out as a bicarbonate salt, which is excreted and actually appears to play a significant role in marine carbon cycling (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation). The urine flows of marine teleosts are quite low, and there are some marine teleosts that have secondarily 'lost' the blood-filtering renal glomerulus and produce urine by ionic secretion in the proximal tubule (**see also Role of the Kidneys**: The Kidney). Indeed, it was investigations of these aglomerular species that provided direct evidence for proximal tubular ionic secretion in the vertebrate kidney (including mammals), which was controversial until the aglomerular teleost species were discovered.

Elasmobranchs

The marine sharks, skates, and rays have evolved very different mechanisms of osmoregulation, and it is not clear why there is such disparity between the teleost and elasmobranch mode of marine osmoregulation. This is a good case of 'divergent evolution'. Elasmobranch plasma contains exceedingly high concentrations of the organic solutes urea and trimethylamine oxide (TMAO; **Table 1**). Indeed, the urea concentration in these fishes is 5–10 times higher than coma-producing levels in mammals. Importantly, it is the relatively high TMAO concentrations that counteract the toxic effects of the extraordinarily high urea concentrations in elasmobranchs (**see also Responses and Adaptations to the Environment**: General Principles of Biochemical Adaptations).

Elasmobranchs do not ingest appreciable volumes of SW because they are slightly hyperosmotic to SW, so there is no osmotic loss of water across the gills. In fact, the osmotic uptake of water is balanced by proportional urine excretion in elasmobranchs, produced by glomerular filtration and, relatively unstudied, tubular secretory and reabsorptive processes in the exceedingly complex elasmobranch renal nephrons. There are also ionic gradients producing a net, diffusional gain of NaCl, which is offset by extra-renal and extra-branchial salt secretion by a specialized rectal gland that secretes a hypersaline solution into the cloaca (**see also Role of the Gut**: Dogfish Rectal Gland). The rectal gland has extremely high concentrations of the ubiquitous ion transport enzyme, Na^+/K^+-activated ATPase, which plays a central role in the mechanisms of NaCl secretion by this gland, as well as by the teleost gill epithelium (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). In fact, the transporting cell in the shark rectal gland looks very much like the teleost gill MRC. MRCs are also found in the elasmobranch gill epithelium, but there is no evidence that they function in net salt secretion. It is apparent that the elasmobranch gill MRC function in acid–base regulation by secreting variable amounts of H^+ versus HCO_3^-.

Lampreys

Lampreys are anadromous species that breed in FW; the resulting larval forms (ammocoetes) metamorphose after a few years into juveniles that migrate downstream and live most of their adult life in the marine environment (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development). Because the marine adults are so rarely captured, and the upstream migrating, premating adults have lost the ability to osmoregulate in SW, little is known about the mechanisms for osmoregulation in SW lampreys (**see also Hagfishes and Lamprey**: Lampreys: Environmental Physiology). Their plasma is hyposmotic to SW (**Table 1**), so studies have found that, like teleosts, they ingest SW, and presumably excrete the excess NaCl across the gill, because the kidney cannot produce urine that has greater NaCl concentrations than the plasma. The branchial epithelium has MRCs, but no functional or molecular studies have been published to support the logical suggestion that the pathways and mechanisms for gill salt extrusion are the same as have been well documented in teleosts.

Osmoregulation in Freshwater Fishes

Teleosts

Freshwater teleosts are hyperosmotic to their environment (**Table 1**) and therefore face a net influx of water and loss of NaCl across their branchial epithelium. They balance the osmotic influx by producing a much larger volume of urine than their marine relatives, with a much lesser ionic concentrations to conserve salt. Nevertheless, renal loss of salt adds to the diffusional loss, and must be offset by some uptake mechanism (**Figure 2**). Some salt may be gained by ingestion of food, but this has rarely been quantified and would limit osmoregulation during periods of low food availability. In the 1930s, August Krogh provided direct evidence for the independent uptake of Na^+ and Cl^- by a variety of freshwater animals, including fishes. He also proposed that, in order to avoid bioelectrical problems, it was likely that the uptake of each ion was in exchange for a counter-ion that was relatively abundant in the plasma: H^+ (or NH_4^+) and HCO_3^-, respectively. Subsequent studies have confirmed this proposition, although the actual cell and pathways are still under debate, and may be species specific. It is probable that MRCs are involved, and most species that have been studied possess MRC subtypes that may have separate functions (**Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes). The current debate centers on whether the

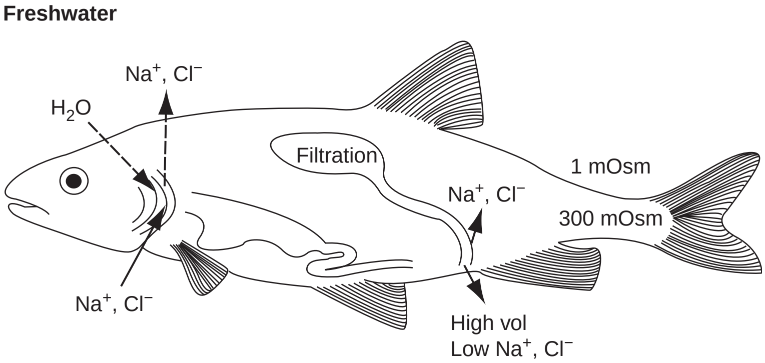

Figure 2 FW teleost osmoregulation.. From Evans DH (2008) Teleost fish osmoregulation: What have we learned since August Krogh, Homer Smith, and Ancel Keys? *American Journal of Physiology – Regulatory, Integrative and Comparative Physiology* 295: R704–R713.

Na^+/H^+ exchange is via an electroneutral chemical linkage (e.g., via a class of proteins termed Na-H exchangers (NHEs), which mediate this exchange in other tissues) or via an electrogenic proton pump (H-ATPase) which produces a cytoplasmic negativity that draws in Na^+ from the freshwater via a Na^+ channel. There is also emerging evidence that a coupled transport of Na and Cl may play some role in this uptake process.

Elasmobranchs

Freshwater elasmobranchs are rare; the most notable example is the euryhaline bull shark (*Carcharhinus leucus*) that can migrate into freshwater in Central America, Australia, and India (and even Illinois, where one was captured in the Mississippi River 3800 km from the Gulf of Mexico). Another example is the Atlantic stingray (*Dasyatis sabina*) that has a resident population in lakes in Central Florida. The only truly freshwater stingray, *Potamotrygon* sp., is found in tributaries of the Amazon and Orinoco Rivers in South America. The euryhaline species all display reduced plasma NaCl and urea levels when captured in lowered salinities, and *Potamotrygon* plasma contains nearly no urea (**Table 1**). Indeed, *Potamotrygon* can neither increase the plasma urea concentrations nor tolerate substantial increases in salinity. The rates of urea synthesis are much lower than in marine elasmobranchs, and the inability to increase plasma urea concentrations may also be associated with the loss of specific tubules in the kidney. These tubules have been implicated in renal reabsorption of urea filtered from the plasma. As might be expected, the rectal gland is much reduced in freshwater elasmobranchs, and the osmotic uptake of water is balanced by excretion of extremely high volumes of dilute urine. The diffusional, renal, and small rectal gland loss of salts must be balanced by branchial uptake. At least in *D. sabina*, the extraction of NaCl from the hyposmotic environment is mediated by two cells that have the apical proteins necessary for independent Na^+ and Cl^- uptake.

Lampreys

Larval, juvenile, and adult lampreys in freshwater show much reduced plasma ionic concentrations compared to the marine adults (**Table 1**). The osmotic uptake of water is balanced by production of large volumes of very dilute urine. The renal and diffusional loss of ions is offset by active branchial epithelial uptake via what appears to be two types of freshwater MRCs that disappear as the lamprey migrates into SW and reappear when the adults return to FW. These cells are thought to extract needed NaCl via a combination of the ionic transporters proposed for freshwater teleosts (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes, **Cellular, Molecular, Genomics, and Biomedical Approaches**: Physiology of Triploid Fish; Mechanisms of Ion Transport in Freshwater Fishes; **Hagfishes and Lamprey**: Lampreys: Environmental Physiology).

The Origin of Ionic Uptake Systems in the Early Vertebrates

Despite the uncertainty of the specific transport pathways that mediate NaCl uptake in freshwater fishes, it is clear that the evolution of this system was critical for the entry of primitive marine fishes into the freshwater environment nearly 500 million years ago. Where did it come from? Unlike mammals, fishes cannot substantially alter their blood pH by changes in renal secretion of H^+ or HCO_3^- or changes in respiratory excretion of CO_2. Thus, it has been found that acid–base regulation in fishes is mediated by differential excretion of H^+ or HCO_3^- by the gill epithelium (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation). The demonstration that marine teleosts, elasmobranchs, and even hagfishes use these gill transport mechanisms for acid–base regulation led to the proposition that the evolution of ionic exchange systems that could excrete blood H^+ and HCO_3^- in exchange for external Na^+ and Cl^- predated the evolutionary entrance into freshwater. Thus, the origin of ionic exchange mechanisms for acid–base regulation presumably afforded a pre-adaptation for ionic regulation in reduced salinities.

Why Aren't All Fishes Euryhaline?

If the gill epithelium of all fishes, including hagfishes, possess the ionic exchange systems (for acid–base regulation) that potentially can be used for ionic uptake in freshwater, why aren't all fishes euryhaline? One might propose that intestinal and renal functions are limiting, but these are usually quantitative rather than qualitative differences. Presence of a putative ionic uptake system is qualitative; without it, freshwater osmoregulation is not possible. It appears that the limiting factor for euryhalinity is the efficiency of the ionic uptake systems versus the ionic permeability of the branchial epithelium itself. The best example of this relationship is the finding, nearly 80 years ago, that normally stenohaline marine reef fishes (e.g., angel fish, puffer, gray snapper, and horse-jack) are found in freshwater lakes in the Bahamas and springs in western Florida (e.g., Homosassa Springs). Because these water bodies have relatively high concentrations of Ca^{2+} (studies have shown that it can decrease the passive loss of ions from fishes), it has been suggested that one of the primary limiting factors for invasion into freshwater is the water calcium concentrations and the overall permeability of the gill.

Glossary

Cystic fibrosis transmembrane conductance regulator (CFTR) The chloride channel that allows the passive movement of Cl^- down its electrochemical gradient from the cytoplasm to the outside of a variety of cells. Mutations in the gene for CFTR produce the human disease called cystic fibrosis.

Electrical gradient The gradient of electrical charge across a plasma or epithelial membrane. Positive ions will move from areas of relative positivity to areas of relative negativity; negative ions will move in the opposite direction.

Electrochemical gradient A difference in concentration and charge between two solutions separated by a semi-permeable membrane, including a plasma epithelial membrane, that produces a net movement of an ion by diffusion.

Epithelium A relatively flat tissue (composed of one or a few cells layers) that lines cavities and surfaces in multicellular organisms.

Immunohistochemistry Cellular or subcellular localization of specific molecules by staining them with antibodies labeled with a fluorescent or pigmented material.

Messenger RNA (mRNA) transcripts Messenger RNA sequences coding for proteins specific to a given cell or tissue.

Microvilli Plasma-membrane-bound, cellular extensions that often characterize epithelial cells. They provide for an elaboration of the surface, plasma membrane, and are common, for instance, in intestinal cells that absorb nutrients.

Mitochondrion A cellular organelle that acts as the 'powerhouse' of the cell and produces the chemical energy source adenosine triphosphate, using oxygen as the final electron acceptor.

Mitochondrion-rich cell Cell in the gill epithelium of fishes that has many mitochrondria on the extensive basolateral membrane and expresses relatively high levels of the transport enzyme Na^+–K^+-activated ATPase.

NKCC An ion-translocating enzyme that utilizes a sodium gradient to transport Na^+, K^+, and Cl^- into the cell.

Operculum The covering over the gill chamber of a fish. In most species, movement of the operculum is part of the respiratory cycle.

Osmotic or ionic gradient The concentration gradient of either water or a specific ion. Both water and ions usually flow down their respective gradients.

Introduction

The NaCl and total salt concentration of the plasma of marine teleosts are distinctly below that measured in seawater (specifically table 1 from **Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). This generates both osmotic and ionic gradients across the permeable gill epithelium, leading to potential salt loading and dehydration of the fish. The osmotic loss of water is balanced by oral ingestion of seawater, but this adds to the salt loading of the fish and the need to excrete even more salt. Contrary to mammals, marine teleosts are unable to produce urine that is more salty than the blood. Instead, the pathways for salt secretion that have evolved in fishes are extra-renal. In teleost fishes, these pathways are located in the epithelium of the gills (**see also Design and Physiology of Arteries and Veins**: Branchial Anatomy and **Ventilation and Animal Respiration**: Gill Respiratory Morphometrics), which contains the requisite cell membrane transport proteins and channels that are remarkably similar to those found in a variety of transporting tissues throughout the animal kingdom.

The Mitochondrion-Rich Cell

The teleost gill epithelium is composed of a variety of specialized cells, including pavement cells (PVCs), which predominate (~90%), and a smaller population (~10%) of cells that contain extraordinary numbers of mitochondria and are therefore termed 'mitochondrion-rich cells' or MRCs. Next to the MRCs are accessory cells (ACs), which may be immature MRCs. In the seawater epithelium, the MRCs and adjacent ACs usually form clusters that open into an apical crypt, overlain by surrounding PVCs (**Figures 1**(**a**) and **1**(**c**)). This is to be contrasted with the gill epithelium of freshwater teleosts, which is characterized by the lack of apical crypts, and MRC microvilli protruding between the overlying PVCs (**Figures 1**(**b**) and **1**(**d**)). The MRCs are usually on the trailing edge of gill filaments in both marine and freshwater teleosts, and also may appear on the gill lamellae in some freshwater species.

Fortunately for physiologists, the skin lining the inner surface of the operculum in a few species, most notably the killifish, *Fundulus heteroclitus*, contains about 60% MRCs on a flat epithelium. This opercular epithelium has provided the tissue that has been used to delineate much of what we know about the actual pathways for NaCl secretion by the fish gill, which is a much more structurally complex tissue (**see also Role of the Gills**: Morphology of Branchial Ionocytes). Using the opercular epithelium, research has made clear that the MRCs are the transporting cells because their number correlates well with the rate of transport across the epithelium, and microprobe studies have shown that the current of transport is directly over the MRC. An electron micrograph of the MRC (**Figure 2**) clearly shows why they are termed mitochondrion rich.

Numerous mitochondria line the tubules formed by invagination of the basolateral membrane. In fact, there is very little open cytoplasm in these cells, which has precluded some of the electrophysiological techniques that have been used to delineate the ionic transport steps in other epithelia, such as the vertebrate kidney, bladder, or intestine. For clarity, a single MRC is diagramed in **Figure 3**.

Mechanisms of NaCl Transport across the MRC

When the ubiquitous transport enzyme, $Na^{+}+K^{+}$-activated adenosine triphosphatase (NKA) was first described in the fish gill, it was assumed that it was probably on the apical surface of the MRC, and merely extruded cellular Na^{+} in exchange for seawater K^{+}. However, it was soon found that the NKA was on the basolateral surface, making it unable to directly excrete Na^{+} from the cell.

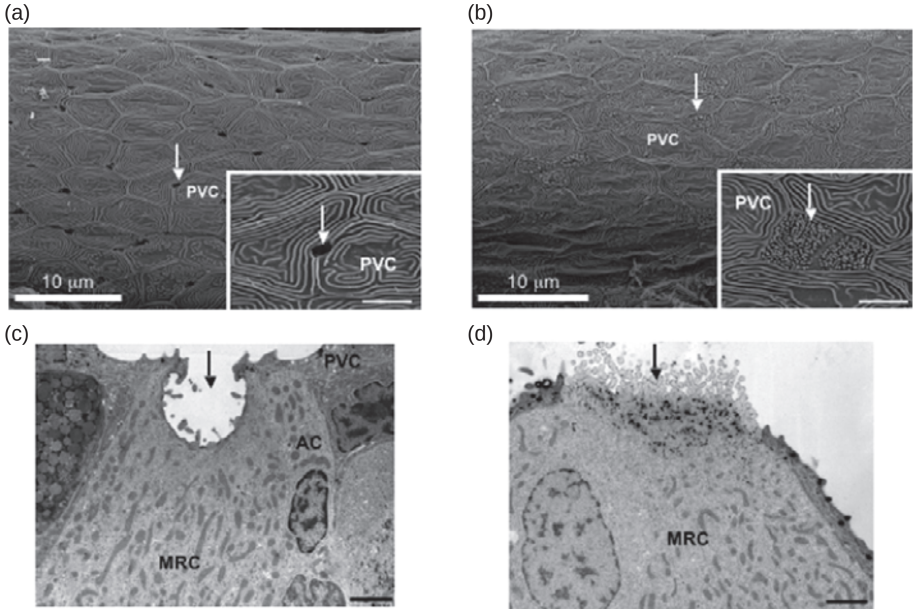

Figure 1 Scanning electron and transmission electron micrographs of gill filaments from killifish in seawater ((a) and (c)) and killifish transferred from seawater to freshwater after 30 days ((b) and (d)). Note transformation of the apical region of MRC (arrows) from a smooth, concave crypt that is recessed below the pavement cells (PVCs) ((a) and (c)) to a convex surface studded with microvilli that extend above the surrounding PVC ((b) and (d)). Also note that an accessory cell (AC) is not associated with the MRC from freshwater-acclimated killifish ((c) and (d)) and that the distinct, whorl-like microridges on the surfaces of PVC do not change with salinity ((a) and (c)). Scale = 1 um, in (c) and (d). (a) MRC from the sole (*Solea solea*) containing numerous mitochondria (m), a tubular system (ts), a subapical tubulovesicular system (tvs), and an apical crypt. ((b) Apical region of an MRC from the killifish. This MRC forms deep tight junctions (**) with surrounding PVC and shallow tight junctions (*) with surrounding accessory cells (AC), which share an apical crypt with the MRC. (a) From Evans (1993) *The Physiology of Fishes*. (b) Modified from Evans DH, Piermarini PM, and Potts WTW (1999) Ionic transport in the fish gill epithelium. *Journal of Experimental Zoology* 283: 641–652; and from Evans DH, Piermarini PM, and Choe KP (2005) The multifunctional fish gill: Dominant site of gas exchange, osmoregulation, acid–base regulation, and excretion of nitrogenous waste. *Physiological Reviews* 85: 97–177.

Subsequent studies demonstrated that the extrusion of Na^+ and Cl^- was linked and became reduced by applying inhibitors of either NKA or the coupled transport of NaCl (via the co-transporter NKCC) to the basolateral side of the opercular epithelium. With the knowledge that both NKA and coupled NaCl transport were on the basolateral membrane, a model for the transepithelial transport of NaCl was proposed that involved basolateral uptake of NaCl, followed by apical extrusion of Cl^- through the same type of Cl^- channel (cystic fibrosis transmembrane conductance regulator (CFTR)) that is defective in the human disease – cystic fibrosis. Sodium is recycled back across the basolateral membrane and then moves down its electrochemical gradient between adjacent MRCs (through relatively leaky cell-to-cell protein strands) into seawater. Even though there is significantly more Na^+ in seawater than in fish extracellular fluids, there is an electrochemical gradient produced by the electrical potential (*c.* +20 mV, extracellular fluids vs. seawater) across the gill epithelium. The net result is the transepithelial secretion of NaCl (**Figure 4**). The K^+ that enters the MRC via the basolateral NKCC appears to be recycled back into the extracellular fluids via a K^+ channel that has recently been described.

Molecular Evidence for Routes of NaCl Transport

The revolution in the technologies of molecular biology has produced a variety of data supporting this model for NaCl extrusion. For instance, the messenger RNA (mRNA) transcripts for all the relevant transport proteins can be extracted from fish gill tissue, and antibodies produced against the proteins can be used in immunohistochemistry to localize CFTR to the apical membrane and NKA and NKCC to the basolateral membrane of the MRC. Moreover, as a fish acclimates to seawater, both the

mRNA and protein for these transport proteins increase, and CFTR moves to the apical membrane. In some cases, the total NKA does not appear to increase, but this has been shown to be caused by the differential decrease of one isoform of the enzyme, which offsets the increase of another isoform. In fact, recent evidence suggests that there are distinct seawater versus freshwater forms of NKA, which may exist in different MRCs.

Glossary

Co-transporter A transporter that is involved in simultaneous transport of two or more different molecules or ions across the cell membrane in the same direction.

Electrogenic (or electroneutral) transporter A transporter for which the transport pathway causes a change (or no change) in the electrical charge. In the case of passive diffusion, the transport is driven down an electrical (or chemical) gradient across the cell membrane.

Exchanger A transporter that is involved in counter-transport of two or more different molecules or ions across the cell membrane in the reverse directions.

Influx (or efflux) The movement of solute or solvent into (or out of) a cell across the cell membrane.

Ionocytes (mitochondrion-rich cells) A function-specific type of epithelial cell, which expresses ion transporters or enzymes and is responsible for transepithelial transport functions of specific ions. In fish gills, ionocytes responsible for ion regulation are named mitochondrion-rich cells based on the characteristic of abundant mitochondria.

Loss of function A gene mutation approach through which the product of the target gene has less or no function, compared to that of the wild type without mutation. In the present article, loss-of-function experiments were conducted by injecting fertilized zebrafish eggs with antisense morpholino oligomers. The morpholinos were designed and synthesized to knock down the function of a specific gene by blocking the protein translation of the target gene.

Morpholino A molecule used to knock down gene translation. This is achieved by blocking access of ribosomal initiation complex to a messenger RNA (mRNA) with modified antisense oligomers, and thus preventing from making a targeted protein.

Orthologs Genes, or peptides expressed by genes, in different species that have evolved from a common ancestral gene.

Scanning ion-selective electrode technique (SIET) A noninvasive electrophysiological approach, which uses ion-selective microelectrodes to measure the strength of specific ions on the surface of an intact organism (or cell). After taking SIET measurements, the intact organism can be subjected to subsequent analyses. SIET is a powerful *in vivo* approach for analyzing ion transport.

Transporter (or enzyme) isoforms Different forms of the same protein transporter (or enzyme), produced either from related genes, or from the same gene by alternative splicing.

Introduction

Freshwater (FW) fish inhabit aquatic environments that vary greatly in their ionic composition and pH (**Table 1**), but uniformly these environments have much lower concentrations of total salts than the fish's body fluids. As a result, all FW fishes are continuously subject to water gain and ion loss due to passive diffusion down osmotic and ionic gradients between the body fluids and FW environment (**Figure 1**). Without ion/osmoregulation, fish in FW would simply expand in volume and die.

Instead, to cope with living in a dilute environment, FW fishes have evolved highly efficient ion/osmoregulatory mechanisms for maintaining a constant internal ionic environment. In addition, their water content varies very little. They compensate for passive water uptake by not drinking water (or drinking very little), while the kidneys produce copious amounts of dilute urine that involves salt reabsorption. They compensate for ion loss by actively

Figure 1 Ion uptake and acid–base regulation mechanisms in freshwater fishes (for details refer to text). Passive water gain and ion loss (bold dashed arrow) mainly occur in the gills. For compensation, fishes produce dilute urine by salt reabsorption (thin solid arrow) in the kidneys to minimize ion loss (thin dashed arrow) and extrude excess water, while actively absorbing salt (bold solid arrow) from the environment through the gills. Internal pH homeostasis is mainly achieved by differentially regulating H^+ and HCO_3^- effluxes across the gills. The kidneys also contribute to the regulation of plasma HCO_3^- levels by HCO_3^- reabsorption (thin dashed arrow). Bold or thin arrow reflects the relative fluxes of ions.

extracting salts from external water across the gill epithelium (**Figure 1**). The gills are responsible for the majority of ion (Na^+, Cl^-, Ca^{2+}, Mg^{2+}, etc.) uptake into the animal, which is mainly achieved through active transport by specific ion-transporting cell types, termed 'ionocytes'. The main ionocyte in the gill of the FW fish is the mitochondrion-rich (MR) cell, formerly called chloride cells (**Figure 2**), and there are several distinct types of these cells. This article reviews what is currently known about the mechanism of Na^+, Cl^-, and Ca^{2+} uptake at the gill and the specific ion transporter proteins or enzymes that move these ions from the environment to the internal body fluids (**Figure 2**).

In FW fish, the biochemical process involved in ionregulaiton (i.e., the maintenance of internal Na^+, Cl^-, Ca^{2+}, and Mg^{2+} levels) cannot be separated from the process of acid–base or pH regulation, because the two processes occur at the same site (the gill) and share common pathways. This is unlike the situation in air-breathing tetrapods, which regulate their internal acid–base status primarily through adjustments to ventilation (respiratory compensation) and urinary acid excretion (metabolic compensation). In contrast, the majority of fishes achieve internal pH balance by adjusting plasma HCO_3^- levels by varying the excretion (efflux) of H^+ and HCO_3^- across the gills (**Figure 1**). Moreover, H^+ and HCO_3^- efflux is mechanistically coupled to the influx of Na^+ and Cl^-, respectively, at the fish gill (**Figure 2**). The kidney of FW fish plays a minor role in maintaining whole-body pH balance relative to the gill.

In order to move charged ions from the water into the fish (or vice versa in the case of acid), the gills use a variety of transport proteins embedded within the membranes of gill ionocytes. These transport proteins first move ions from the fluid on one side of the cell, across a membrane into the cell, and then another set of proteins move the ions across the other membrane into the fluid on the other side of the cell. The cell membrane separating the inside of the gill from the water environment is called the 'apical membrane' and the cell membrane separating the cell from the blood or other cells inside the body of the fish is called the 'basolateral membrane'. The gill cells, like other animal cells, have a negative membrane potential (extracellular medium reference). In addition, the transepithelial potential difference (TEP), which is the voltage across an epithelial cell layer, is

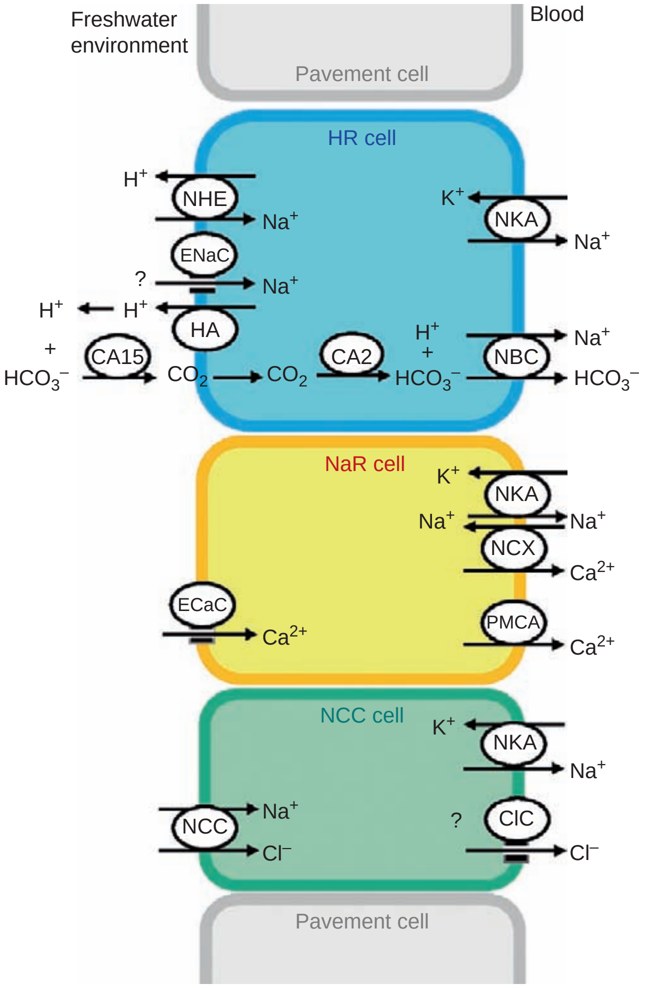

Figure 2 Model of the ion uptake and acid–base regulation mechanisms in zebrafish skin/gill ionocytes. Three types of ionocytes, H^+–ATPase-rich (HR) cells, Na^+–K^+–ATPase-rich (NaR) cells, and Na^+–Cl^- co-transporter (NCC) cells, express different sets of ion transporters and/or enzymes, and are respectively responsible for acid secretion/Na^+ uptake, Ca^{2+} uptake, and Cl^- uptake (for details refer to text). A question mark indicates an unidentified pathway.

generally between −5 and −40 mV (outside FW reference) for FW fish gill epithelia. The gill TEP is sensitive to environmental Ca^{2+} levels (+5 to +10 mV in hard FW) and this switch in polarity has substantial effects on the ion-regulatory pathways in the gill epithelia. These voltage gradients, like concentration gradients, influence how ions are transported across the gill epithelia.

Table 1 shows the considerable variation in the ion composition among different FW environments; pH of FW also varies due to acid rain, pollution, or the accumulation of naturally occurring tannins, especially in waters from peat bogs. Soft water, waters with poor buffering capacity, is especially vulnerable to acidification. The wide variation in ion composition of FW means that FW fish must be able to differentially modulate the uptake mechanisms for each ion to maintain plasma osmolarity and acid–base homeostasis. This is probably one of the reasons why the mechanisms of ion regulation in FW fish appear more intricate than those in saltwater fish and why there has been decades of debate on the precise nature of FW ion regulation (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). The following describes our current understanding.

Na^+ Uptake/Acid Secretion

Ionic gradients between FW environment and FW fish blood favor passive efflux of Na^+ (and other ions) down a concentration gradient, but typically opposed by the TEP. In fact, to maintain internal ionic homeostasis, FW fish gill ionocytes have to actively absorb Na^+ (and other ions) from the water against, in the case of Na, an ~1800-fold concentration gradient (calculated from **Table 1**). At these gill ionocytes, Na^+ uptake from the water is coupled to H^+ efflux from the blood. The gill ionocytes can secrete H^+ from the blood, which becomes acidified due to the metabolic/respiratory acidosis or the impacts of environmental pH fluctuations.

Early studies suggested two models for the apical transport of Na^+ and H^+ in fish ionocytes (**Figure 2**). The first model proposed that protons were actively pumped from the cell into the environment by an apical V-type of H^+-adenosine triphosphatase (ATPase) and that Na uptake in the opposite direction was accomplished by electrically linking the H^+ movement to Na^+ absorption through the apical membrane Na^+ channel (ENaC). The second model proposed an electroneutral exchange of Na^+ and H^+ via an apical Na/H exchange (NHE) protein. There has been much debate, which is far from over, about which model applies to different fish species and various experimental water conditions. According to most models, an apical membrane H^+-ATPase actively pumps H^+ from the gill ionocytes (efflux), which in turn generates a negative intracellular electrical potential. This negative intracellular electrical potential is a driving force to allow Na^+ entry from the water down an electrochemical gradient through the apical ENaC. Molecular physiological and pharmacological evidence supports the role of H^+-ATPases in these pathways; however, so far, ENaC-like proteins have not been identified in fish. On the other hand, theoretical calculation of the ratios of intracellular/environmental concentrations of Na^+ and H^+ suggests unfavorable thermodynamic conditions for the operation of an electroneutral apical NHE in most FW environments. However, other molecular and physiological studies suggest analogous Na^+ uptake/acid secretion mechanisms (**Figure 2**) to those in the mammalian kidney proximal tubular cells, which involve H^+-ATPase and NHE, rather than ENaC as suggested above. In this model, a water-facing membrane-bound carbonic anhydrase (CA) catalyzes the rapid condensation of HCO_3^- from the environment with H^+ secreted by the apical NHE or V-type H^+-ATPase, forming CO_2 and H_2O outside of the apical membrane of gill ionocytes. This mechanism facilitates the passive diffusion of CO_2 into ionocytes. Then, cytosolic CA hydrates CO_2 to form HCO_3^- and H^+. Protons are recycled back into the ambient environment by NHE and H^+-ATPase. This recycling mechanism serves to keep HCO_3^- high in the cell to assist with basolateral Na^+ transport. Basolateral Na^+/K^+-ATPase (NKA) pumps cytosolic Na^+ across the basolateral membrane and provides a negative intracellular potential to drive the electrogenic Na^+ transport of the basolateral Na^+–HCO_3^--co-transporter (NBC), a major basolateral transporter in mammalian proximal tubular cells.

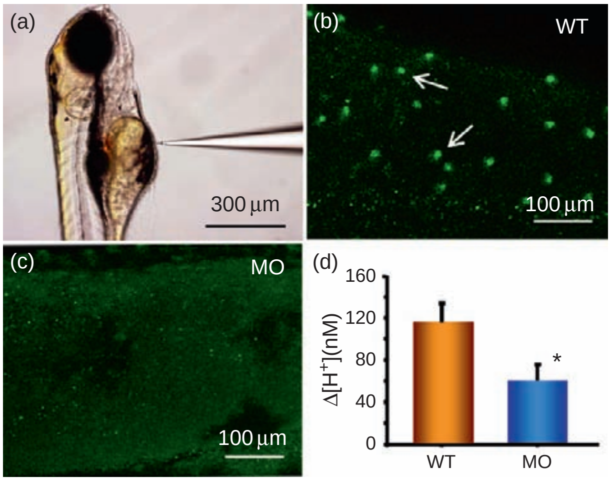

Figure 3 Loss-of-function experiments on zebrafish embryos injected with morpholino oligomers (MO) specific for H^+–ATPase. (a) An ion-selective microelectrode (SIET) approaches an intact embryo for SIET measurement of acid secretion function. (b, c) Compared to wild-type (WT) embryos, embryos injected with MO lost the protein signals of H^+–ATPase (arrow), indicating the effect of translational knockdown of the gene. (d) Knockdown of H^+–ATPase impaired the acid secretion function ($\Delta[H^+]$, difference from the background; measured by SIET, for details refer to text) in zebrafish skin. Mean ± SD ($n = 10$). *Significant difference (unpaired *t*-test, $p \leq 0.05$).

Recent studies in zebrafish (*Danio rerio*) provide the most convincing evidence to support the proximal tubular-like model of Na^+ uptake/acid secretion pathways in FW fish gills (**Figure 2**). These studies used a noninvasive scanning ion-selective electrode technique (SIET) (**Figure 3(a)**) *in vivo* to identify specific ionocytes, which expresses H^+-ATPase on the apical membrane of embryonic skin and secrete H^+ (these ionocytes are called H^+-ATPase-rich cells, or HR cells). In very young zebrafish embryos, the skin serves as the major site of ion uptake and acid–base regulation, because the gills are not fully developed. Loss-of-function experiments using specific morpholinos have shown that knockdown of H^+-ATPase or CA protein amount impacts Na^+ uptake/H^+ secretion in zebrafish embryos, suggesting roles in Na^+ uptake/H^+ secretion mechanisms (**Figures 3(b)–3(d)**). Only HR cells in zebrafish embryonic skin, but not other cell types, accumulated sodium green fluorescence (an *in vivo* marker of Na^+) (**Figure 4**), which was blocked by an NHE-specific inhibitor. Moreover, HR cells co-expressed all the transport proteins essential for this mechanism to work, including NHE3b, membrane-bound CA15a, cytosolic CA2-like a, and NKA.

Cl^- Uptake/Base Secretion

FW fish gill ionocytes can actively absorb Cl^- from the water against a ~4000-fold concentration gradient (calculated from **Table 1**) and secrete HCO_3^-, which

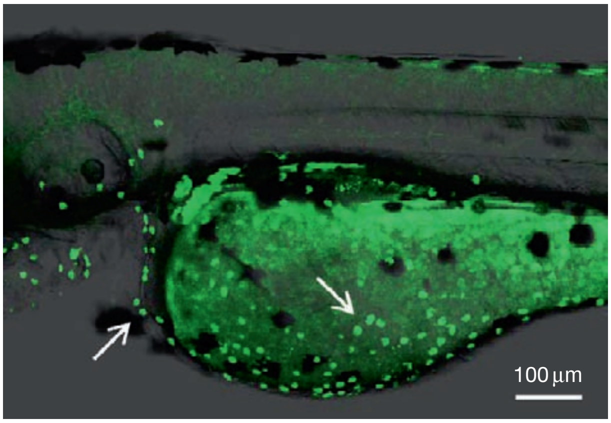

Figure 4 *In vivo* evidence for the Na^+ uptake function in zebrafish skin ionocytes. Accumulation of sodium green fluorescence (arrow) occurs in a group of ionocytes (HR cells; for details refer to the text) in zebrafish embryonic skin.

accumulates in blood due to metabolic processes (CO_2 production) and changes in environmental pH or CO_2. It has long been proposed that Cl^- uptake is closely linked with base (HCO_3^-) secretion; however, compared to our understanding of the mechanisms of Na^+ uptake/acid secretion in fish, even less is known about Cl^- uptake/base secretion.

The central mechanism for Cl^- uptake/base secretion involves a direct exchange of Cl^- with HCO_3^- via an apical anion exchanger (AE). There are at least two different candidate proteins that could play this role in the apical membrane of the gill. They are AE1 (a solute carrier from a group of proteins called SLC4) and pendrin (a SLC26 member). Some physiological and pharmacological data support the possible role of AE1 in the apical transport of Cl^- and HCO_3^-; however, there is still no convincing evidence to demonstrate that an AE is actually expressed in the apical membrane of fish gill ionocytes and functions in apical Cl^- uptake. On the other hand, some other types of Cl^-/HCO_3^- exchangers, several members of the SLC26 family including pendrin, have recently been implicated in Cl^- uptake/base secretion. Recent studies using loss-of-function experiments in zebrafish showed that knockdown of several SLC26 members, namely a3, a4, and a6, impairs Cl^- uptake and HCO_3^- secretion in embryos, strongly suggesting a role in Cl^- uptake/HCO_3^- secretion. However, evidence to demonstrate co-localization of these SLC26 members with basolateral H^+-ATPase or Cl^- channels in the same ionocytes is lacking, and this type of co-localization is necessary for transepithelial base secretion and Cl^- uptake. As a result, this transporter is not included in **Figure 2**.

The Na^+–Cl^- co-transporter (NCC, a member of SLC12) was first discovered in the urinary bladder of a flounder (*Pseudopleuronectes americanus*), and then was demonstrated to be important in the Na^+/Cl^- reabsorption mechanism in the distal convoluted tubular (DCT) cells of the mammalian kidney. Recent studies suggest that an NCC-like protein (termed ortholog) may be involved in Cl^- uptake in fish skin and gills (**Figure 2**). NCC-like protein resides on the apical membrane of specific ionocytes in gills and embryonic skin of tilapia (*Oreochromis mossambicus*) and zebrafish. Loss-of-function studies with NCC-like protein reduced both Cl^- uptake and whole-body Cl^- levels in zebrafish embryos, implicating an NCC-like mechanism in Cl^- uptake. Similar to mammalian DCT cells, Cl^- movement across the basolateral membrane is thought to involve a basolateral Cl^- channel and this channel, along with NCC, has been proposed as one of the mechanisms responsible for transepithelial Cl^- uptake in NCC-expressing ionocytes.

Both the Cl^-/HCO_3^- exchanger and NCC are likely electroneutral; however, importantly, the ion (Na^+, Cl^-, and HCO_3^-) gradients across the apical membranes of gill ionocytes do not appear to favor the operation of the two transporters in FW environments and experiments to resolve these issues are still lacking.

Ca^{2+} Uptake

Unlike terrestrial vertebrates, FW fishes obtain the majority of their calcium via absorption from the aquatic environment rather than through their diet. Gills are responsible for >97% of the whole-body Ca^{2+} uptake and MR cells have long been thought to be the main site for transepithelial Ca^{2+} transport in fish gills. According to the current model for mammals, active transepithelial Ca^{2+} uptake is carried out through the operation of apical epithelial Ca^{2+} channel (ECaC), the basolateral Na^+/Ca^{2+} exchanger (NCX), and plasma membrane Ca^{2+}-ATPase (PMCA). A similar model for Ca uptake has been proposed for fish gills (**Figure 2**). The intracellular Ca^{2+} concentration of gill ionocytes is presumably $<1 \times 10^{-6}$ M, and therefore the gradient appears to favor diffusional Ca^{2+} uptake via an ECaC even from soft FW with $\sim 1 \times 10^{-5}$ M Ca^{2+}. Following the diffusion of Ca^{2+} from the water into the gill ionocyte, cytosolic Ca^{2+} probably diffuses via shuttles (e.g., Ca^{2+}-binding proteins) to the basolateral membrane where Ca^{2+} is extruded out of the cell via the NCX (operating down the Na^+ gradient created by NKA) and PMCA. Only recently has ECaC been identified in fish gill ionocytes and its expression is positively associated with Ca^{2+} uptake in fish. In zebrafish, ECaC and two specific isoforms of NCX and PMCA (NCX1b and PMCA2) are co-expressed in the same ionocytes, providing molecular evidence to support the role of these Ca^{2+} transporters in fish gill Ca^{2+} uptake mechanisms. Among these three Ca^{2+} transporters, ECaC is thought to be the rate-limiting step in transepithelial Ca^{2+} uptake; therefore, its regulation is likely important when coping with environmental changes.

Different Subtypes of Ionocytes

In mammalian kidneys, different types of ionocytes variously express specific ion transporters and enzymes within kidney segments, which each have their own functions. As described earlier, ion uptake and acid–base regulatory mechanisms of FW fish gills are, in some respects (transporter expression patterns and ion-transport pathways), analogous to those of mammalian kidneys. From an evolutionary standpoint, it is reasonable to generalize that FW fish gills also possess similar types of ionocytes (or MR cells) to achieve a variety of distinct ion-transport functions.

The early literature on this subject proposed functional subtypes of MR cells mainly based on cell morphologies, expression of NKA, and/or related ion fluxes. Direct evidence to support the notion of ionocyte heterogeneity emerged only recently with the adoption of molecular/cellular physiological approaches in zebrafish, rainbow trout (*Oncorhynchus mykiss*), and tilapia. In the zebrafish (**Figure 2**), three types of gill ionocytes, HR cells, NKA-rich (NaR) cells, and NCC cells, have been identified mainly based on evidence from double/triple immunocytochemistry/*in situ* hybridization and loss-of-function studies. HR, NCC, and NaR cells were deemed involved in Na^+ uptake/acid secretion, Ca^{2+} uptake, and Cl^- uptake, respectively, based on the specific expression and functioning of distinct sets of ion transporters and enzymes as described earlier.

In rainbow trout, two subtypes of MR cells have been identified based on their ability to bind peanut lectin agglutinin and are termed PNA^- and PNA^+ MR cells, which show high expression of H^+-ATPase and NKA, respectively. A series of *in vitro* physiological and pharmacological studies demonstrated the distinct ion-transport functions of the two MR cell types: H^+-ATPase-dependent Na^+-uptake by PNA^- cells and Ca^{2+} uptake (via the ECaC) by PNA^+ cells. However, convincing data to support the existence and function of other transporters or ion channels in MR cell types are still lacking. Using immunocytochemistry, MR cells in tilapia skin/gills were classified into four types: type I which shows only basolateral NKA staining, type II which shows basolateral NKA and apical NCC staining, type III which shows basolateral NKA/$Na^+-K^+-2Cl^-$ co-transporter (NKCC1a) and apical NHE3 staining, and type IV which shows basolateral NKA/NKCC1a and apical cystic fibrosis transmembrane conductance regulator/NHE3 staining. Based on the distinct expressions of NHE3 and NCC, zebrafish HR and NCC cells are likely respectively analogous to tilapia type II and III MR cells. However, there is no direct physiological data to demonstrate the functions of these subtypes of MR cells in tilapia so far.

Functional Regulation to Cope with Fluctuating Environments

As suggested above, fish regulate transport functions and capacities of gill ionocytes and their proteins to maintain ion and acid–base homeostasis in fluctuating FW environments. Many studies report that acclimation to low-Na^+ (or -Cl^-, -Ca^{2+}) or low-pH FW can lead to an increase in Na^+ (or Cl^- and Ca^{2+}) uptake or proton secretion in gills (or embryonic skin) as a compensation. Upon exposure to a new environment, gill ionocytes must be able to adjust their transporter activity and function quickly in order to prevent large changes in blood ion and acid–base composition. In tilapia embryos, acute exposure to low-Cl^- FW converted inactive to active ionocytes after only 4 h and stimulated Cl^- uptake within 24 h. After 48 h, the number of ionocytes increased. Similarly in zebrafish, embryonic skin HR cells altered apical surface structure and acid secretion within 10–120 min after acute transfer from pH 7 to pH 4. These rapid changes appear to involve the trafficking of transporter proteins between intracellular compartments and apical cell membranes, as reported for ionocytes of the mammalian kidney. A recent loss-of-function study in zebrafish embryos indicated that blocking the function of Nherf1, a regulator of apical trafficking of ion transporters that includes NHEs, impaired the Na^+ uptake function of HR cells.

With longer acclimation (days to weeks) to ion-deficient or acidic FW, numerous studies involving a variety of fish species report increases in the number and/or activity of ionocytes in gills. Whether the increase in the number of cells is mediated by the proliferation and differentiation of newly recruited ionocytes is an important, but unresolved issue. In tilapia embryos, most (75–90%) skin ionocytes survived 24–96 h after transfer to low-Cl^- FW, indicating little ionocyte turnover and only <10% of ionocytes are new recruits, presumably originating from undifferentiated cells. However, recent studies on zebrafish shed new light on the mediation of cell proliferation and differentiation in the functional regulation of ionocytes during acclimation to fluctuating environments. In zebrafish, acclimation to acidic (pH 4) FW for 3–4 days induced a compensatory enhancement in acid secretion, which was achieved not only by increasing the number of HR cells but also by increasing the acid-secreting function of individual cells. Examination of expression of p63 (a marker for the epithelial stem cells) and GCM2 (a transcription factor regulating HR cell differentiation) further demonstrated that additional HR cells in acid water had differentiated from ionocyte precursor cells and also from newly proliferating epithelial stem cells.

Summary

Taken together, fish appear to cope with harsh environments with different compensatory strategies. These include: (1) acute modulation of existing mechanisms (transporters and ionocytes) and, for long-term acclimation, (2) increasing the number of ionocytes (through cell proliferation and/or differentiation) and synthesizing new transporters, resulting in an enhancement of the overall ion-regulatory function.

Glossary

Basolateral tubular network A network of membranous tubules that are thought to be an internal extension of the basal plasma membrane of chloride cells of the gill. The network runs throughout much of the basolateral (inside facing) portion of the cell and there is speculation that tubules may be permanently or temporarily connected to lateral plasma membranes of chloride cells and consequently be connected to the paracellular space (between cells).

Mitochondrion-rich cells This is often synonymous with branchial chloride cells but is a broader category, because not all mitochondria-rich cells are necessarily chloride cells (engaged in chloride transport). As the name suggests, mitochondrion-rich cells are recognizable due to their preponderance of mitochondria, which suggests that are metabolically very active and may potentially be involved in active ion transport.

Osmoregulation/osmotic homeostasis Osmoregulation is, generally speaking, the regulation of the internal osmotic environment. In fish, this has many physiological and/or biochemical components. Physiologically, this would include the control of (1) the permeability of the gills to ions and water, (2) the rate of drinking and water and ion intake from the diet, and (3) the loss of ions and or water from urine production. These together control the osmolality (osmotic concentration) and overall volume of body fluids and produce osmotic homeostasis (maintaining the osmolality of body fluids at a constant level). Biochemically, this would include the net effect of water gain or loss and ion excretion or absorption processes across the gills. Ion absorption in the esophagus. Ion and water absorption or secretion in the intestine and kidney, and water absorption in the urinary bladder.

Osmolality This as a simple definition is the number of moles of dissolved particles per liter of solvent (usually water). However, in reality the osmotic effect of dissolved substances varies from one compound/molecule to another (due to differences in hydration shells and, for larger molecules, surface area to volume ratios) and would therefore need to be calculated taking into account osmotic coefficients of the individual component solutes of a solution. In practice, it is usually measured empirically.

Osmosis Essentially diffusion for water molecules. As with diffusion for dissolved solutes, water moves due to random thermal oscillations, in a net sense, from where there is a higher water concentration (amount per unit volume) to where there is a lower water concentration. This is generally inversely related to the situation for dissolved solutes, as higher levels of these occupy space leaving less space for water and reducing its concentration. Water therefore (again in a net sense) moves from where the osmolality is lower to where it is higher (the opposite of what occurs for the diffusion of solutes).

Paracellular/transcellular pathways/transport Transport of solutes or water across an epithelial cell layer involves two different pathways, either transcellular (through the cell, i.e., crossing the basolateral and apical plasma membranes usually through transporter proteins) or paracellular (between the cells where there is a small paracellular space and transport would involve diffusion, osmosis, or bulk flow, but this is crucially determined by the permeability properties of the tight junctions that seal off the basolateral side (internal environment side) of epithelial cell layers from the apical side (external environment)).

Introduction

Water homeostasis in fish can be broken down into different components. Overall, the total body fluid volume is a key parameter; however, this is made up of intracellular (cell) volume and extracellular fluid volume. As the water transport performed by cells and tissues is thought to be a passive process, this is driven by or considerably impacted by ion and osmolyte movement. Teleost and other fish species occupy a variety of osmotic environments and the nature of the fish's environment determines the osmoregulatory mechanisms that are employed to achieve both ion and water homeostasis.

In freshwater (FW) teleost fish, the main osmotic problem is the continuous ingress of water due to osmosis, as FW, while variable, is of low osmotic strength, whereas a fish's body fluids are of much higher osmolality. Consequently, there is a net influx of water across permeable body surfaces, particularly the gills. FW teleost fish deal with the continuous inflow of water in a similar way to mammals, by producing large quantities of dilute urine to eradicate the water from the body. Some additional ions may be reabsorbed by the urinary bladder. However, as these mechanisms cannot produce a urine output of pure water, some ions are lost in the process and these have to be regained by specialized ion transporting cells of the gill, called 'chloride cells' or 'mitochondria-rich cells', or through the diet (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes).

Marine teleost fish have the opposite osmotic problem with their FW counterparts, in that seawater (SW) is of considerably higher osmotic strength than that of the body fluids; therefore, fish tend to lose water to the external environment across permeable body surfaces. The fish counteracts this in a manner that might not be anticipated; they drink SW to regain the lost water. Of course, this is somewhat counterintuitive as it also results in the ingestion of a considerable salt load. The imbibed SW is first desalinated down to approximately isosmotic levels before passage through the stomach where little change in osmolality of the fluid is thought to occur. When the fluid reaches the intestine, further salts and water are absorbed into body fluids, resulting in around 90% of the imbibed fluid being absorbed and the equivalent of 10% then being excreted rectally. The salts absorbed from intestinal fluid are then excreted across the surface of the gills by mitochondria-rich cells (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). This achieves an uptake of fluid that counteracts dehydration.

In addition to stenohaline FW or marine fish species, there are also some (euryhaline) fish species capable of survival in a wide variety of osmotic environments, including FW up to many times the osmotic strength of SW. Euryhaline species have been widely used to study osmoregulation and water homeostasis, as differences in the mechanisms operating in different osmotic environments can easily be identified and studied. However, euryhalinity has evolved independently numerous times in teleosts; thus, the precise natures of the mechanisms differ between species.

Overall, the general mechanisms of ion and water homeostasis in diverse fish species have been known for some time and a great deal is known about the molecular aspect of ion transport in many of the major osmoregulatory organs (gill, esophagus, kidney, intestive, and urinary bladder). However, much less is known of the molecular aspects of water transport, which is the focus of this article.

General Aspects of Osmosis

One of the important factors concerning water homeostasis, particularly in external environments that are not in osmotic equilibrium with the fish's internal fluids, is that all tissues/organs interacting with the external milieu have epithelial barriers composed of cells. These epithelial barriers control the flow of substances into and out of the body and its composition and ability to control the flow of water is crucial to water homeostasis. All the major osmoregulatory organs, including the skin or integument, have an epithelial barrier composed of cells. Between these cells occur tight junction complexes that seal off one side of the epithelium from the other. Conventionally, the part of the cell facing the outside world is the apical plasma membrane domain and that facing the inside of the body are the basolateral membrane domains. The tight junctions, as well as sealing off one side of the cell layer from the other, also prevent movement of plasma membrane components from one membrane domain to the other. An additional consequence is that the fluid composition on either side of the epithelial layer can be different, creating gradients for the various dissolved substances. Osmotic gradients can also exist on either side of the epithelial and these may drive the flow of water from one side of the epithelium to the other depending on the permeability of the epithelium to water.

As a consequence of the composition of the epithelial barrier, water can really only flow across these barriers via two main routes – either through the cell (transcellular) or, between the cells, through the tight junctions (paracellular). Concerning the transcellular route, it is generally considered that small amounts of water can pass between temporary gaps between phospholipids of the plasma membranes of cells, allowing some water to move into or out of the cell. Otherwise water must go through some kind of transporter or channel in the membrane and this usually involves transmembrane proteins (**Figure 1**). By far, the most widely studied water transport membrane proteins are the aquaporin (AQP) water channels discovered by Preston and Agre in 1991, for which Peter Agre received the Nobel prize for chemistry in 2003. As the name suggests, these allow water molecular to cross the plasma membrane passively (i.e. depending on the prevailing osmotic gradients) through

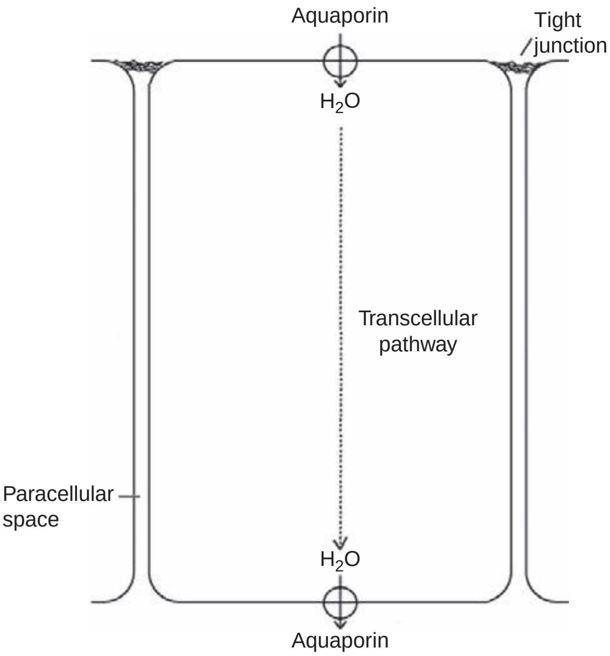

Figure 1 Cartoon of the transcellular water transport pathway.

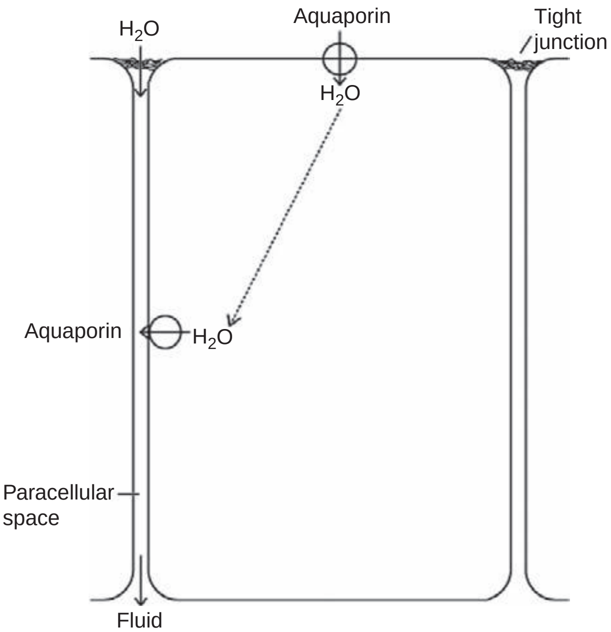

Figure 2 Cartoon of possible routes for paracellular water transport.

(often exclusively) water-selective channels they form in the plasma membrane.

Concerning the paracellular route for water movement across an epithelium (**Figure 2**), water can move by osmosis between the cells depending on the water permeability of the tight junctions. Tight junctions are composed of various proteins of which the main two are occludins and claudins. The exact type, or combination of types of claudins (in particular) that are present, seems to determine the overall water and ion permeability characteristics of tight junctions. Due to the theory concerning osmosis, it is generally the case that water flows down osmotic gradients toward solutions with a higher osmotic strength. However, there may well be situations where water can be transported isosmotically or even against an osmotic gradient as suggested by Diamond in the 1960s. What is necessary for this transport to occur is a locally occluded area that has a standing gradient of solutes and can attract water locally even when the overall osmotic gradient would otherwise be unfavorable for net water transport. Such areas could potentially be created inside cells (if the plasma membrane is invaginated) or between cells (i.e., in the paracellular space). In fish osmoregulation, there are at least two places where this may be relevant. First, this may occur in mitochondria-rich cells of the gill that have an extensive internal invagination of the basolateral plasma membrane. Second, the surface epithelial cells of the intestine may utilize such a mechanism in their paracellular spaces.

Water absorption against an apparent osmotic gradient has been shown to occur in the eel intestine and this may at least partly be explained by the actions of Na^+/K^+-ATPase, an enzyme that is thought to be predominantly laterally located and would continuously transport sodium ions into the paracellular space, elevating the local osmotic concentration. Water may then flow from the intestinal lumen (space in the center of the intestine) across permeable tight junctions or transcellularly through water transporting membrane proteins such as AQPs located in the apical and lateral plasma membranes. The arrival of water by osmosis creates an expanded volume and/or hydrostatic pressure in the paracellular space that would tend to force fluid to flow out of the space to the basolateral side of the epithelium.

The final considerations necessary, when thinking about water transport, are the hydration shells of solutes, solvent drag, and bulk fluid flow. All dissolved solutes have a hydration shell of water molecules but this varies depending on the ions or molecules concerned. In general, for small molecules and ions, it is reasonable to think that the osmotic effects of 1 mol of a dissolved substance are similar to 1 mol of another dissolved substance (e.g., 1 mol sucrose compared to 1 mol of sodium ions); however, this is not the case with large macromolecules such as proteins. Consequently, it may be necessary to consider the osmotic coefficients of dissolved substances to fully understand a solute's osmotic effect. These coefficients take into account the moles of water temporarily attached in a hydration shells per mole of solute. When solutes are moved across membranes by transport proteins, it is not yet clear whether or to what extent the hydration shells are removed during the transport process. If hydration shell removal is not complete, some water will be transported along with the solute and this process is known as solvent drag. Furthermore, when fluid is transported in a mechanical fashion (e.g., due to force from hydrostatic pressure), which is known as bulk flow, this occurs irrespective of the solute content of the fluid and consequently dissolved substances can potentially be transported against their gradients.

Gill Water Transport

Due to the large surface area (roughly 70% of the total body surface) of the gill required for gas exchange, the gill represents the main site of water movement and therefore is an important barrier to examine. Although it is difficult to measure accurately, gill osmotic water permeability (net gain/loss of water) is thought to be greater in stenohaline FW teleosts than in marine teleosts and increases with increasing size of the fish and with increasing temperature. Some euryhaline teleosts such as eels also show a similar trend having greater gill osmotic water permeability in FW, whereas other species such as trout and flounder have gill permeabilities that are the same or greater in SW than in FW.

There are three main routes for water movement across the gill cell membranes and each route can probably be regulated to a degree. The first route involves water moving directly through the plasma membrane lipids. There is some evidence that cholesterol in the apical membrane of gill cells may decrease the permeability, and therefore changes in the amount of cholesterol present may change the permeability of the gill cell membranes.

The second pathway for water movement across gills involves the paracellular system and/or the basolateral tubular system of mitochondria-rich cells. The characteristics of the gill cell tight junctions differ between FW and SW acclimated fish, particularly between mitochondria-rich cells and their adjacent cells. In FW fish, tight junctions are deeper with increased numbers of strands, whereas the tight junctions in SW-acclimated fish are thought to be shallow (i.e., with lower numbers of strands). Recent research suggests that a number of claudin tight junction protein isoforms may be differentially expressed and regulated in FW compared to SW acclimated fish.

There are around 56 claudin isoforms (numbered 1–33 with additional duplicate copies of most types) in the pufferfish (genus *Fugu*) genome, and there are probably more present in other fish species. Studies suggest that gill claudins 3(a,c), 4, 8(d), and 30 show gill mRNA and/or protein expression at higher levels in FW-acclimated compared with SW-acclimated euryhaline fish. By contrast, claudin 10(e) shows increased mRNA expression in SW-acclimated fish gill relative to the FW gill. Clearly, differences in the makeup of tight junction proteins in different environments could affect the permeability characteristic of the tight junctions and affect water flow through the paracellular system. However, it is not yet clear what combinations of claudins in the tight junctions lead to what permeability characteristics.

Depending on the nature of the basolateral tubular network in mitochondria-rich cells and how this system interacts with the paracellular system, it may be involved in generating standing osmotic gradients within the tubular system lumen and possibly by extension in the paracellular system (**Figure 3**). If this were

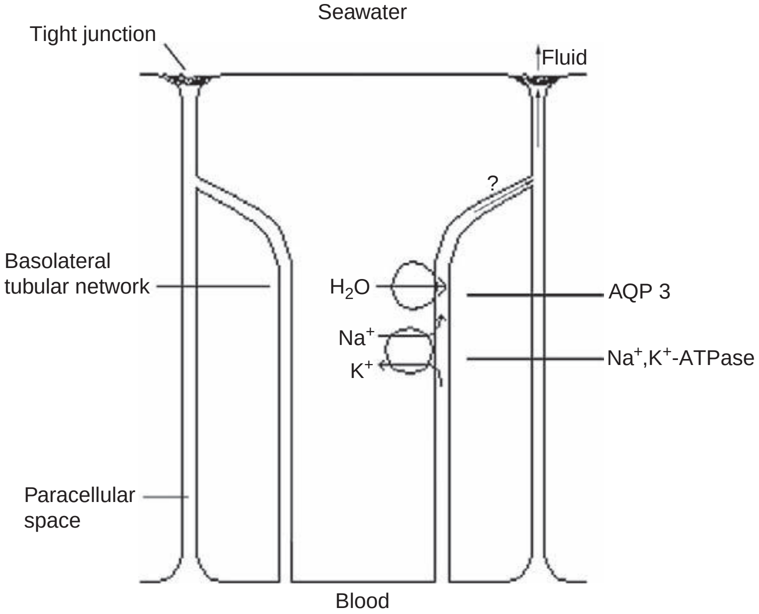

Figure 3 Cartoon diagram of possible gill mitochondria-rich cell fluid transport.

true, it would impact water flows through the paracellular system either through osmosis or possibly even through some kind of bulk fluid flow mechanism. However, this is as yet unproven and is consequently purely speculative.

The third potential route for gill water flow involves a transcellular route through the cell via AQP water channels in the cell membrane. In mammals, AQP isoforms are numbered from 0 to 12 and where the counterpart genes have been identified in fish, similar nomenclature has been used. Some fish AQPs are not clearly identifiable as counterparts of mammalian AQPs or are duplicate copies, and have been named differently. Many studies have shown that there is up to a 97% increase in mRNA and protein levels of AQP3 in the gills of euryhaline teleosts when acclimated from FW to SW. Furthermore, various studies have shown that AQP3 is expressed in mitochondria-rich cells and sometimes in surface pavement or respiratory cells, especially in epithelial cells covering the branchial arch of the gill. In the mitochondria-rich cells, AQP3 expression is localized to the basolateral tubular network but there is also a pool of AQP3 protein located in the apical pole of these cells but not in the apical plasma membrane itself.

The precise function of AQP3 in the SW mitochondria-rich cells is unknown; however, several hypotheses exist. First, AQP3 may be necessary to provide water as a substrate for the enzyme carbonic anhydrase in the cell. Second, AQP3 may play an important role in osmosensing (sensing the osmotic concentration as part of a regulatory response to changes in osmolallity; **see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmosensing). Third, it is present in the cell as an exit pathway for water that is likely to inundate the cell when the fish experiences an FW environment. Finally, it may provide a flow of water to the basolateral tubular network, if this generates an osmotic standing gradient that produces fluid flow due to hydrostatic pressure. All these roles and other possibilities have some merit but again are purely speculative. Infusions of the hormone cortisol have been shown to downregulate gill AQP3 mRNA expression in FW fish. This suggests that cortisol, which is elevated during SW acclimation, may be at least partially responsible for the decreased expression of AQP3 in SW-acclimated fish (**see also Hormonal Control of Metabolism and Ionic Regulation**: The Hormonal Control of Osmoregulation in Teleost Fish).

Gastrointestinal Water Transport

In SW, teleost fish drink to counteract the effects of dehydration due to water loss across the gills. Imbibed water is first desalinated in the esophagus and this is thought to occur due to ion absorption via secondary active (ion exchangers) rather than active transport (directly due to Na^+,K^+-ATPase or V-type H^+-ATPase ion pumps). It has long been thought that there is very little net water movement across this epithelium and as a consequence the epithelium has been labeled as 'tight' with low permeability. Despite this notion, the small amount of data available suggest that the unidirectional water fluxes (flows in each individual direction) may be quite high. High unidirectional fluxes however may still yield low net fluxes if the inward flux is of similar magnitude as the outward flux, consequently canceling each other out yield low net flux measurements. Of course, the ion absorption/desalination is a dynamic process beginning at the mouth, and water transport studies usually use the whole esophagus, so it is possible that at the anterior (head) end there may be a net loss of water to the imbibed fluid in the lumen due to osmosis, cancelled out by a matching net water absorption toward the posterior end of the esophagus, where the osmotic concentration of fluid would be much more favorable for this to occur. Unfortunately, there are no data available to know whether these hypotheses are correct. One thing that is becoming apparent is that the esophagus expresses a number of different AQP isoforms. AQP mRNA expression, including AQP3, AQP1 and its duplicate copy (ADP1dup), and other AQP transcripts, have been shown to be present in the eel and may play a role in protecting surface cells from the dehydrating effect of the SW in the esophageal lumen. However, the actual role these AQPs play is yet to be determined.

Following desalination of the imbibed SW in the esophagus, it then passes into the stomach where it is generally thought that there is no further change in the osmolality or fluid volume. Once the desalinated fluid reaches the intestine, further salts are absorbed together with water. The water absorption is tightly coupled to salt absorption. Divalent cations (e.g., Mg^{2+}) precipitate with carbonates in the lumen, taking these ions out of the osmotic equation and ultimately allowing more water to be absorbed. What is not clear is how the water is absorbed from the lumen. Water absorption could occur via a paracellular system or through a transcellular route, probably involving AQPs, or water uptake could involve a mixture of the two processes (**Figure 4**). Part of the reason why salt and water absorption are tightly coupled is due to osmosis, where water follows salts that have elevated the osmotic concentration. It is also possible that standing gradients are generated in the paracellular spaces due to the action of Na^+/K^+-ATPase located on the lateral side surfaces of the tall columnar epithelial cells that are the predominant cell type lining the intestinal lumen. This would lead to the continuous elevation of the paracellular sodium concentration and this region of elevated osmotic concentration would draw in water from the intestine lumen. There are two possibilities of

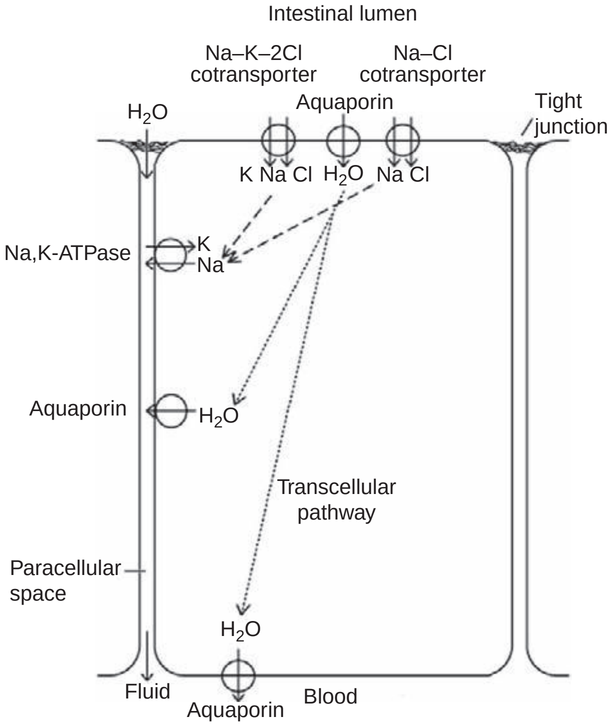

Figure 4 Cartoon of an intestinal enterocyte and possible routes for water transport.

where the water could come from. First, across the tight junctions, if these are permeable to water, and/or second from any AQP water channels located in the lateral membranes of the cells. Either way, the expansion of fluid volume in the space would produce hydrostatic pressure to push fluid out at the open end of the paracellular space on the basolateral side of the cell layer. Currently, there is only limited evidence for the lateral localization of AQPs on this cell type in some teleosts. However, there is indirect evidence suggesting that standing gradients may exist, as fish such as eels have been shown to be able to absorb water against an apparent osmotic gradient.

Recent evidence suggests that different portions of the intestine may rely on different modes of water transport. In the puffer fish (genus *Tetraodon*), there are data suggesting that the depth or number of strands in the intestinal epithelium tight junctions increases toward the posterior end of the tract leading to a decreased permeability. Overall, this suggests that at least in the puffer fish, there is the potential to absorb less water toward the posterior segments of the gut such as the rectum. However, it may also suggest a switch to a more transcellular path for water absorption, possibly involving AQPs toward the end of the intestine/rectum. There are also changes in the distribution of tight junction (claudin 3) isoform proteins along the intestine, and the expression of claudin 3 isoforms also changes with acclimation of fish from FW to SW. Several AQP isoforms are expressed in the intestine. AQP3 is thought to be located in macrophages in the intestine and mucus cells in the rectum and probably plays no role in water uptake. Likewise, AQPe/SbAQP (possible mammalian AQP10 counterpart) is expressed in intestine but may be located in tissues underlying the epithelium; thus, it is unlikely to be involved in water uptake. More interesting is the potential role of AQP1 and AQP1dup. In eels, AQP1 is expressed in the apical (brush border) membranes of intestinal tall columnar surface epithelial cells and in blood vessel endothelium. In FW-acclimated eels and sea bass, AQP1 protein and mRNA expression levels are higher toward the posterior end of the gut, and when fish are acclimated to SW eel, mRNA levels increase by up to 25-fold higher than in FW. These elevated levels found in SW fish mimic the infusion of cortisol into FW fish, suggesting that cortisol contributes to the regulation of AQP1 mRNA. Localization studies suggest that eel AQP1 protein is expressed in surface epithelial cells and mainly found near the sphincter delineating the posterior intestine from the rectum. Clearly, this protein is in a location that suggests that it may be involved in water uptake but that is yet to be demonstrated directly. The situation for AQP1dup is more variable between species, showing only sporadic expression in eel intestine. AQP1dup counterparts (AQP1o/AQP1b) are expressed in the intestine of sea bream but not in sole or zebrafish. In sea bream the expression pattern is somewhat different, where AQP1a is expressed in apical (brush border) and lateral membranes of tall columnar surface epithelial cells in the duodenum and hindgut, whereas AQP1b, not AQP1a, is expressed in rectum. Sea bream AQP1a protein expression was downregulated in all gut segments with SW to FW acclimation, whereas AQP1b protein levels only decreased in the rectum and this response was quite variable between individual fish.

Renal Water Flows

One of the most important facts to realize about the teleost kidney is that some fish are aglomerular, which means that they have renal tubules without a glomeruli that filters fluid from the blood into renal tubules (**see also Role of the Kidneys**: The Kidney). Consequently, some fish species have renal tubules that produce urine entirely due to secretion (transcellular fluid movement from renal tissue fluid) into the tubule lumen. In all probability, all fish and possibly all animals have the possibility to secrete fluid into the renal tubule. In marine fish, fluid secretion probably occurs to enhance divalent cation secretion since fish cannot make significantly concentrated urine. As this would contribute to water loss, urine production tends to be the minimum needed for this purpose. In FW fish, fluid secretion may be a mechanism used to increase renal (fluid, i.e., water) output, and while salts are transported into the tubule lumen along with water, these salts can mostly be reabsorbed further down the renal tubule (in more distal segments) probably due to the action of NaCl cotransporters (NCC and NKCC2). The consequence of this from a water homeostasis point of view is that there are two (in some ways opposing) water transport mechanisms occurring in the renal tubule. First, the proximal tubule secretion and second, in the distal segments, there is a mechanism for water reabsorption. Mammals are able to produce hyperosmotic concentrated urine due to water reabsorption using AQP2. Teleost fish do not possess an AQP2 homolog and this may be the main reason why fish cannot concentrate urine. Other AQP isoforms are however present. AQP3 is expressed in the renal tubule but its location is unknown. By analogy to mammals, it is most likely located in a distal segment and may be involved in the process of reabsorption. AQP1 and AQP1dup are also expressed in the kidney and their mRNA levels have been shown to decrease when eels are transferred from FW to SW. This is the opposite of what might be expected if fish renal tubules were only engaged in reabsorption and it consequently suggests that AQP1 and AQP1dup may be involved in the fluid secretion mechanism.

Urinary Bladder

The urinary bladder of SW teleosts can also reabsorb water (and monovalent salts) and this further concentrates urine divalent cations. The mechanism of salt reabsorption varies from species to species, probably involving cotransporters (NCC in flounder; NKCC2 in eel) or ion exchangers (a Na^+/H^+ exchanger and Cl^-/HCO_3^- exchanger in trout). The purpose of the NaCl reabsorption in the urinary bladder is essentially to allow further reabsorption of water (to reduce dehydration) and this has the secondary consequence of concentrating divalent cations. The mechanism of water reabsorption, transcellular or paracellular, is currently unknown.

Glossary

Cytokine A biologically active peptide or small protein that mediates systemic and cellular signaling.

Euryhalinity The ability of an organism to tolerate a wide range of environmental salinity.

Hormone Signaling molecule released by a cell that either stimulates the cell of origin (autocrine), nearby cells (paracrine), or travels via the bloodstream to distant cells (endocrine).

Hyposmotic Containing a lesser concentration of solutes than another solution.

Hyperosmotic Containing a greater concentration of solutes than another solution. If the solutions are separated by a permeable membrane (such as gill epithelium), solute will diffuse from a hyperosmotic to a hyposmotic solution and water will move from the hyposmotic to hyperosmotic solution.

Mechanosensory The ability of cells and organisms to recognize and measure mechanical forces.

Signal transduction A process by which an extracellular signal (e.g., a hormone, the first messenger) initiates intracellular processes; generally involves a receptor, linking proteins, an enzyme that generates a second messenger (e.g., cAMP), that activates downstream protein kinases which alters regulator-phosphorylation patterns.

Why Do Fishes Need to Sense Environmental Salinity?

Fish inhabit all but the most extreme aquatic habitats, ranging from freshwater (FW) to hypersaline. Some species can even survive extended periods in completely dried up riverbeds and ponds. Many of these habitats are also characterized by greatly fluctuating salinity. Examples include desert salt lakes, the marine intertidal zone, estuaries, and salt marshes (**see also Intertidal Fishes**: Intertidal Habitats). In addition, global climate change is predicted to cause an overall decrease in ocean salinity and a rise in sea level that could greatly alter the salinity in large areas of low-altitude estuarine areas. Because of these environmental salinity fluctuations that occur in many habitats, it is important to understand how fishes sense changes in the salinity of their environment to trigger appropriate acclimatory responses. Moreover, since fishes constitute by far the most diverse group of vertebrates with greatly differing abilities to tolerate salinity fluctuations, they provide a great system for understanding how euryhalinity (the ability to tolerate a wide range of environmental salinity) has evolved. Evolvability (the rate of evolutionary change) of salinity tolerance depends on many variables, including the number and properties of key genes involved in salinity tolerance and osmosensing.

Of the three main taxa of fishes (Agnatha, Chondrichthyii, and Actinopterygii), only the ray-finned fishes (actinopterygii, largest group = bony fishes, teleosts) are osmoregulators that maintain a constant osmotic concentration in their extracellular body fluids (blood plasma, interstitial fluid, etc.) when the environment changes, much like the other vertebrate classes. The osmolality of teleost blood is approximately 300–350 mosmol kg^{-1}, corresponding to a salinity of about 10 parts per thousand (ppt) or roughly one-third of that of the oceans (35 ppt). FW fishes have plasma that is hyposmotic to the environment (FW < 0.4 ppt), whereas seawater (SW) fishes have plasma that is hyperosmotic to the environment (SW = 35 ppt). Nevertheless, the osmolality of extracellular body fluids such as plasma is roughly equal in both FW and SW fish (*c.* 300–350 mosmol kg^{-1}) and the mechanisms of salt movement involved in maintaining this osmolality in these different environments is outlined elsewhere (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**:

Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes).

To activate the appropriate mechanisms of salt transport (secretion or absorption), fish must be able to sense the salinity (osmotic concentration) of their environment. In particular, euryhaline fish that move between hyposmotic and hyperosmotic environments need to accurately monitor environmental salinity to activate either salt secretion or salt absorption to the appropriate degree that is necessary to offset passive ion movements between extracellular fluid and the external milieu. Therefore, osmosensing mechanisms are required to monitor environmental salinity and control signaling networks, which are responsible for tuning the direction and the mechanisms of active, transepithelial salt transport in fish. Despite the clear importance of osmosensing in fish, the entire field is underdeveloped relative to other aspects of ionregulation in fish (e.g., the mechanisms for ion transport; (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes). The exception is the knowledge of the actions of osmoregulatory hormones and the regulation of short-circuit current and ion transport across opercular epithelium, which is an experimental model with ion transport properties similar as gill epithelium.

Basic Principles of Osmosensory Signal Transduction

It has become clear during the past decade that the vertebrate (including fish) osmosensor systems are quite different and much more complex compared with those of unicellular organisms and invertebrates. This is true even though the molecular and cellular triggers are similar and both groups use similar proteins for osmosensing. The main difference is due to increased complexity, functional differentiation, and more elaborate signaling contingencies in vertebrates. The once-prevailing notion of a single or a few specific osmosensor(s) connected to a handful of osmosensory pathways that control the multitude of osmoregulatory effector mechanisms is now obsolete.

Instead, it is likely that osmosensory input at the cellular level of vertebrates is integrated from a large number of molecular osmosensors, each of which monitors a different event associated with a change in environmental salinity. Such osmosensors may include specific ion sensors, membrane stretch-activated channels activated, molecular chaperones that monitor protein folding efficiency, DNA damage sensors, and cytoskeleton-associated proteins. At the organismal level, coordination of acclimatory responses to salinity change is achieved via cytokines, hormones, and neurotransmitters. There is evidence for the existence of both central (e.g., systemic osmoreceptors) and local osmosensors. Central osmosensors sense changes in plasma osmolality, whereas local osmosensors have the potential to sense direct external osmolality changes (e.g., gill epithelial cells) in addition to plasma osmolality changes. Experiments with isolated opercular membrane preparations of killifish (*Fundulus heteroclitus*) indicate that a reduction of Cl^- secretion can be rapidly initiated via alpha2-adrenergic receptors and inositol-3-phosphate (IP3), suggesting an involvement of the sympathetic nervous system (SNS) in osmosensing. Central osmosensors of fishes also include systemic osmoreceptors and baroreceptors that monitor plasma osmolality, extracellular fluid volume, and blood pressure. They appear to be located primarily in gills and pituitary gland of fishes.

The operating range of various osmosensors differs considerably and it is likely that information about the particular magnitude of environmental salinity change can be derived through integration of signaling input from multiple osmosensors. For instance, cell volume, cytoskelelatal strain, and macromolecular damage sensors respond to more severe osmotic stress compared to the activation of calcium-sensing receptors (CaSRs) or transient receptor potential (TRP) ion channels. Another benefit of integrating input from multiple osmosensors is that the specific combination of sensory input can be highly stressor specific without the need for having any single stressor-specific osmosensor. Different and unique combinations of input from a steady set of sensors could be utilized for sensing different environmental stimuli (**Figure 1**). This strategy seems to be what has evolved in multicellular organisms such as fishes that have a great need for multitasking with the limited set of proteins they can accommodate in the crowded cellular space. As a result of this strategy, the complexity of osmosensory (and other types of) signal transduction in fishes and other vertebrates is tremendous. Consequently, tight linkages and interactions between mechanisms and protein elements of osmosensory signal transduction networks and other vital physiological functions exist, including immunity, apoptotic volume decrease, cell proliferation and differentiation, and development.

Molecular Osmosensors

Calcium as a Central Stimulus for Osmosensing

Calcium is a ubiquitous second messenger of intracellular signal transduction pathways. This divalent cation has been identified as a central element in osmosensory signal transduction networks of tilapia (*Oreochromis* sp.) and other fishes and plays a critical role in acclimation to salinity change. Calcium is necessary for organic osmolyte release and cell volume regulation during hyposmotic stress in gill cells of sea bass (*Dicentrarchus labrax*), but not in renal proximal

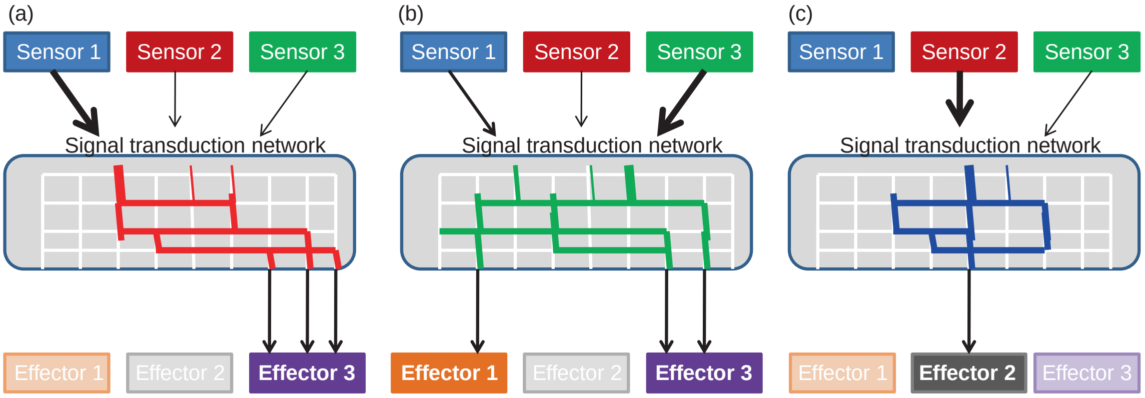

Figure 1 Schematic illustration of a strategy for utilizing a conserved set of proteins for sensing and transducing information about specific environmental parameters, including salinity. Osmosensory signaling networks are controlled by multiple sensors that monitor changes in salinity/osmolality and the particular combination of osmosensors as well as their relative activity control the information flow through the signaling network. (a) Moderate osmotic stress activates sensor 1 strongly and sensors 2 and 3 weakly, which is integrated into a distinct pattern of information flow through the signaling network resulting in activation of a specific set of effectors (effector 3). (b) Severe osmotic stress results in a different pattern of osmosensor activation leading to modification of information flow through the signaling network and allowing assessment of osmotic stress severity. (c) During environmental stresses other than osmotic stress, many (but not all) of the same proteins involved in osmosensing and signaling are utilized but the different activity pattern of the combined set of sensors allows for a stressor-specific outcome.

tubule cells of rainbow trout (*Oncorhynchus mykiss*). Thus, effects of calcium on osmosensory signal transduction mechanisms may depend on species and/or type of tissue/cell. Intracellular calcium levels are modified by multiple mechanisms during salinity stress, including activation of voltage-gated calcium channels, regulation of release from intracellular calcium stores, and systemic factors such as cortisol and angiotensin II (ANGII).

Extracellular calcium concentration is sensed by the large membrane-bound glycoprotein CaSR. The CaSR is a dimeric, seven-transmembrane-domain, G-protein-coupled receptor that senses the concentration of extracellular calcium. It is conserved throughout the Chordata. CaSR is expressed in the pituitary gland, corpuscles of Stannius, olfactory epithelium, and in ion-transporting tissues such as kidney, intestine, gills, and shark rectal gland. In these tissues is it thought that CaSR may have direct effects on monovalent and divalent ion transport that are independent of systemic factors. CaSR recognizes multiple types of ligands, including calcium and magnesium ions, other polyvalent cations, and amino acids. It senses calcium concentration in the millimolar range, which is appropriate in particular for marine fishes. CaSR is thought to sense extracellular calcium as a surrogate measure of environmental salinity in marine and brackish environments. Interestingly, monovalent cations shield CaSR-binding sites in a competitive manner and therefore may influence the osmosensory function of CaSR.

CaSR has been identified in phylogenetically diverse groups of fishes, where it is thought to be the main osmosensor. In addition to sensing extracellular osmolality directly, CaSR stimulates stanniocalcin secretion in salmon and may, therefore, also modulate calcium-regulated osmotic stress signaling more indirectly. Teleost CaSR has been shown to activate downstream intracellular signaling pathways, a function that is essential for any physiological osmosensor. Signaling pathways activated by CaSR include phospholipase C regulated pathways and mitogen-activated protein kinase (MAPK) pathways.

Cytoskeletal Strain as an Osmosensory Signal

Cytoskeletal strain and membrane stretch can result from severe osmotic stress such as that generated during acute transfer between salinities that differ by more than 10 ppt. In such a scenario, it is possible that changes in cell volume occur in gill and other epithelial cells that are directly exposed to the external milieu or (less likely) even in internal cells as a result of significant changes in plasma osmolality. Multiple proteins have been identified in mediating the immediate osmotic stress response in tilapia exposed to acute salinity increases. Several of these proteins regulate the actin-based cytoskeleton and may be involved in sensing changes in actin cytoskeleton organization during salinity stress. These proteins include annexin 11A (ANX11A), gelsolin, and galectin 4. All three of these proteins represent functional links between calcium signaling, discussed above, and cytoskeleton dynamics. ANX11A is a member of the Ca^{2+}-dependent, phospholipids-binding protein family. It is important for organizing the interface between plasma membrane and cytoskeleton due to its ability to bind the negatively charged phospholipids of the inner leaflet of the plasma membrane and the cytoskeleton. Annexins are also involved in phospholipase inhibition, intracellular signaling, anticoagulation, and membrane fusion. Gelsolin is a Ca^{2+}-regulated and polyphosphoinositide 4,5-bisphosphate-regulated actin filament severing and capping protein that promotes actin remodeling. Galectins also regulate interactions between the cell membrane and the cytoskeleton, which are critical targets of osmotic stress-induced cell volume changes. Galectin-4, in particular, organizes lipid rafts and membrane microdomains consisting mainly of glycosphingolipids and cholesterol in the outer leaflet of the plasma membrane lipid bilayer. Such remodeling may also support changes in tight junction structure during salinity acclimation. Collectively, these data support the notion that acute osmotic stress causes cytoskeletal strain that acts as an osmosensory signal.

The Rho-GTPase pathway is also a promising candidate for an early transducer or even a sensor of cytoskeletal strain. This pathway is overrepresented in the osmoregulatory tissues of sharks and represents an integral part of osmotic stress response networks identified in sharks and teleosts. In particular, Rho guanine exchange factors (Rho-GEFs) and Rho-GTPase seem to play a role for osmosensory signal transduction in fish. Rho is a small G protein that interacts with the cytoskeleton and is capable of activating MAPK pathways in response to cytoskeletal strain. Ezrin/moesin, an actin-interacting protein, may also be involved in transducing cytoskeletal strain to downstream signaling pathways. This protein has been identified in gill tissue of tilapia and sharks using proteomics and represents a major target of Rho kinase.

Stretch-activated/mechanosensory ion channels have been implicated as potential osmosensors in fish and are thought to be responsible for triggering signal transduction that controls prolactin (PRL) secretion from the pituitary. However, unlike in PRL cells of the fish pituitary, membrane stretch may not occur in epithelial cells that are extensively folded at both the basolateral and apical membranes. Instead, relaxation or compression of microridges and other membrane infoldings as a result of cell volume changes are more likely to modulate the underlying cytoskeleton. Thus, molecular sensors triggered by cytoskeletal strain are more likely to function as osmosensors during acute osmotic stress in epithelial cells than stretch-activated ion channels. Macromolecular crowding and dilution are also signals that result from cell volume changes. Such signals could affect essentially any protein in the cell and are virtually impossible to experimentally separate from other triggers such as cytoskeletal strain and changes in membrane folding.

Membrane Protein Osmosensors

In addition to CaSR, several other membrane proteins, including TRP channels, aquaporin (AQP), and adenylate cyclase (AC), have been implicated as osmosensors of fish. Transient receptor potential vanilloid receptor 4 (TRPV4) senses salinity changes in diverse animals and has been cloned from zebrafish (*Danio rerio*), although there is no direct evidence for TRP being an osmosensor in fish. Consistent with the model shown in **Figure 1**, TRP channels are activated by multiple stimuli, not just osmotic stress. AQPs are important effector proteins of osmoregulation in fish (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Water Balance and Aquaporin) and play a role in altering the water permeability of plasma membranes in response to salinity changes. Moreover, AQPs are known to function as osmosensors in other vertebrates. AC is known to be an osmosensor in bacteria and there is mounting evidence that it may play a similar role in fish. In many euryhaline fishes, AC controls chloride secretion across gill epithelium, PRL, and growth hormone (GH) secretion from pituitary gland cells in response to salinity stress. In addition, forskolin (an activator of AC) stimulates chloride secretion across killifish opercular epithelium.

The Ion–Damage–Cytokine Model of Osmosensing

Cells sense environmental stress using two avenues. One is relatively stimulus specific and termed the cellular homeostasis response (CHR) and the second is a nonspecific response to damage, termed the cellular stress response (CSR). During osmotic stress, the CHR, on the one hand, is responsible for conferring specificity to osmosensory signal transduction and is presumably based on sensing concentrations of specific cations such as calcium, sodium, and potassium in intra- and/or extracellular fluid and on sensing intracellular ionic strength. The CSR, on the other hand, is important for counteracting damage and strain on macromolecules caused by osmotic stress and is responsible for the cross-tolerance phenomena. In addition to these two cellular modes of osmosensing, fishes have systemic osmoreceptors that coordinate osmosensory signal transduction in different tissues and organs in an effort to synchronize osmoregulation at the whole organism level.

Osmoregulatory hormones and more broadly cytokines are important mediators of this whole organism synchronization. The interplay of ion concentrations, macromolecular damage, and cytokines/hormones during osmosensing is schematically summarized in **Figure 2**. Like cytokines, systemic regulation mediated via neurotransmitters may also serve to synchronize and

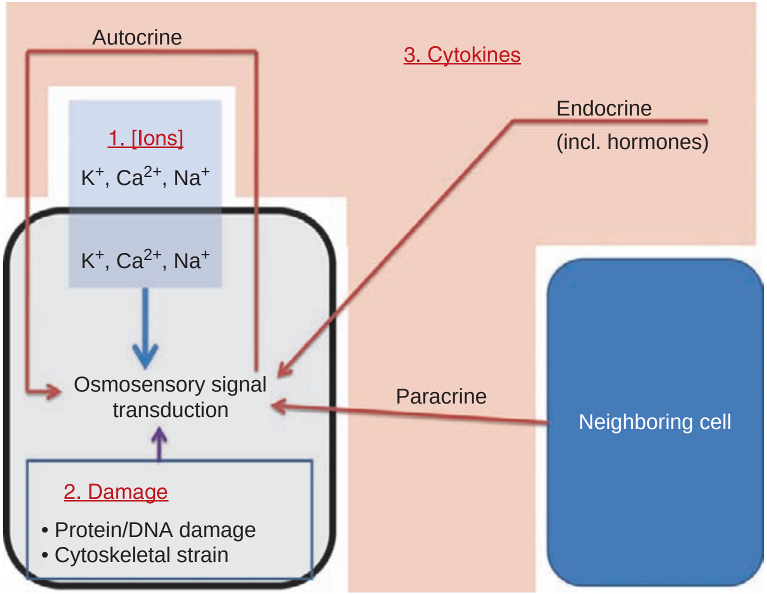

Figure 2 The ion–damage–cytokine model of osmosensing. The first two elements of osmosensing (ions and macromolecular damage) are cell autonomous and do not depend on systemic factors. The third element (cytokines, including peptide hormones and other regulatory peptides) coordinate osmosensory signal transduction at the whole organism level and act in autocrine, paracrine, and endocrine fashion. In addition to cytokines/peptide hormones, some steroid hormones and neurotransmitters also contribute to systemic osmoregulation. Components 2 and 3 are also involved in other types of environmental stress responses and responsible for cross-tolerance phenomena, whereas component 1 (ions) confers stressor specificity.

fine-tune osmoregulatory responses at the whole organism level. The overly simplistic 'one sensor–one pathway–one specific response' concept that prevailed through much of the twentieth century has been replaced by the realization that environmental stress signaling networks in multicellular animals, in particular vertebrates, are much more complex and interdependent than in unicellular organisms. These highly differentiated animals need to make repeated use of each protein present in the limited set of proteins encoded by their genome. In fishes and other vertebrates, almost every protein is likely used for many different functions depending on the developmental, environmental, and life history context of organisms. Which function of a particular protein dominates depends on its interaction with other proteins and its intracellular compartmentalization and localization, which in turn are regulated via posttranslational protein modifications (PTMs).

Macromolecular Damage Contributes to Osmosensing

An important avenue of osmosensory input is macromolecular damage. This signal is presumably relatively nonspecific and responsible for cross-tolerance to other types of environmental stressors. However, if integrated with additional ion-sensory input signals, the signaling pathways controlled by protein and DNA damage sensors are modulated in specific ways that enable activation of an appropriate array of effector mechanisms (**Figure 1**). In addition, such signal integration and amplification is likely also responsible for accurate quantification of the severity of osmotic stress and an appropriate degree of activation of effector mechanisms. Very little is known on how the severity or extent of osmotic stress is measured in cells and this is an important area for future studies. Although most macromolecular damage may be nonspecific, the possibility that certain types of DNA or protein damage are unique during osmotic stress cannot be excluded. Preferential degradation of particular proteins in response to osmotic stress may serve as an osmosensory signal. In agreement with this notion, several specific proteins involved in DNA, RNA, protein stabilization, repair, and degradation are rapidly induced in gill of teleosts and rectal gland of elasmobranchs exposed to hyperosmotic stress. In addition, key signaling proteins of DNA and protein damage response pathways are integral parts of osmosensory signaling networks in teleosts and elasmobranchs. Moreover, osmoregulatory actions of cytokines/peptide hormones and osmotic stress signaling proteins are controlled by proteolysis events mediated by peptidases and proteases. Differences in peptidase activity in osmoregulatory tissues of teleosts have been attributed to their different osmoregulatory mechanisms in FW versus SW.

Cytokines Coordinate Osmosensory Signal Transduction

The term 'cytokine' is used as a common denominator of a diverse array of soluble proteins and peptides that regulate cell and tissue functions via humoral actions at low concentrations. Many of them (like growth factors) regulate cell survival, differentiation, and apoptosis. Cytokines are secreted proteins/peptides and several are synthesized as procytokines and activated by proteolytic cleavage, which sometimes coincides with shedding of a membrane-bound form, from the cell membrane, into the extracellular fluid (e.g., tumor necrosis factor alpha (TNF-α)). Most cytokines are glycoproteins that are secreted via classical secretory pathways from cells. They are not usually stored in cells but there are exceptions that are relevant to osmosensing, for example, TGF-β and TNF-α procytokines. In general, differences between classical hormones and cytokines are: (1) cytokines are not necessarily produced by specialized glands or tissues; (2) all cytokines are peptides/proteins encoded in the genome (unlike steroid hormones); and (3) cytokines have a generally wider spectrum of target tissues/cells. However, there are exceptions to these general rules, and the distinction between cytokines and hormones is blurred. Classical peptide hormones and growth factors that are important for teleost osmoregulation are also considered to be cytokines in the mammalian literature (e.g., GH, insulin-like growth factor 1 (IGF-I), atrial natriuretic peptide (ANF), and PRL (**Figure 3**)).

TNF-α and interleukins

We have recently performed several transcriptomic and proteomic screens for osmotic stress signaling proteins in teleosts and elasmobranchs. The results of these studies and bioinformatic pathway modeling showed that classical cytokines, including TNF-α and several interleukins (ILs), constitute conserved elements of osmosensory signal transduction networks in fishes. These classical cytokines are also critical in many environmental contexts, including pathogen invasion stress, and for mounting an appropriate immune response. Their involvement in osmosensing may explain why abiotic environmental stresses, such as osmotic stress, modulate the immune system and change the ability of fish to ward off infections by bacteria and viruses. TNF-α and ILs are cytokines that can act in autocrine and paracrine fashions and, therefore, reinforce and coordinate epithelial responses to salinity change. In tilapia, TNF-α amd IL signaling during osmotic stress is in part mediated by the MAPK and toll-like receptor pathways. From work on other vertebrates, it is known that transforming growth factor beta-activated kinase 4 binding protein 2 (TAB2; an MAP3K interacting protein) is stimulated by IL-1 and activates the MAP3K TAK1. TAK1 interacts with TNF receptor-associated factor 6 (TRAF6), which is activated by TNF-α and controls downstream signaling pathways for cell differentiation, proliferation, apoptosis, and stress-responsive gene expression.

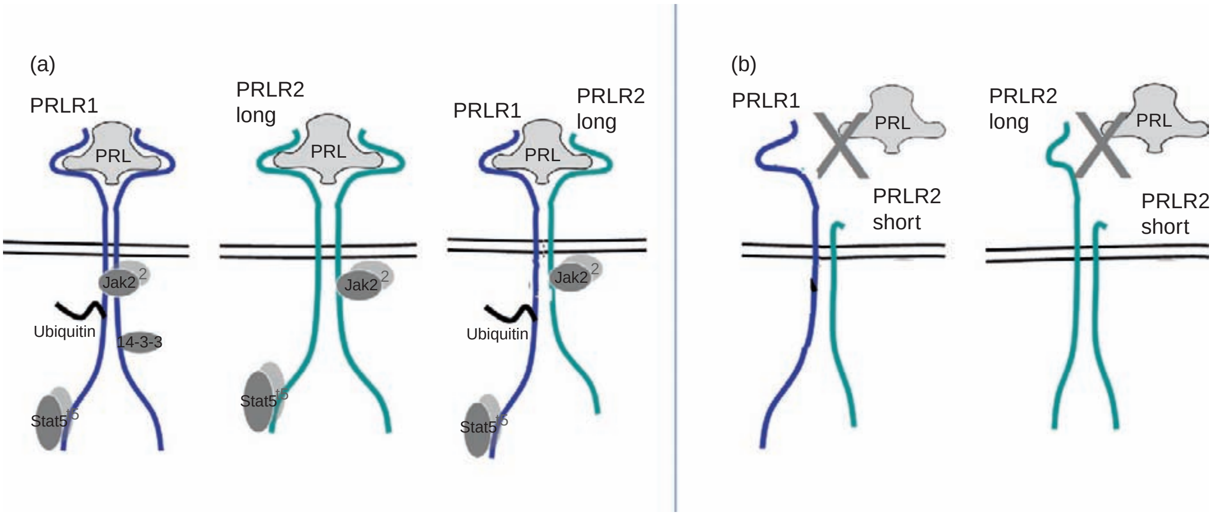

Figure 3 Model for prolactin receptor (PRLR) regulation during salinity stress. (a) In FW long splice variants of both PRLRs are expressed that homo- or hetrodimerize and effectively bind PRL, which is present in high concentration in plasma. On ligand-binding, PRLR dimers activate intracellular signaling pathways, including the Jak2/ Stat5 pathway. (b) In SW expression of PRLR2 is induced and the abundance of a short splice variant of PRLR2 increases. The short PRLR2 variant lacks much of the extracellular domain and dimerizes with long PRLR variants to turn them into inactive decoy receptors. Together with a decrease in plasma prolactin, this mechanism turns off intracellular PRL signaling in target cells. Modified from Fiol DF *et al*. (2009) A novel tilapia prolactin receptor is functionally distinct from its paralog. *Journal of Experimental Biology* 212: 2006–2014.

Cellular Osmosensing and Chloride Cell Differentiation

Chloride cells (or more general mitochondrion-rich cells, MRCs) are the main cellular engines of transepithelial ion transport in euryhaline teleost gill and shark rectal gland. MRCs undergo extensive re-differentiation in response to salinity change and these events are controlled by osmosensing and osmotic stress signaling mechanisms. MRC in preparations of sealed tilapia yolk sac membranes undergo the same transformation (increase in size, formation of multicellular complexes, ion transporter compartmentation, etc.) as those observed in yolk sac and gill epithelium of intact animals but administration of cortisol (0.1–10 $\mu g\,mL^{-1}$) had no effect on MRC differentiation. Thus, major parts of MRC reprogramming in response to salinity change can proceed independent of cortisol or other systemic (neuroendocrine) signals. Likewise, expression of osmotic stress transcription factor 1 (OSTF1) in primary cultures of tilapia gill epithelial cells is independent of cortisol or other systemic signals indicating that expression of (at least some) osmotic stress signaling genes can be regulated autonomously at the cellular/epithelial level. The lack of dependence of OSTF1 expression on cortisol was a surprise because of known corticosteroid regulation of the OSTF1 ortholog glucocorticoid-induced leucine zipper (GILZ) in mammalian cells. Even though major MRC reorganization events triggered by salinity change appear to be autonomous, presently it is still unclear to what degree salinity-dependent epithelial reorganization can be completed in the absence of systemic signals (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts, Mechanisms of Ion Transport in Freshwater Fishes, Osmoregulation in Fishes: An Introduction, and The **Hormonal Control of Metabolism and Ionic Regulation**: Hormonal Control of Osmoregulation in Teleost Fish).

According to elegant *in vivo* sequential observations on chloride cells in the yolk sac membrane of tilapia, single FW-type MRCs are transformed into multicellular SW-type MRCs in response to SW transfer, suggesting plasticity in the ion-transporting functions and the directionality of active NaCl transport of MRCs. Individual MRC observed sequentially over time increased in size in response to SW transfer but not in FW controls in tilapia yolk sac preparations. Moreover, the compartmentalization of key ion transporters changed dynamically in tilapia yolk sac membranes during transfer from FW to SW. Three types of FW MRCs with either basolateral NKA, basolateral sodium–potassium–adenosine triphosphate (NKA), and apical $Na^+/K^+/2Cl^-$co-transporter (NKCC), or basolateral NKA and basolateral NKCC compartmentation transform into SW MRCs having basolateral NKA, basolateral NKCC, and apical cystic fibrosis transmembrane receptor. These studies suggest that existing MRC can re-differentiate into a different phenotype depending on environmental salinity. Other studies show that MRC turnover, programmed cell death of MRC, and differentiation of ionocyte precursor cells are influenced by environmental salinity implying that FW-type MRCs are replaced by SW-type MRCs during salinity change. It appears likely that both of these general mechanisms contribute to MRC reprogramming in response to osmotic stress in fish gills, perhaps with different time courses.

In stenohaline zebrafish the transcription factor glial cell missing 2 (Gcm2) is highly expressed in gills and necessary for development of H^+-ATPase-rich, mitochondrion-rich cells (HR-MRCs) that promote acid secretion and Na^+ absorption in FW. The expression of Gcm2 is subject to positive feedback from the forkhead transcription factor Foxi3a and vice versa. Foxi3a is also necessary for the development of HR-MRCs. In the zebrafish mutant mind bomb characterized by impaired Notch function Foxi3a expression is increased and differentiation of precursor cells is greatly shifted toward the HR-MRC cell fate. Conversely, overexpression of Notch drives precursor cell differentiation toward the keratinocyte cell fate. Collectively, these experiments indicate that Delta C and Foxi3a signaling pathways promote differentiation into HR-MRC, whereas Notch promotes the alternative keratinocyte cell fate. Thus, determination of ionocyte precursor cell differentiation into either HR-MRC or keratinocytes depends on Delta–Notch inhibition and paracrine signaling that precludes HR-MRC neighboring cells from differentiating into the same cell type (**Figure 4**). Analysis of another zebrafish mutant (*quadro*) that is deficient in Foxi1 expression revealed that Foxi1 is also essential for HR-MRC differentiation and positioned upstream of Delta C, Foxi3a, and Gcm2 in the pathway that promotes HR-MRC differentiation. Although these studies were done in stenohaline zebrafish larvae in a developmental rather than salinity acclimation context, they provide groundbreaking insight into signaling mechanisms that may control the epithelial and MRC reorganization during salinity stress in euryhaline teleosts. Future study of the role of Foxi1, Foxi3a, and Gcm2 transcription factors as well as Delta–Notch signaling for osmosensory signal transduction in euryhaline fish is warranted.

In the context of the findings on the regulation of zebrafish HR-MRC differentiation, it is noteworthy to point out a signaling link to bone morphogenetic proteins (BMPs) that may be central for osmosensory signal transduction in euryhaline teleosts. Vertebrate BMP2 and BMP7 are downregulated in Delta C (also known as Jagged) mutants likely as a result of negative feedback, and it has been proposed that BMPs control the Delta–Notch signaling pathway and HR-MRC differentiation in

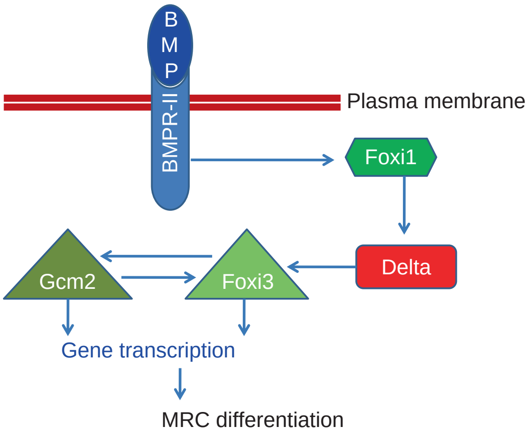

Figure 4 Model for the regulation of MRC differentiation by bone morphogenetic proteins (BMPs), which represent a subfamily of cytokines. During hyperosmotic stress BMP receptors (BMPRII) are upregulated in gill epithelium leading to the activation of the Delta C pathway that controls MRC differentiation. Key components of the BMP–Delta C pathway are shown. Foxi3 and Gcm2 are transcription factors. Modified from Esaki M *et al*. (2009) Mechanism of development of ionocytes rich in vacuolar-type $H^{(+)}$-ATPase in the skin of zebrafish larvae. *Developmental Biology* 329: 116–129.

zebrafish. In addition, we have previously identified a receptor for BMPs (BMPRII) as an immediate early gene whose expression is induced very rapidly in response to salinity stress in tilapia gill epithelium resulting in enhanced BMP signaling. Therefore, an increase in BMPRII during hyperosmotic salinity stress may change the balance between Delta–Notch signaling in any given cell, which could explain alteration of MRC differentiation and multicellular MRC complex formation when euryhaline fish transition between plasma-hyposmotic and plasma-hyperosmotic environments (**Figure 4**).

Role of Osmosensing for Fish Sperm Motility

Fish sperm motility is controlled tightly by osmolality and the concentration of cations. Therefore, fish sperm represents an excellent model for studying general mechanisms of cellular osmosensing in fish. Depending on habitat salinity and osmoregulatory strategy, sperm motility is either activated or inhibited by increased osmolality. In marine teleosts, sperm motility increases when released into a plasmahyperosmotic environment (SW), whereas in FW teleosts it increases upon release into a plasmahypoosmotic environment (FW). In striped bass sperm motility is promoted by Ca^{2+}-free solutions and suppressed when $[Ca^{2+}]$ exceeds 10 mM. The effect of $[Ca^{2+}]$ is transient and irreversible; once sperm motility has been activated, it cannot be suppressed by high $[Ca^{2+}]$ (80 mM) and reactivation by Ca^{2+}-free medium after suppression is also not possible. Verapamil, a Ca^{2+} channel inhibitor, and cAMP had no effect on sperm motility in striped bass suggesting that Ca^{2+} acts through other pathways. These data reinforce the notion that calcium is of central importance for osmosensing (see above). Because of the rapid time course of initiation of sperm motility, the study of sensory and signaling mechanisms underlying this event in marine versus FW fishes may provide critical clues about mechanisms of osmosensing in fish. In addition to calcium, intracellular $[K^{+}]$ has also been shown to be critical for the regulation of sperm motility in FW (zebrafish) and marine (pufferfish) species. Thus, intracellular inorganic cation concentrations are critical signals for osmosensory signal transduction in fish sperm.

Glossary

Basal labyrinth The elaborate infoldings of the basolateral plasma membrane increasing surface area.

Freeze-fracture electron microscopy A technique used to visualize the inside (p-face) and outside (e-face) leaflet of lipid bilayer of cellular membranes; cells are rapidly frozen and fractured, which exposes the bilayer surfaces *en face*. A replica is created and viewed by scanning electron microscope. This technique reveals the pattern of integral membrane proteins.

Ionocytes (mitochondrion-rich cells) A function-specific type of epithelial cell, which expresses ion transporters or enzymes and is responsible for trans-epithelial transport functions of specific ions. In fish gills, ionocytes responsible for ion regulation are named mitochondrion-rich cells based on the characteristic of abundant mitochondria.

Interlamellar space (ILS) The part of the filament epithelium found between the bases of the gill lamellae.

Lamellae Also known as secondary lamellae, these are attached in rows to the gill filaments. They are the primary sites for gas exchange in fish gills. Each lamella is made up of two epithelial layers separated by pillar cells. Oxygen is taken up by erythrocytes flowing inside the lamellae from water flowing between the lamellae.

Tubular system A network of regularly anastomosing tubules of uniform diameter that is continuous with the basolateral plasma membrane, characteristic of chloride cells.

Tubulovesicular system A collection of subapical irregular tubules and vesicles.

Introduction

Aristotle noted in his work *Historia Animalia* (345 BC) that the fish gill was indeed a special organ. However, it was not until the pioneering work of Homer Smith in the 1930s that an ionoregulatory function could be ascribed to the gills (**see also Osmotic, Ionic and Nitrogenous-Waste Balance:** Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes). Since Keys and Willmer's identification in 1932 of presumptive chloride-secreting cells, with their greater affinity for eosin, ovoid shape, and granular cytoplasm, much effort has been put into the study of branchial ionocytes. Branchial ionocytes are found in all taxa of fish from the osmoconforming hagfish to the air-breathing lungfish. Light and electron microscopic descriptions have been complemented by enzyme and immunohistochemistry to characterize the expression of ion transport proteins that make these cells ionocytes (**see also Osmotic, Ionic and Nitrogenous-Waste Balance:** Mechanisms of Gill Salt Secretion in

Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes). Two cell types potentially function as ionocytes in the fish gill, the pavement cell (PVC) and mitochondrion-rich cell (MRC), and their morphological attributes form the subject of this article. Functional consideration of these cell types in ion and acid–base regulation are detailed in **Osmotic, Ionic and Nitrogenous-Waste Balance:** Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes.

Pavement Cells

PVCs are the squamous to cuboidal cells that cover much of the gill (>90% of the surface area; **Figures 1**(**a**) and **1**(**b**); **see also Design and Physiology of Arteries and Veins:** Branchial Anatomy). The apical surface of PVCs is usually large and polygonal and may be smooth or have microvilli (finger-like projections) or microridges, which typically form concentric rings (referred to microplicae when viewed in cross section). A double ridge generally marks the border of neighboring PVCs. The types of apical features present show variation between species and also within and between the different gill epithelia (lamellar vs. filament). PVCs typically have low mitochondrial densities and unelaborated basolateral membranes (**Figure 2**(**a**)). The nucleus in squamous PVCs is compressed, while it is rounded in cuboidal PVCs. PVCs have the typical intracellular organelles, rough and smooth endoplasmic reticulum (ER), Golgi apparatus, lysosomes, and vesicles with contents of various electron densities. In the nonteleost fishes, PVCs display abundant mucous secretory granules in the apical cytoplasm (**Figure 3**). PVCs are joined by desmosomes and the peripheral cytoplasm contains microfilaments. The tight junctions associated with PVCs have multiple strands and are not characterized as leaky, minimizing paracellular fluxes of ions (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes). In the hagfish and lamprey, communicating gap junctions have been found between neighboring PVCs, and PVCs and undifferentiated cells, however, not with MRCs. The presence of communicating gap junctions is significant because they allow the electrochemical coupling of the cells of the epithelium, which is important in coordinating cell growth, differentiation, and function. No studies have been undertaken in other fishes to specifically determine the presence of gap junctions.

PVCs have been shown to be involved in the covering and uncovering of MRCs during acid–base and ionoregulatory disturbances, but the role of the PVC in the process is somewhat secondary to that of the MRC in the functional response. Generally, PVCs themselves have been shown to be morphologically unresponsive to changes in environmental conditions. However, part of the problem stems from the fact that the MRCs are generally the focus of attention in morphological studies and the changes in PVCs may have been overlooked. It also might be difficult to recognize these changes if they only occur in a subpopulation of PVCs, since there are proportionally many more PVCs (90% of epithelial cells).

With that said, there have been a few studies that have shown that PVCs increase apical surface area (densities of microvilli and microplicae) in response to hypercapnia and alkaline exposure which induce acid–base disturbances. It has also been found that there are studded subapical vesicles that resemble the proton pump containing vesicles from other animals. These morphological characteristics of PVCs help support the hypothesis that they are the site of proton-pump-driven sodium uptake at least in some species (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts).

MRCs or Chloride Cells

The descriptive morphological study of the gill has been dominated by the mitochondrion-rich chloride cell (CC) and its subtypes (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes). In general, the numerous mitochondria in these cells are thought to supply the adenosine triphosphate (ATP) for ion transport proteins to drive the vectorial transport of ions as part of ion and acid–base regulation.

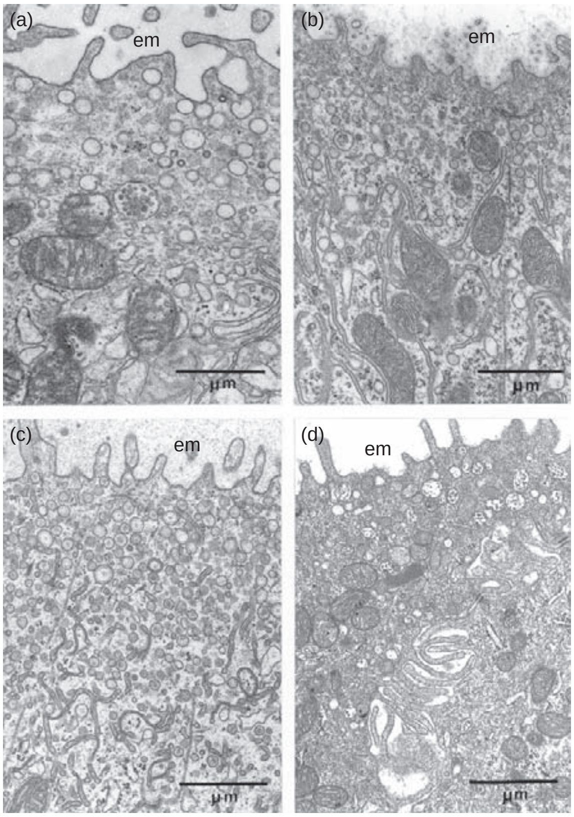

Figure 3 TEMs of the apical regions of the MRCs of (a) *Raja erinacei*, (b) Acipenser beari, (c) *Perca fluviatilis*, and (d) *Protopterus annectens* showing the tubulovesicular system. Scale = 1 μm. MRCs tend to be concentrated in the afferent region of the filament epithelium and have an intimate association with the arteriovenous circulation, notably the central venous sinus, although in the interlamellar region MRCs also are associated with the basal channels of the lamellar arterioarterial circulation (**see also Design and Physiology of Arteries and Veins:** Branchial Anatomy 2000). The defining morphological feature of this cell type is a high mitochondrial density. However, MRCs also generally have an amplification of their basolateral membrane through either folding forming a basal labyrinth or the presence of a tubular system (**Figures 2, 4, 5,** and **7**). Although basolateral amplification can be less developed as in lamprey intercalated cell (IC)-type MRCs (**Figure 6**) and lacking in mitochondrion-rich PVCs. Associated with the basolateral membrane

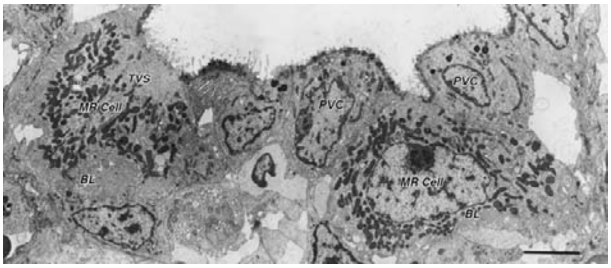

Figure 4 TEM micrograph montage of the interlamellar region of the primary filament from the gill of a dogfish *Squalus acanthias*. Note the mitochondria-rich (MR) cells identified by their ovoid shape, numerous mitochondria, dense subapical tubulovesicular system (TVS), and extensive basal labyrinth (BL). amplification is the important ionoregulatory enzyme Na^+/K^+-ATPase. The presence of Na^+/K^+-ATPase has been observed by freeze-fracture electron microscopy as dense studding of the tubular elements (**Figure 2**(**d**)). In the apical region of MRCs is a collection of tubules and vesicles (tubulovesicular system), which is distinct from the tubular system (**Figure 3**). The apical membrane can be quite variable in appearance ranging from concave to convex, sometimes forming deep crypts. In addition, the surface topography has been shown to be smooth, or having microvilli of varying densities and lengths, as well as being highly branched to give a sponge-like appearance (**Figures 1**(**d**), **2**(**a**), and **3**–**7**). The use of morphological features has led to the classification of different types of MRCs.

The term chloride cell relates to the function of the MRC in Cl^- elimination. In seawater teleosts, the MRCs have quite convincingly been shown to be sites of active Cl^- elimination and hence the name is fitting (**see also Osmotic, Ionic and Nitrogenous-Waste**

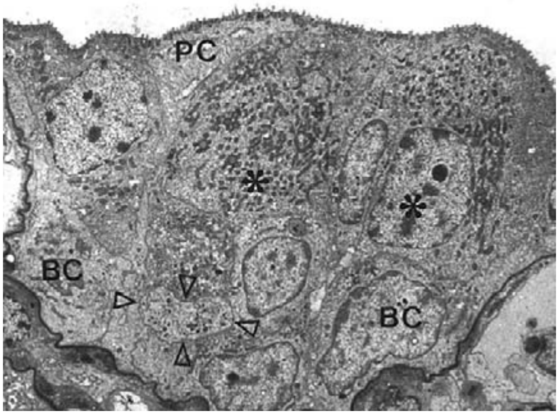

Figure 7 Epithelium covering a gill lamella of the Atlantic hagfish *Myxine glutinosa*. The following cell types can be distinguished: pavement cells (PC), mitochondrion-rich cells (asterisks), basal cells (BC), small granule cells (indicated by open arrowheads), and granulocytes (G). The arrow points to the microvilli-bordered apical surface of an MRC. Magnification ×2000. Reproduced from figure 1 in Bartels H (1984) Orthogonal arrays of particles in the gill epithelium of the Atlantic hagfish, *Myxine glutinosa*. *Cell and Tissue Research* 238: 657–659 with kind permission of Springer Science + Business Media.

Balance: Mechanisms of Ion Transport in Freshwater Fishes). In the agnathans, chondrichthyans, chondrosteans, holosteans, and freshwater teleosts, the evidence that MRCs are involved in Cl^- fluxes is limited to the few teleosts and elasmobranchs. Therefore, in order to avoid any confusion on the matter, we will only use the term chloride cell when referring to the seawater teleost MRC, unless otherwise noted.

The teleost MRC is characterized by its elaborate intracellular system of branching tubules that is continuous with the basolateral membrane (tubular system; **Figures 2**(**a**)–**2**(**d**)). This network of anastomosing tubules is closely associated with the mitochondria and is only excluded from the area of the Golgi apparatus and the band immediately beneath the apical membrane. The elements of the tubular system can be found alongside the ER, making identification somewhat problematic. Extracellular space markers such as horseradish peroxidase and ruthenium red have been used to clearly establish the basolateral continuity of the tubular system and its separation from the ER. The Karnovsky potassium ferrocyanide-reduced osmium stain has also been used to unambiguously differentiate the membrane elements of the tubular system from the ER without the need of extracellular markers. The selective heavy staining of the tubular system contrasted markedly with the poorly stained ER (**Figures 2**(**a**) and **2**(**b**)). Environment ionic conditions have a marked effect on the morphology of the teleost MRCs, which of course relates to the role of these cells in active ion transport (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). In seawater, the gill is involved in active ion elimination, while in freshwater active ion uptake takes place.

The mitochondrion-rich CC and accessory cell (AC) are two types of MRCs that are universally expressed in seawater teleosts (**Figures 1**(**d**)–**1**(**f**)). These cells form multicellular complexes in the filament epithelium. The larger chloride cell may be elongate, ovoid, or cuboidal in shape, which depends upon the species. The tubular and the tubulovesicular systems are highly developed and the cell is packed with mitochondria. High densities of Na^+/K^+-ATPase are associated with the CC tubular system. The apical membrane of a CC is recessed from the surface of neighboring PVCs and may be further deepened through invagination (**Figures 1**(**b**)–**1**(**d**). The smaller AC is superficially located, semi-lunar or pear-shaped, and generally has a less extensive tubular system and a poorly developed tubulovesicular system. Notably, they have low levels of Na^+/K^+-ATPase, unlike the CCs. The AC sends cytoplasmic processes into the larger CC which emerge at the apical surface to form a complex mosaic. Notably, the tight junctions found between CC and AC contain fewer strands than do tight junctions formed with PVCs. Therefore, the AC interdigitations within the CC apical membrane would greatly increase the linear distance of leaky tight junction, which is functionally important for the paracellular sodium efflux. There is also ample evidence that Cl^- efflux occurs transcellularly through the CC (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts).

In freshwater teleost fishes, there is less consensus about MRC subtypes, which might relate to the instability and variability of the freshwater environment itself. Pisam and co-workers, however, have described α and β subtypes of MRCs with electron-lucent (light or pale) and electron-dense (dark) cytoplasms, respectively, in a number of species. It should be noted that this naming system is unrelated to that used to describe acid- and base-secreting cells in other epithelia (kidney collecting duct and bladder). In addition to a pale cytoplasm, α-cells were found at the edges of the interlamellar space (ILS) in contact with the basal lamina opposite the arterioarterial circulation. The β-cells, on the other hand, were generally observed in the ILS in contact with basal lamina associated with the arteriovenous circulation. Besides, a manganese–lead (Mn–Pb) stain was found that selectively stained the contents of a population of variably sized membrane bound bodies in the apical cytoplasm of only the β-cell type. The material in the apical vesicles of the β-cell has been shown to include carbohydrate material, and binding of the lectin wheat germ agglutinin (WGA: sialic acid and *N*-acetylglucosaminyl residues) to the apical vesicles of a subpopulation of MRCs has also been found in tilapia (presumably β-cells). In the guppy (*Poecilia reticulatus*), it was shown that the α-cell has high levels of Na^+,K^+-ATPase immunoreactivity, while the β-cell has only weak labeling. In studies with rainbow trout (*O. mykiss*) and Atlantic salmon, differentiation of these two subtypes was not made.

Transfer to seawater of euryhaline freshwater fishes results in the degeneration of the α-cell through apoptosis and hypertrophy of the β-cell. The β-cell is transformed into what is recognized as the seawater CC. The transformation consisted of an increase in the size of the β-cell, density of the cytoplasm, number of mitochondria, the tubular system network with a tighter polygonal mesh size, and the apical tubulovesicular system. A mitochondrion-poor cell type has been described that possesses a well-developed tubular system but has relatively few mitochondria. This cell increases in frequency following seawater acclimation and infrequently contacts the water. No function was suggested for this cell type.

Although typically associated with marine fishes, the accessory cell type has also been described in some freshwater euryhaline species. These cells are associated with the α-cell type in tilapia and Atlantic salmon but β-cell type in brown trout (*Salmo trutta*), and are similar to the AC described in the seawater fish gill, but they are less common and do not send cytoplasmic processes into the apical cytoplasm of the CC. Upon transfer to seawater or in anticipation of transfer (smolting), their numbers increase and interdigitations develop. The ACs are presumably present in fishes living in freshwater in order to facilitate the rapid switch to NaCl elimination. In a tilapia species (*Alcolapia grahami*) found in the extremely alkaline (pH 10) brackish water of Lake Magadi in Kenya, seawater ACs associated with larger CC-type MRCs have also been found. The lake water has very high HCO_3^- and CO_3^{2-} concentrations of 40 and 265 mEq l^{-1}, respectively, with Na^+ and Cl^- at 342 and 108 mEq l^{-1}, respectively. One model proposes that the CC–AC complex facilitates paracellular Na^+ efflux via the leaky tight junction, while HCO_3^- is pumped out by the CC.

In freshwater tilapia (*O. mossambicus*), three MRC types have been classified according to the apical membrane appearance by scanning electron microscopy (SEM), including wavy-convex, shallow-basin, or deep-hole types. The wavy-convex type has a convex apically exposed area with variable ornamentation with microvilli and a relatively large two-dimensional area. The surface of the shallow-basin-type MRCs is flat but recessed below neighboring PVCs. The density of the wavy-convex-type MRCs increases in low NaCl and the shallow-basin-type MRCs increases in low Ca^{2+} water, suggesting different roles in Na^+, Cl^-, and Ca^{2+} uptake, respectively. Results have been corroborated by immunohistochemistry (IHC; **see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes). The deep-hole MRCs are also recessed between PVCs, like the shallow-basin type, but they form a deeper apical crypt characteristic of seawater CCs. In the fathead minnow (*Pimephales promelas*), the deep-hole MRCs are associated with exposure to acid conditions, suggesting a role in acid excretion. However, in other species, like the rainbow trout, this system of classification is not applicable, and an alternative system using lectin histochemistry has arisen, using peanut agglutinin (PNA; terminal β-galactose residues) ± staining to identify functionally different MRC subtypes in trout. Lectins bind to specific glycoproteins and differential staining patterns have been used to identify subtypes with concanvalin A (Con-A; α-mannopyranosyl, and α-glucopyranosyl glycoprotein residues), and WGA (*N*-acetylglucosamine and *N*-acetylneuraminic acid (sialic acid) residues) as well.

Although MRCs tend not to be as frequently found in the lamellae as in the filament epithelium in freshwater and especially seawater fishes, acclimation of rainbow trout to ion-poor (<0.01 mM $[Na^+]$) conditions elicits a massive proliferation of MRCs in the lamellar epithelium. The number and area of exposed surface of these cells both increase dramatically. The effects of ion-poor water on MRC proliferation can also be reproduced using hormone treatments with cortisol and growth hormone (**see also Hormonal Control of Metabolism and Ionic Regulation**: The Hormonal Control of Osmoregulation in Teleost Fish). Since MRCs are generally quite large, proliferation on the lamellae results in the thickening of the epithelium and, consequently, the blood to water diffusion distance is increased, leading to an osmo-respiratory compromise (for more detail, **see also Role of the Gills**: The Osmorespiratory Compromise).

In the other Osteichthyans, which includes the Chondrosteans (e.g., sturgeon and paddlefish), Holosteans (e.g., *Amia* and gars), Dipnoans (lungfishes), and Coelacanth, MRCs have all been described (see **Figure 3**). However, in marine or euryhaline forms, evidence for AC–CC complexes is still lacking.

The chondrichthyan (elasmobranchs and chimaeras) salt-secreting rectal gland replaces the gill as the dominant salt-secretory organ. Yet, branchial MRCs remain in significant numbers. Even so, the important ionoregulatory enzymes Na^+/K^+-ATPase and H^+-ATPase are associated with distinct subpopulations of these cells and have been implicated in acid–base regulation rather than NaCl secretion (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). Branchial MRCs are generally found singly in the filament epithelium and are cuboidal or ovoid in shape with a basally located nucleus (**Figure 4**). In addition to their high mitochondrial densities, they have a basolateral membrane amplified through heavy folding into basal labyrinth, and a densely packed subapical tubulo-vesicular system. The tight junctions between MRCs and neighboring PVCs consist of many strands and are not considered leaky. The apical surfaces of elasmobranch MRCs range from being deeply invaginated to convex and are covered by microvilli of varying densities.

The agnathans or jawless fishes represent the most primitive group of fishes, consisting of the osmoconforming marine hagfishes and the osmoregulating lampreys. These differences in osmoregulatory abilities are reflected in the differences in MRC morphology among the agnathans. In freshwater lamprey, three different types of MRC have been described, one of which is associated with the preadaptation to seawater and is the dominant type found in the seawater-adapted lamprey (**see also Hagfishes and Lamprey**: Lampreys: Energetics and Development and Lampreys: Environmental Physiology). The seawater-type MRC (swMRC) is commonly referred to as the chloride cell due to its morphological similarities with the teleost chloride cell (**Figure 5**). In seaward-migrating freshwater lamprey, the swMRCs are found in a continuous row along the length of the ILS of the filament epithelium. The swMRCs are disk-shaped and covered over by neighboring PVCs with the apically exposed surface containing microvilli. Following acclimation to seawater, the overlying PVCs retract and the apical surface increases to extend the full width of the ILS. The surface bulges slightly, and is relatively smooth with few microvilli. The number of strands in the tight junction between neighboring swMRCs also decreases following seawater transfer. The shallow tight junction is an important morphological characteristic that gives a good indication of the cell's function, namely NaCl elimination.

In the freshwater lamprey, the MRC types are referred to as IC MRCs, and one of the noticeable differences to the swMRC is the lack of a tubular system (**Figure 6**). One type is only present in the larval ammocoete and is characterized by electron-dense mitochondria, small secretory mucus granules, short microvilli and/or microplicae, and the presence of globular particles in its apical membrane (as shown by freeze fracture). They are found in both the lamellar and filament epithelia, and comprise approximately 60% of the total epithelium. The function of this ammocoete MRC type is unknown, but it disappears following metamorphosis and does not appear to be involved in ion regulation. The second IC type is generally found singly or in pairs in the interlamellar region and at the base of the lamellae, where it intercalates with neighboring PVCs and/or other MRC types. It is characterized by an apical membrane with elaborate microplicae, the absence of secretory mucous granules, the presence of numerous small vesicles and membranous tubules, and the presence of rod-shaped particles in either the apical or lateral membranes (as determined by freeze-fracture electron microscopy). These rod-shaped particles are similar to those described in the mitochondrion-rich ICs of other acid-secreting epithelia. The plasma membrane domains having dense rod-shaped particle aggregates also show strong immunoreactivity for the proton pump (vacuolar type H^+-ATPase), which has been demonstrated by IHC. When the proton pumps are in the apical location, these cells function in acid excretion while in cells in which the particles have a basal lateral location, the function is for base excretion.

In the hagfish, MRCs are restricted to the lateral wall of gill pouches and the lateral half of gill folds. All MRCs occur singly, being separated by PVCs, and lack leaky tight junctions. The hagfish MRCs have abundant, large mitochondria and a tubular system continuous with the basolateral membrane along with a subapical vesiculotubular system (**Figure 7**). These cells also have perinuclear glycogen and high levels of carbonic anhydase, H^+-ATPase, and Na^+/K^+-ATPase expression. Since hagfish are osmoconformers and therefore lack active NaCl regulation, their presence is linked to acid–base regulation. Communicating gap junctions are not found between hagfish MRCs and its neighbors (PVCs and nondifferentiated cells). Their apical membrane contains microvilli and is usually convex and deep apical crypts are not common. Freeze-fracture electron microscopy has shown the presence of rod-shaped particles in the apical membrane which represent proton pumps as confirmed by IHC.

MCR Identification

In addition to direct morphological analysis, MRCs have been identified by their affinity for eosin, and acid Fuschin stain, associated with abundant mitochondria and Champy–Maillet solution ($ZnI–OsO_4$), which reacts specifically with membrane and thus the reaction with the abundant membrane systems of the MRC results in its selective blackening. Additional techniques are directed at the detection of the abundant mitochondria which results in a stronger signal than background. The mitochondrial vital stains dimethylaminostyrylmethylpyridiniumiodide (DASPMI), dimethylaminostyrylethylpyridiniumiodide (DASPEI), and Mitotracker^{TM} (Molecular Probes), as well as immunohistochemical techniques directed against mitochondria-specific proteins have been used to this end.

Another approach has been to target the enzyme Na^+/K^+-ATPase, which has been shown to be expressed in high concentrations in MRCs. Ouabain specifically binds and inhibits the Na^+/K^+-ATPase and both ^{3}[H] ouabain autoradiography and anthroylouabain fluorescence have been found to localize to MRCs. Enzyme histochemical and immunohistochemical methods have been used in the past to localize Na^+/K^+-ATPase to MRCs. The use of antibodies directed against the Na^+/K^+-ATPase have proven very useful as is evident in the large number of studies published recently using this approach (**Figure 1**(**f**)). Practically all of these studies make use of either the mouse monoclonal or rabbit polyclonal antibodies directed against conserved epitopes or regions of the Na^+/K^+-ATPase α-subunit. The further study of MRC functional subtypes through the use of multiple immunohistochemical labeling with additional ion transporters is addressed in the articles **Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes .

Glossary

Acclimation Physiological and/or biochemistry adjustments made by an organism in response to a prolonged change in their environment, e.g., temperature.

Catecholamine Any of a class of amines derived from a catechol that acts as chemical messengers (a hormone or neurotransmitter). The fish's main catecholamines are dopamine, adrenaline, and noradrenaline and these are secreted by neurons of the autonomic nervous system or specific chromaffin cells of the head kidney.

Critical swimming speed (U_{crit}) The U_{crit} is determined in a swim tunnel where the fish are forced to swim against a current. The current velocity is increased in steps and each step is maintained for a specified time (usually 10 min to 1 h) or until the fish fatigues.

Diffusion Net movement of a solute from an area of higher concentration to an area of lower concentration.

Epinephrine Catecholamine hormone secreted by the adrenal gland.

Hypoxia Low partial pressures of oxygen in external or internal environments.

Norepinephrine Catecholamine hormone secreted by the adrenal gland.

Normoxia Normal levels of oxygen in water or arterial blood.

Oxygen consumption ($\dot{M}O_2$) Amount of oxygen consumed by an animal per unit time.

P_{crit} The environmental O_2 tension below which an animal cannot sustain a routine rate of O_2 uptake independent of environmental O_2 tensions. The lower a fishes P_{crit}, the better able it is to maintain normal levels of activity and therefore fish with lower P_{crit}'s are belived to be more hypoxia tolerant than those with higher P_{crit} values.

Trans-epithelial potential The electrical potential across an epithelium as a function of concentration differences and relative permeabilities of all salts.

What Is the Osmorespiratory Compromise?

The gill epithelium is the primary site of both gas exchange and ion regulation in fish and the term 'osmorespiratory compromise' refers to the functional clash that can exist between these two processes. The basis for the osmorespiratory compromise is that diffusion is involved in movement of both gases and salts (primarily Na^+ and Cl^-) across the branchial epithelium. Diffusion of O_2 across the gill is a function of surface area, diffusion distance, mean water-to-blood P_{O_2} difference, and O_2 permeability of the epithelium. Diffusion of Na^+ and Cl^- across the gill depends upon surface area, diffusion distance, mean blood-to-water concentration differences, epithelial permeability to salts, and trans-epithelial potential (TEP). Thus, both gill surface area and water-to-blood diffusion distance are common to the diffusion of gases and ion. In freshwater, any increase in surface area or reduction in diffusion distance to promote gas diffusion will also elevate diffusive ion loss, which must be replaced actively. Conversely, any reduction in surface area and/or increase in diffusion distance to limit ion losses could restrict O_2 uptake. The term 'respiratory/osmoregulatory compromise' coined in early studies eventually morphed into the slightly more user-friendly osmorespiratory compromise in the early 1990s, by which it is generally known today. The first studies of the osmorespiratory compromise used exercise to induce changes in branchial surface area and monitored its effects on gas and/or ion transfer. Subsequent studies have used acclimation to a variety of water conditions to induce changes in branchial diffusion distance and monitored the consequences for gas and ion movement.

The Effect of Changes in Branchial Surface Area

Exercise

The first researchers to examine the osmorespiratory compromise argued that when fish begin to swim faster, a suite of cardiovascular and respiratory changes, mediated by catecholamine release, alter branchial blood flow in order to promote O_2 uptake. Changes include decreased vascular resistance, increased blood pressure, and re-direction of blood from more central paths to lamellar circuits, which presumably would increase exchange area (**see also Gas Exchange**: Respiration: An Introduction). Indeed, resting rainbow trout (*Oncorhynchus mykiss*) perfuse less than 60% of their gill lamellae but when given a dose of epinephrine or exposed to hypoxia, the number rises to about 75%. The implication is that during exercise, when O_2 demand rises, fish increase the 'functional surface area' of the gills to promote O_2 uptake. Such an increase in surface area, it was hypothesized, would lead to elevated rates of ion loss (primarily Na^+ and Cl^-). Sure enough, when rainbow trout are forced to swim by occasional prodding or electric shock, rates of appearance of radioactive ^{22}Na in surrounding media are higher than in resting fish. Similarly, fish injected with the catecholamine norepinephrine also had higher rates of ^{22}Na loss relative to controls or sham injected fish. Ensuing studies measured actual rates of Na^+ efflux while distinguishing between short, exhaustive exercise and extended, more aerobic swimming. When fish are forced to swim exhaustively for short periods, their rates of Na^+ efflux rise 70% above resting levels, confirming the previous findings.

When both Na^+ efflux and O_2 uptake are measured simultaneously, additional factors are revealed to be involved in the initial high rates of ion loss. With exercise, increased O_2 uptake is driven not only by the increase in functional surface area, but also by greater water-to-blood P_{O_2} difference mainly due to higher rates of O_2 consumption in muscle tissue. The increased functional surface area to promote O_2 uptake would lead to elevated rates of ion loss, but since there is no change in the blood-to-water concentration difference corresponding to the P_{O_2} difference, one would expect a smaller rise in ion loss than O_2 uptake. In fact, at the onset of exercise the opposite is true. Immediately after being chased for 5 min or during the first 30 min of chronic swimming at 85% U_{crit} (about 4.5 body lengths s^{-1}) O_2 consumption in rainbow trout rises 2.8–3.4 times, but Na^+ efflux jumps 4.5- to 5.2-fold (U_{crit} – maximum prolonged swimming speed; **Table 1**). To put it another way, the ion to gas flux ratio rises by almost 65%. The cause of the disproportionate rise in Na^+ efflux appears to be increased epithelial permeability to salts brought about by a catecholamine-induced increase in intra-lamellar pressure at the beginning of exercise, which stretches paracellular tight junctions (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes).

Table 1 Na^+ efflux (J_{out}^{Na}), rate of O_2 consumption ($\dot{M}_{O_2}$) and ion to gas flux ratio (IGR) for rainbow trout (*Oncorhynchus mykiss*) at rest and immediately after exhaustive exercise

Treatment	J_{out}^{Na}	$\dot{M}_{O_2}$	*IGR*
At rest	8.8±0.8	72.2±2.2	122.2
Post-exercise	39.7±2.3	200.7±5.4	200.0±12.3

Units for J_{out}^{Na} and $\dot{M}_{O_2}$ are nmol g^{-1} min^{-1}, and units for IGR are pmol Na^+/nmol O_2.
Values are means ± SE.

While the marked increase in branchial permeability at the onset of swimming is striking, it does not last long. During recovery from exhaustive exercise, Na^+ efflux falls to within 10% of resting rates in trout while at the same time O_2 consumption returns to a resting rate. Part of the reduction in ion permeability can be ascribed to lower intra-lamellar pressure due to declining catecholamine levels and/or downregulation in catecholamine receptor density, but it appears that in addition there is a significant level of control of epithelial ion permeability applied at the tight junctions. This marked ability to regulate paracellular ion permeability raises the possibility that during chronic swimming any increase in ion loss due to increased functional surface area could be negated by reduced permeability. Indeed, at moderate swimming speeds of 2 body lengths s^{-1} Na^+ efflux falls to resting levels within an hour and it falls well below resting levels within 5 h. At a higher swimming speed, 4.5 body lengths s^{-1}, Na^+ efflux remains elevated well above resting rates for the duration of the exercise, although they drop from higher initial rates. It appears that vigorous swimming may interfere in some way with the control of ion permeability. Such high rates of Na^+ efflux with vigorous exercise lead to high rates of net ion loss, which cannot be sustained for prolonged periods since they would lead to a significant depletion of internal stores and initiate a cascade of cardiovascular disturbances. The key adjustment in this case is not a control of Na^+ efflux, but rather a rapid up to threefold stimulation of ion transport. The rise in active uptake allows the fish to maintain internal levels despite the higher loss rates.

All work on the effects of exercise on the osmorespiratory compromise to this point had been performed on rainbow trout, which is an active, coldwater species. When other species that differ in energetic lifestyle and temperature preferences, but had similar gill sizes, were examined, significant differences were found. Resting rates of O_2 consumption vary more than threefold among the species (**Table 2**), and the likely physiological basis for such a range is differences in branchial O_2 permeability. Further, after exhaustive exercise elevation of O_2 uptake for the less active species is associated with much greater rates of ion loss. For instance, after exercise banded sunfish (*Enneacanthus obesus*) have a rate of O_2 consumption less than half that of common shiners (*Notropis cornutus*), but its rate of Na^+ loss is more than 50% higher. Consequently, while ion to gas flux ratio for the shiner rises only 25% immediately after exercise, it is more than quadruples for the sunfish. Since shiners have

Table 2 Na^+ efflux (J_{out}^{Na}), rate of O_2 consumption ($\dot{M}_{O_2}$) and ion to gas flux ratio (IGR) for common shiners (*Notropis cornutus*), golden shiners (*Notemigonus crysoleucas*), smallmouth bass (*Micropterus dolomieui*), yellow perch (*Perca flavescens*), and banded sunfish (*Enneacanthus obesus*) at rest and immediately after exhaustive exercise

	At rest			*Post-exercise*		
Species	J_{out}^{Na}	$\dot{M}_{O_2}$	*IGR*	J_{out}^{Na}	$\dot{M}_{O_2}$	*IGR*
Common shiner	4.8±0.5	118.6±13.5	40.5	9.3±0.8	191.8±15.0	50.3±6.8
Golden shiner	12.7±1.3	141.0±16.6	90.1	18.1±1.2	192.6±10.4	94.9±8.0
Smallmouth bass	3.5±0.3	74.7±8.6	46.9	21.3±2.3	152.0±4.6	141.0±14.8
Yellow perch	4.2±0.4	72.7±5.7	57.8	21.9±1.5	133.4±4.6	164.2±10.2
Banded sunfish	3.0±0.3	41.3±3.4	72.6	28.9±3.7	90.1±3.6	317.6±35.7

Units for J_{out}^{Na} and $\dot{M}_{O_2}$ are nmol g^{-1} min^{-1}, and units for IGR are pmol Na^+/nmol O_2.
Values are means ± SE.

higher branchial O_2 permeability, they can achieve higher rates of O_2 uptake without the need for big changes in surface area brought about by high intra-lamellar pressures that stimulate ion losses. Sunfish, in contrast, require much greater increases in surface area, brought about by the elevated pressure that promotes ion loss. Interestingly, species such as smallmouth bass (*Micropterus dolomieu*) and yellow perch (*Perca flavescens*), that are intermediate in resting O_2 consumption, experience intermediate elevations in ion loss. These findings indicate that less active species such as banded sunfish, that inhabit densely vegetated coastal swamps, place less emphasis on conserving ions with activity since they probably rarely experience prolonged bouts of activity in their native habitats. The more active a fish is, the greater the potential osmotic costs. Very active species, such as the stream dwelling common (*N. cornutus*) and golden shiners (*Notemigonus crysoleucas*), avoid exorbitant osmotic costs of activity by virtue of their high branchial O_2 permeability.

Studies of the osmorespiratory compromise in exercising fish seem to confirm, in general terms, the existence of a conflict between ion and gas flux across the gills of fish based upon surface area. Such conflict is most notable when exercise is commencing and catecholamine-induced cardiovascular adjustments are occurring to enhance O_2 pickup. Under those circumstances, ion loss increases more than predicted based only on functional surface area considerations due to additional elevation of branchial ion permeability. The rise in permeability is transitory and disappears within an hour or less as catecholamines dissipate from circulation. Further, fish show considerable ability to regulate anion and cation permeability independently and can significantly lower branchial ion permeability well below resting levels and upregulate transport. Studies with a range of species indicate that branchial gas permeability also varies among species and this influences the severity of the impact of increased gas uptake on ion loss. Fish with high O_2 permeability can take up more additional O_2 during exercise without much ion loss, while fish with low O_2 permeability incur much higher rates of ion loss even with lower absolute rates of O_2 uptake.

Osmorespiratory Compromise in Seawater

The basis of the osmorespiratory compromise in seawater is essentially the same as in freshwater except that the concentration differences for Na^+ and Cl^- are reversed (lower internally). For example, a freshwater fish typically has a Na^+ concentration difference across the gill epithelium of around 149 mmol L^{-1} (inside higher), while in seawater it is over 350 mmol L^{-1} (outside higher), which means that increases in surface area with activity could potentially be more costly in seawater than in freshwater (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts). The issue is complicated, however, by the role TEP plays in salt excretion at the gills. The general model uses a positive TEP (blood relative to water) to excrete Na^+ across the gills. Despite the concentration difference, Na^+ would not enter across the gills because of the opposing TEP. Further complicating the issue is the fact that the gut absorbs salts in order to take up water to replace what is lost. In fact, elevated water loss with exercise is likely a bigger problem due to the ion load incurred in order to replace it.

Few studies have examined the osmorespiratory compromise in seawater probably because of the technical difficulty of measuring ion fluxes in saline waters. For this reason, the few studies available have used indirect measures of ion regulation such as gill and gut Na^+/K^+-ATPase activity and have tended to compare species that vary in energetic lifestyle and branchial surface area. More active fish have larger gills (with greater surface area) and thus should incur a greater osmoregulatory cost. Indeed, branchial Na^+/K^+-ATPase activities of some active epipelagic species are higher than in sluggish meso-pelagic fishes. It was argued that the sluggish fish had lower metabolic rates and thus reduced osmoregulatory costs. In contrast, branchial Na^+/K^+-ATPase activities are not higher in the epipelagic yellowfin tuna *(Thunnus albacares)* or skipjack tuna *(Katsuwonus pelamis)*, which are among the most aerobically active of all fish and have very large branchial surface areas, compared to less active species; it was concluded that osmoregulatory costs are not elevated in tunas. Based on this diversity of results and paucity of studies, it is difficult to reach any conclusions of the osmorespiratory compromise in seawater fish.

The Effect of Changes in Branchial Diffusion Distance

Acclimation to Soft Water

For many freshwater fish, exposure to soft water (water low in Na^+ and/or Ca^{2+}) disrupts the ability to regulate internal salt levels. Exposure to low $[Ca^{2+}]$ water leaches Ca^{2+} from paracellular tight junctions and promotes diffusive ion loss, while exposure to low $[Na^+]$ water reduces concentration-dependent active Na^+ uptake. Extended time in either or both water conditions can lead to significant depletion of internal ion levels. One way to restore ion balance is to upregulate ion transport, which will either compensate for the scarcity of Na^+ in the surrounding water, or counteract the higher rates of ion loss in low Ca^{2+} water. Upregulation of ion transport is typically associated with a proliferation of mitochondrion-rich cells (MRCs) in the branchial epithelium. In ion-rich waters, MRCs, which are much larger than the surrounding pavement cells, are primarily found on filaments and filling-in the intra-lamellar spaces; they make up less than 10% of the surface area of the gills. As they proliferate, MRCs appear on the lamellar epithelium, which acts to raise the average water-to-blood diffusion distance for gases. Thus, acclimation to restore ion balance in soft water could, in theory, act to impede gas exchange. Whether or not this happens in reality depends upon the degree of MRC proliferation, its effect on average water-to-blood diffusion distance, and the presence of any compensatory adjustments.

When rainbow trout are exposed to soft water or treated with a combination of cortisol and ovine growth hormone, MRC density more than doubles and fractional area rises from about 5% to 20%. Visual inspection alone is enough to illustrate the impact (**Figure 1**). Measurements of average water-to-blood diffusion distance along the lamellae show that it almost doubles following MRC proliferation. This appears to be a general consequence of soft water acclimation, because similar results were obtained from the tropical *Hoplias malabaricus*.

The proliferation of MRCs and associated increase in diffusion distance across the branchial epithelium suggests the potential for impairment of O_2 uptake, but in normoxic water results vary. Some studies show a lower arterial P_{O_2} in trout undergoing MRC proliferation, but some do not. The uptake of O_2 by resting fish in normoxic waters is thought to be perfusion limited and may not be influenced by the reduction in diffusion potential. Alternatively, a compensatory elevation in ventilation frequency may be important in maintaining arterial P_{O_2}. Thickening of branchial epithelium should also act to impair diffusion of CO_2, and since CO_2 excretion is thought to be diffusion limited, one would expect to see the effects of MRC proliferation in normoxic waters. Again results vary among studies. One study reported elevated arterial P_{CO_2}, while two did not.

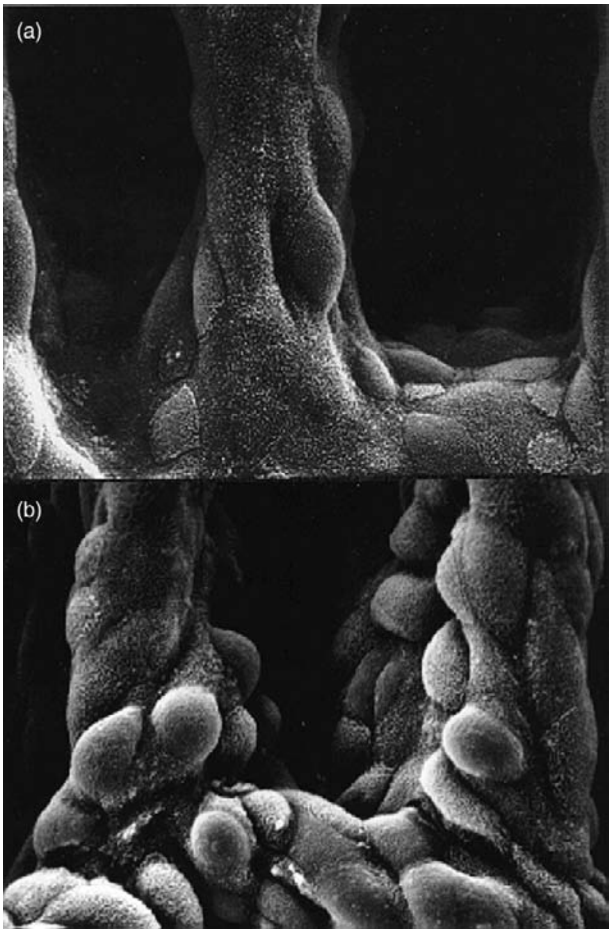

Figure 1 Scanning electron micrograph of gills of rainbow trout in ion-rich water (a) and after acclimation to soft water (b). Photos by permission of S. Perry.

While the effects of lamellar thickening on gas exchange in normoxic waters are not completely apparent, what is clear is that thickening does have a significant effect on gas exchange when fish are challenged with hypoxia. Researchers observe reduced arterial P_{O_2} in fish with thickened epithelia during exposure to hypoxia. Likewise, during exercise when O_2 demand is elevated, soft water-held trout have lower U_{crit} values and rely more heavily on anaerobic metabolism while swimming. It appears that as water-to-blood P_{O_2} difference falls or O_2 demand is elevated with exercise, then O_2 uptake becomes diffusion limited and lamellar thickening becomes important.

Acclimation to soft water does not fit the original model of the osmorespiratory compromise based upon changes in functional surface area, but it does highlight other possibilities for conflict between these two processes. In the original scenario, alterations to enhance diffusion of O_2 for uptake also enhance diffusive ion loss. Here we see that proliferation of MRCs, to upregulate active ion transport, causes a thickening of lamella that affects O_2 and CO_2 diffusion. An acclimatory response to restore or defend internal ion levels is achieved at the cost of gas exchange.

Acclimation to Changing Salinity

Movement between freshwater and seawater requires a fish to make a host of osmoregulatory adjustments to successfully regulate internal ions. For instance, movement from seawater to freshwater requires a hyporegulating teleost that actively excretes ions and drinks seawater (incurring an additional salt load to absorb the water) to suddenly stop drinking, start actively taking up salts, and reduce branchial ion losses. Morphological adjustments made to assist maintenance of ion balance could in theory influence gas exchange (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction).

Prickly sculpins (*Cottus asper*), primarily a freshwater species, can still successfully and tightly regulate Na^+ and Cl^- in full seawater. In contrast, closely related Pacific staghorn sculpins (*Leptocottus armatus*) are marine and less tolerant of freshwater. Prickly sculpins have smaller gills (on a mass specific basis) than Pacific staghorn sculpins, which allows for lower ion permeability during exposure to freshwater. Further, during exposure to freshwater, prickly sculpins increase the thickness of their branchial epithelium by about 40%, which raises the water-to-blood diffusion distance. This means that prickly sculpins drop an already low branchial ion permeability even further when in freshwater, thereby controlling diffusive ion loss and maintain internal levels. However, the adjustment in diffusion distance to help conserve salts comes with a price for the prickly sculpin. Measurements of critical oxygen tensions (P_{crit}) show a marked $\sim$15 torr increase in freshwater-held prickly sculpins compared to those in seawater. In other words, the increase in epithelial thickness to limit ion losses hinders O_2 uptake at low environmental P_{O_2} levels. As with acclimation to soft water, adjustments made to aid ion regulation, in turn, impede gas exchange. The morphological adjustments were different in the two cases – one a proliferation of MRC and the other a general thickening of the epithelium – both increased the water-to-blood diffusion distance for O_2. In each case, differences were not obvious in normoxic waters, but became evident during exposure to hypoxic waters.

Effect of Branchial Remodeling

Gills of crucian carp (*Carassius carassius*) undergo a striking morphological transformation in normoxic waters at low temperature when metabolic O_2 demand is low (**see also Bony Fishes**: Crucian Carp). Cells proliferate between branchial lamella filling in the space creating an intra-lamellar cell mass (ILCM) and greatly reducing surface area and increasing average diffusion distance With exposure to hypoxia or high temperatures, when O_2 demand is elevated, these ILCMs disappear revealing the underlying lamella, restoring the higher respiratory area and reducing diffusion distance. A similar response is seen in the goldfish (*Carassius auratus*) and in the Lake Qinghai scaleless carp (*Gymnocypris przewalskii*) native to a high-altitude lake in central China. Similarly, the osteoglossid (*Arapaima gigas*) from the Amazon River actually loses its lamellae during ontogenetic transition from obligate water breathing at hatching to obligate air breathing (**Figure 2**). In this case, however, the change is irreversible. A very similar response is reported for

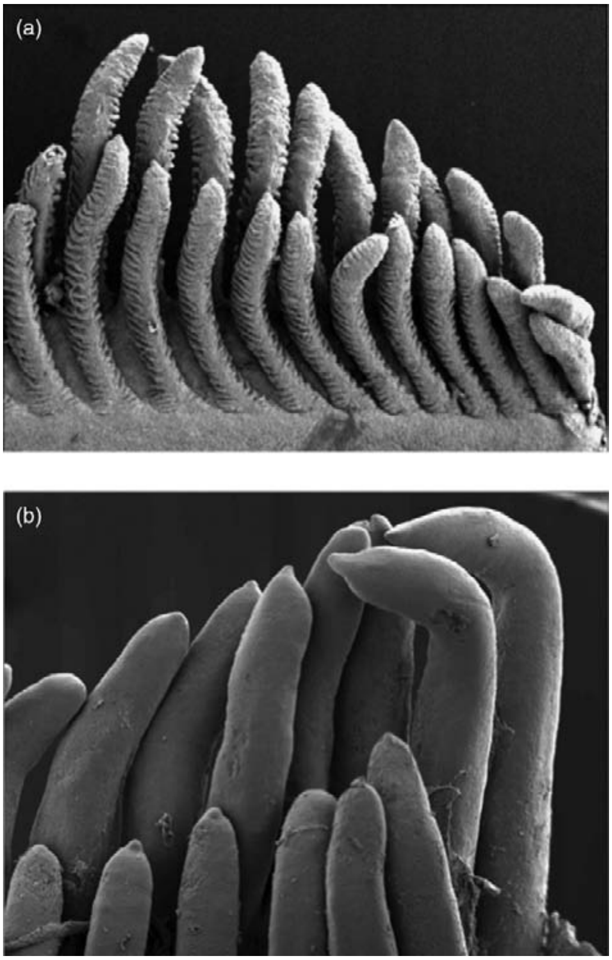

Figure 2 Scanning electron micrographs of gills of (a) 10 g *A. gigas* and (b) 1000 g *A. gigas*. Photos by permission of C. Brauner.

overwintering large mouth bass (*Micropterus salmoides*) and for fathead minnows (*Pimephales promelas*) exposed to toxic water left over from refining oil sands. The explanation generally offered for such morphological changes is that a reduction in surface area and an increase in diffusion distance when O_2 supplies are ample to meet demands lower osmotic costs.

Results generally support the osmotic cost hypothesis. Goldfish with ILCM at low temperature have lower Cl^- and polyethylene glycol (indicator of paracellular diffusion) fluxes than goldfish at higher temperature without ILCMs. Similarly, Lake Qinghai scaleless carp that lose ILCMs in hypoxic waters experience a 10–15% drop in plasma Na^+ and Cl^- concentrations, suggesting higher rates of diffusive loss. In contrast, larger *A. gigas* that have lamellae-less gills and a fourfold greater water-to-blood diffusion distance actually have diffusive ion loss rates 3 times higher than smaller fish with lamellae-bearing gills. The likely difference here is probably reduced branchial ion permeability in smaller fish that more than compensates for higher surface area and shorter diffusion distance.

In stark contrast to the response to hypoxia we see in Crucian carp, goldfish, and Lake Qinghai scaleless carp is the response observed in the Amazonian oscar (*Astronotus ocellatus*) – an extremely hypoxia-tolerant fish that can tolerate complete anoxia for up to 6 h and severe hypoxia for 1–2 days. During exposure to severe hypoxia (10–20 torr), oscars show no increase in functional gill surface area and/or reduction in diffusion distance. In fact, Na^+ efflux actually drops significantly, which acts to preserve ion balance since Na^+ uptake also falls due to the lack of O_2 and downregulation of Na^+/K^+-ATPase. The drop in Na^+ efflux appears to be a result of pavement cells quickly covering over MRCs, thus markedly reducing their surface area and lowering branchial permeability. This is a very different take on the osmorespiratory compromise where adjustments are made to defend ion balance while not interfering with gas exchange. Perhaps conflict avoidance is only possible in such a strikingly hypoxia tolerant fish.

Glossary

Ammocoete Alternate name for the larval stage of the lamprey life cycle.

Amniotes Vertebrates whose embryonic development takes place in a fluid-filled sac called amnion that is responsible for keeping the embryo moist. Reptiles, birds, and mammals are amniotes.

Basal lamina Extracellular supporting layer found beneath all epithelia.

Brush border Closely packed microvilli on the apical surface of cells.

Coelom Continuous sheet of peritoneum entirely enclosing the body cavity – visceral peritoneum over the organs and parietal peritoneum lining the cavity.

Endothelium A thin layer of thin, flat cells forming the lining of all blood and lymph spaces.

Erythrocyte The most abundant cell found in the blood of nearly all fish. It contains the respiratory pigment hemoglobin and is commonly called a red blood cell because of its color.

Fenestrated Having openings in the wall.

Freeze-fracture Tissues are deeply frozen and split with a small blade, much like an axe splitting wood. Contours remaining on the split surface are coated with a thin layer of carbon. The tissue is removed with acid and the remaining carbon impression examined with a transmission electron microscope. Most of the splits occur within the hydrophobic region of cell membranes, thereby revealing details of the membrane, especially junctions.

Hemopoiesis The formation of blood cells.

Juxtaglomerular cells Modified smooth muscle cells in the afferent arteriole of a glomerulus; said to produce the enzyme renin.

Mesangium Space between the loops of glomerular capillaries.

Parietal peritoneum The lining of the coelom.

Renin An enzyme involved in the control of glomerular filtration rate.

Rete mirabile A capillary bed occurring within a small artery or vein so that blood from the heart passes through two capillary beds before returning.

Simple squamous epithelium A single layer of flat cells covering a surface.

Visceral peritoneum A layer enclosing the viscera located within the coelom.

Introduction

Excretion involves the separation and elimination of metabolic waste products from the body. Various organs are involved in this process: the lungs, gills, skin, etc. The kidneys and their ducts are the major full-time excretory organs and comprise the excretory system.

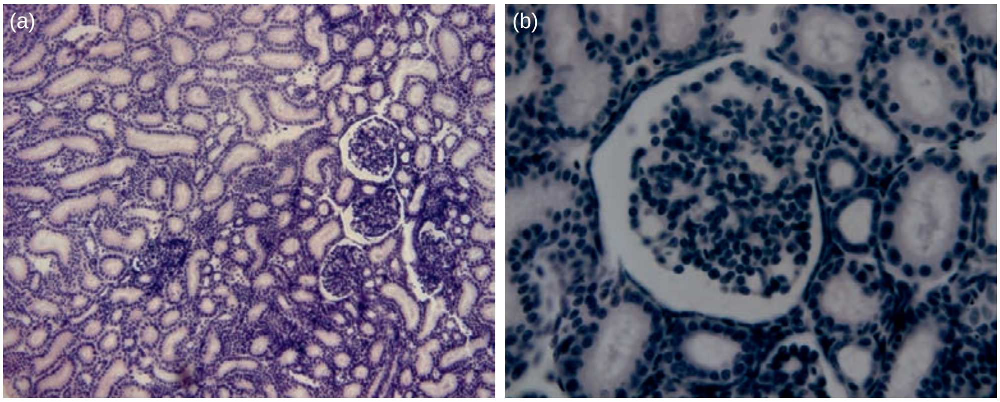

Figure 1 Photomicrographs of a section of the kidney of a spiny dogfish (*Squalus acanthias*). (a) Three glomeruli (singular, glomerulus) at the right are surrounded by masses of renal tubules. Delicate capillaries (not seen) invade the loose connective tissue between the tubules. 10×. (b) One of the glomeruli from (a) is surrounded by a nephric capsule (Bowman's capsule). The capsule consists of a simple squamous epithelium and resembles a balloon which has been pushed in by the glomerulus so that each capillary is covered by the visceral layer of the nephric capsule and the space is enclosed by the parietal layer. Masses of renal tubules fill the remaining field. Occasional capillaries appear between the tubules 40×.

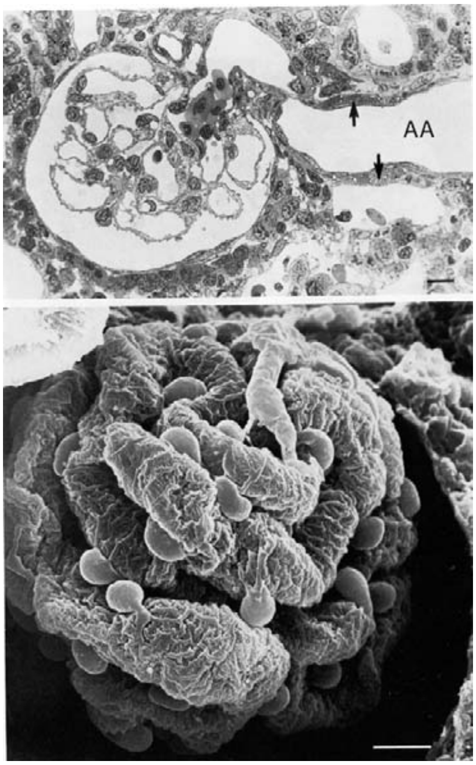

Figure 2 Micrographs to demonstrate the capillary loops in renal corpuscles of a freshwater teleost fish (*Carassius auratus gibelio*) Top: Photomicrograph of a section showing the well-developed knot of capillaries with many loops and widely patent lumina. AA, afferent arteriole with juxtaglomerular cells (arrows). Scale = 10 μm. Bottom: Scanning electron micrograph of the surface of the capillary loops sporting globular podocytes from which extend primary and secondary foot processes. Scale = 10 μm. A scanning and transmission electron-microscopic study. *Cell and Tissue Research* 220: 73–85.

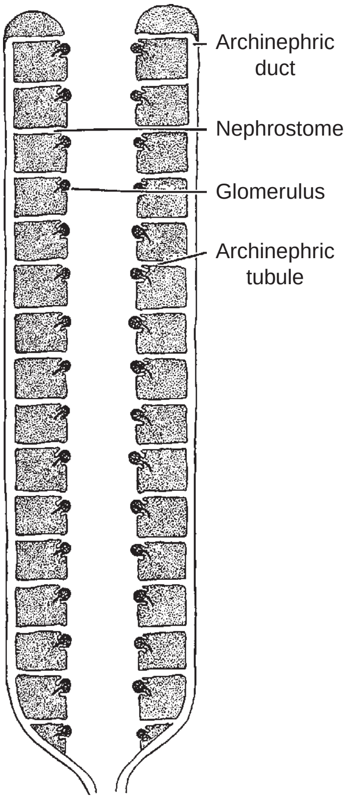

Figure 3 Diagram showing the hypothetical structure of the archinephros. A series of paired segmental tubules opens into the coelom by funnel-shaped nephrostomes that are associated with knots of blood vessels, the glomeruli. From Weichert CK (1965) *Anatomy of the Chordates*, 3rd edn., New York: McGraw-Hill Book Company, figure 7.2.

In addition to the elimination of metabolic wastes, the excretory system functions in the maintenance of a proper water balance in the body: an equilibrium of water, inorganic salts, and other substances in the internal environment of the organism. There is a great difference in the problems of water balance encountered by marine, freshwater, and terrestrial vertebrates, and it is remarkable that their kidneys are as much alike as they are.

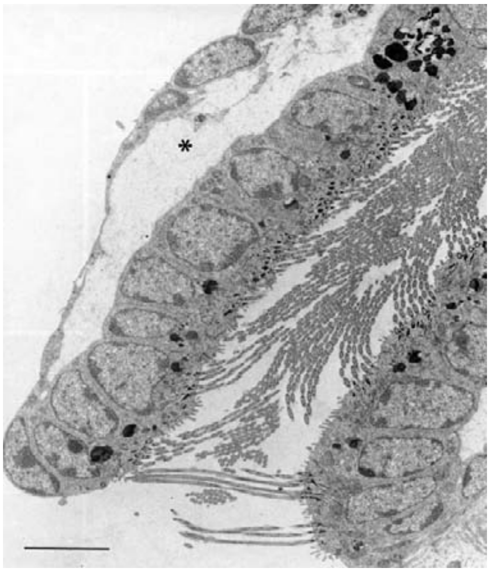

Figure 4 Transmission electron micrograph of a longitudinal section of the nephrostome from the pronephros of an early ammocoete (*Petromyzon marinus*). Both cilia and microvilli extend into the lumen. There is continuity between the peritoneal and tubular epithelium at the lower left. Loose connective tissue (*) lies between the two types of epithelia. Scale = 5 μm; 3700×. From Kluge B and Fischer A (1991) The pronephros of the early ammocoete larva of lampreys (Cyclostomata, Petromyzontes): Fine structure of the renal tubules. *Cell and Tissue Research* 263: 515–528, figure 9.

The kidney of all vertebrates consists of knots of blood vessels, either glomeruli or glomera, closely associated with masses of kidney tubules (**Figures 1**(**a**), **1**(**b**), and **2**). A single tubule, with its associated blood vessels, is a nephron.

Evolution of the Kidney

It is believed that the kidney of the vertebrate ancestor was an archinephros (i.e., first kidney; **Figure 3**), a type found in larval hagfish. It consists of a series of several tubules, one per segment, on each side, that connect to a pair of longitudinal ducts, the archinephric ducts, running along the dorsal wall of the coelom. Each tubule opens into the coelom by a ciliated, funnel-shaped nephrostome (**Figure 4**) and is associated with a knot of blood vessels, the glomerulus (**Figure 5**) (plural: glomeruli).

The knot of blood vessels may protrude into the coelom as an external glomerulus (**Figure 6**). From it a protein-free filtrate of the blood plasma passes through the parietal peritoneum and into the coelom to be picked up by a nephrostome. Instead, the glomerulus may push against one side of a tubule and become almost completely surrounded (like a fist pushed into a balloon) by the wall of the tubule (**Figure 7**). This internal glomerulus passes the plasma filtrate through its wall into the tubule. Sometimes several glomeruli unite to form a larger knot of blood vessels, the glomus (plural: glomera).

The glomerulus and its surrounding tubule is the renal corpuscle (**Figure 8**); in the corpuscle fluids are removed from the blood. These fluids pass down tubules, richly entwined with blood vessels (**Figure 9**), where occurs a selective reabsorption

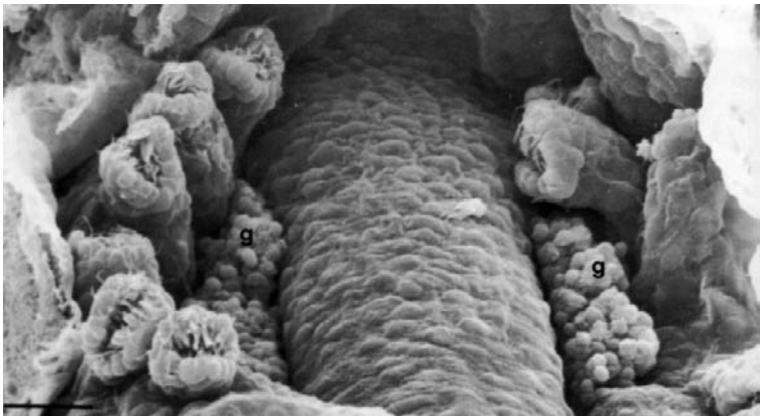

Figure 5 Scanning electron micrograph of the pronephric region of an early ammocoete (*Lampetra fluviatilis*). Two nephrostomes, with oval openings, protrude into the body cavity. There are two glomera (g) on each side of the esophagus. Scale = 20 μm; 170×. From Kluge B and Fischer A (1991) The pronephros of the early ammocoete larva of lampreys (Cyclostomata, Petromyzontes): fine structure of the renal tubules. *Cell and Tissue Research* 263: 515–528, figure 7.

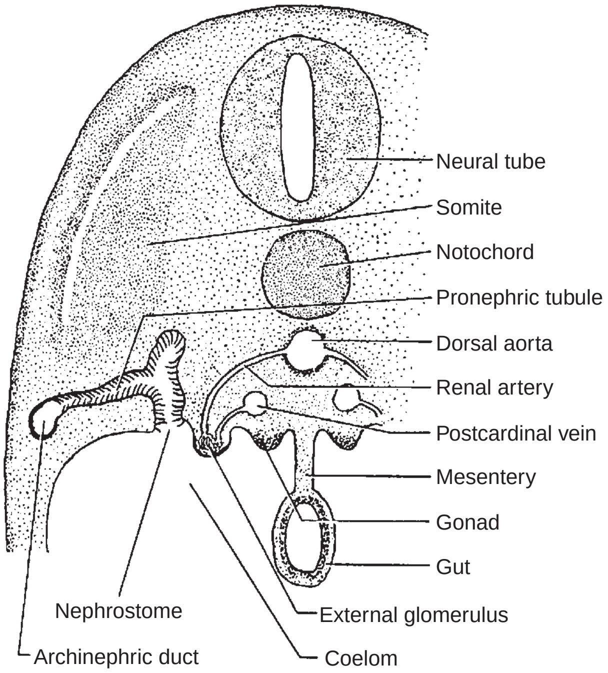

Figure 6 Diagram of a section through a vertebrate embryo showing the relation of an external glomerulus to the pronephric tubule and nephrostome. A protein-free filtrate of the blood plasma passes through the parietal peritoneum into the coelom to be picked up by the nephrostome. From Weichert CK (1965) *Anatomy of the Chordates*, 3rd edn. New York: McGraw-Hill figure 7.4.

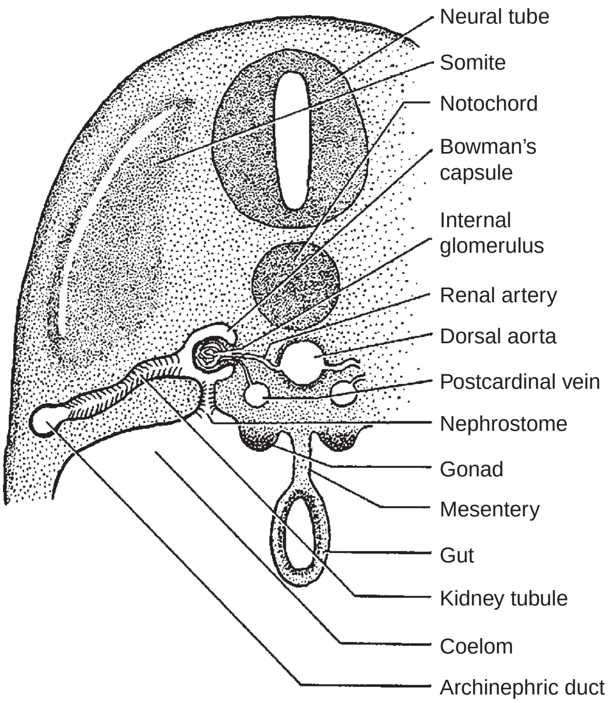

Figure 7 Diagram of a section through a vertebrate embryo showing the relation of the internal glomerulus to the kidney tubule and archinephric duct. The glomerulus has become almost completely surrounded by the wall of the tubule and a plasma filtrate passes through its wall directly into the tubule. From Weichert CK (1965) *Anatomy of the Chordates*, 3rd edn. New York: McGraw-Hill, figure 7.5.

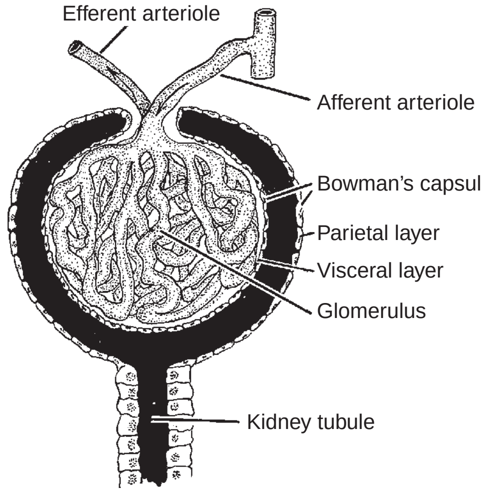

Figure 8 Diagram of a renal corpuscle. The expanded end of the kidney tubule, made up of simple squamous epithelium, becomes invaginated by the glomerulus, thereby forming a visceral layer over the vessels and an outer parietal layer. Fluids removed from the blood plasma in the nephric capsule (Bowman's capsule) pass into the tubules, which are richly entwined by blood vessels. There is a selective reabsorption of much of the water and other valuable constituents. From Weichert CK (1965) *Anatomy of the Chordates*, 3rd ed. New York: McGraw-Hill, figure 7.3.

into the blood of much of the water and other constituents so that a concentrated urine enters the excretory duct. In marine and terrestrial vertebrates, where conservation of water is essential, the glomerulus may be either lost or reduced (the aglomerular kidney of some marine fish). Freshwater fishes, on the other hand, are constantly threatened with becoming water-logged and have well-developed renal corpuscles that allow large amounts of water to escape. The Chondrichthyes appear to contradict these generalizations for, although they live in saltwater, they have large glomeruli and a kidney similar to that of freshwater fish. Excessive water loss is prevented by the retention in the blood of large amounts of urea, thereby raising the internal osmotic pressure to that of the surroundings. The archinephric duct persists in cyclostomes, elasmobranchs, and teleosts.

The most anterior portion of the archinephros, the pronephros or head kidney, appears first in developing vertebrates but is a transitory structure in the embryos of most (**Figure 3**). The remainder of the kidney posterior to the pronephros persists as the opisthonephros (i.e., back kidney) and is the functional kidney of most adult fishes. Only the posterior, unsegmented portions of the kidney tissue are retained in amniotes and these constitute the metanephros (i.e., after kidney).

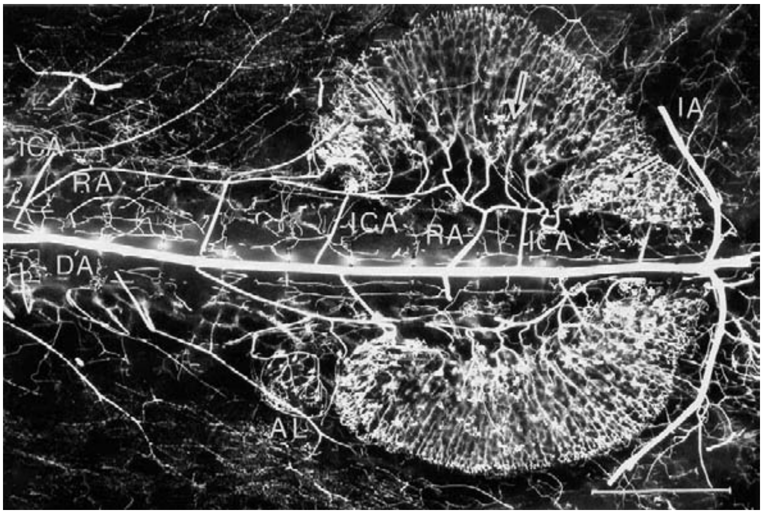

Figure 9 Photomicrograph of a corrosion preparation of the vascular system of a marine skate (*Raja erinacea*) demonstrated by the injection of silicone rubber into the blood vessels and the subsequent dissolution of all tissues. Clumps of the injection mass indicate glomeruli; masses of capillaries entwining the tubules indicate their elaborate vascularization. AL, anterior lobule of the right kidney; DA, dorsal aorta; IA, iliac artery; ICA, intercostal arteries; RA, renal arteries. Scale = 5 mm. From Hentschel H (1988) Renal blood vascular system in the elasmobranch, *Raja erinacea* Mitchill, in relation to kidney zones. *American Journal of Anatomy* 183: 130–147, figure 1.

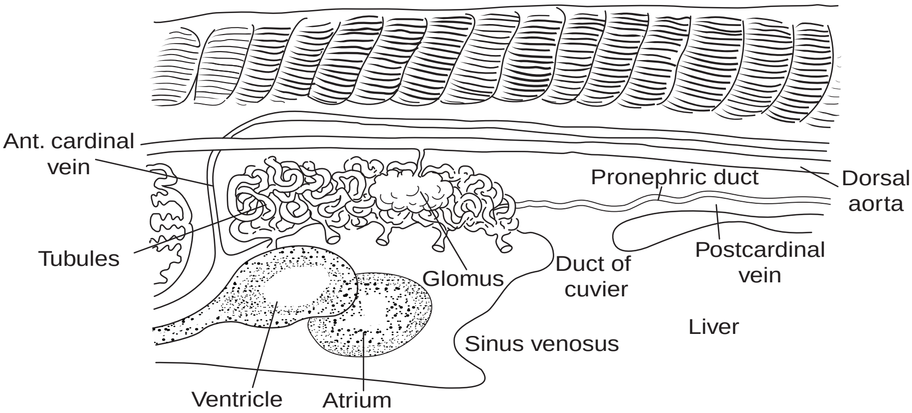

Figure 10 Diagrammatic view of the pronephros in a sagittal section of the cardiac region of a first-year ammocoete; several glomeruli have come together to form a glomus. From Bowen PC (1969) The Cytology of the Pronephros of Lampreys, PhD Thesis, University of Oxford text – figure 1.

Pronephros or Head Kidney

The pronephros, a functioning excretory organ in developing vertebrates, persists only in adult cyclostomes, a few teleosts, and lungfishes (**Figure 10**). Although the pronephros may not always function in excretion, it often supports hemopoiesis (blood cell formation) in the loose vascular connective tissue between its tubules (**Figure 11**). In Chondrichthyes, the pronephros is embryologically short-lived and never survives in the adult.

Near the mouth of each nephrostome may be an external glomerulus, a capillary net branching off the dorsal aorta (**Figures 5** and **6**). Capillaries of the glomerulus are formed of fenestrated squamous epithelial cells, which permit the leakage of fluids into the coelom. These delicate cells are reinforced by the embrace of finger-like pedicels of elaborate podocytes (**Figures 12** and **13**). Each coiled pronephric tubule begins as a ciliated funnel or nephrostome (**Figure 14**) whose flattened epithelium is continuous with that of the peritoneum. Cilia of the nephrostome move fluids into the pronephric tubule, a convoluted tubule, lined with simple cuboidal epithelial cells that are richly provided with an apical microvillous border characteristic of fluid transport; it is likely that these cells retain ions and water.

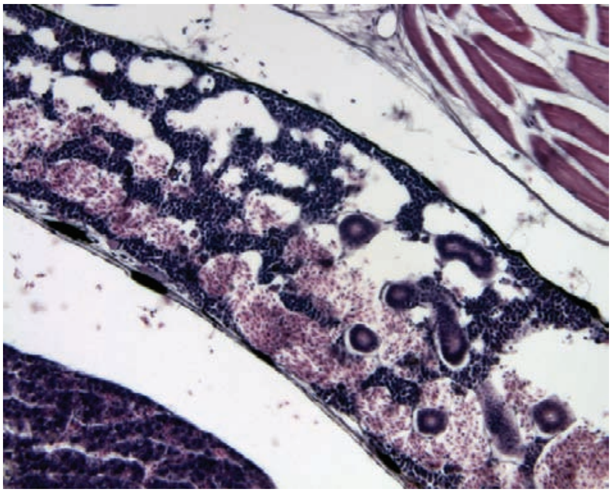

Figure 11 Photomicrograph of a section of the pronephros in a darter. Hemopoietic tissue invades the loose connective tissue between the few vestiges of kidney tubules remaining. 20×.

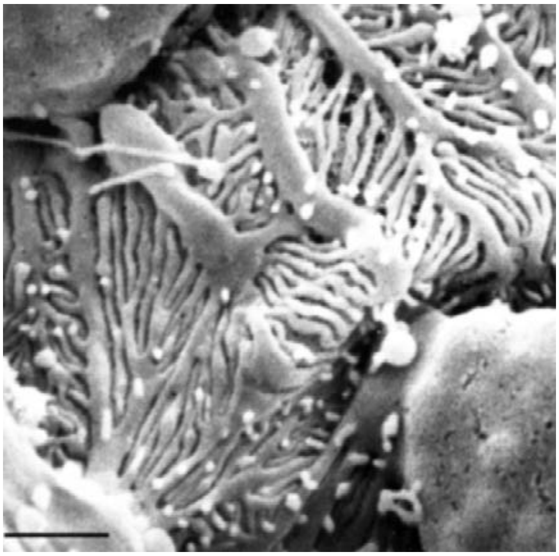

Figure 12 Scanning electron micrograph showing the interdigitation between pedicels of neighboring podocytes embracing a capillary in the glomus of an early ammocoete (*Lampetra fluviatilis*). Scale = 5 μm; 3200×. From Kluge B and Fischer A (1990) The pronephros of the early ammocoete larva of lampreys (Cyclostomata, Petromyzontes): Fine structure of the external glomus. *Cell and Tissue Research* 260: 249–259, figure 13.

Opisthonephros

In most adult fishes, the pronephros disappears and the kidney is an opisthonephros. This kidney is more compact than its predecessor. It is a mass of tubules and blood vessels supported on a framework of loose fibrous connective tissue and contained within a capsule of connective tissue. Often, hemopoietic activity can be seen in the connective tissue between the tubules. The segmental arrangement of tubules is lost in the opisthonephros and several tubules may lie within a single segment.

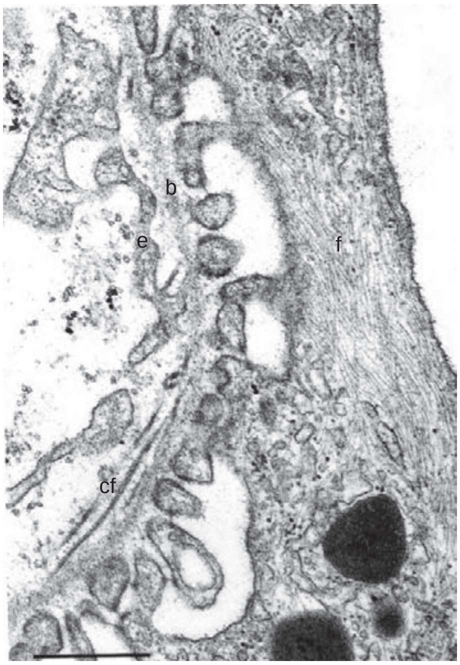

Figure 13 Transmission electron micrograph of a section through the glomus of an early ammocete (*Petromyzon marinus*). Bundles of filaments (f) extend into a large process of a podocyte. Foot processes make intimate contact with the basal lamina (b). Collagen fibers (cf) are interspersed between the basal lamina and the fenestrated endothelial cells (e) of the capillary. Scale = 0.5 μm; 44 000×. From Kluge B and Fischer A (1990) The pronephros of the early ammocoete larva of lampreys (Cyclostomata, Petromyzontes): fine structure of the external glomus. *Cell and Tissue Research* 260: 249–259, figure 8.

The glomerulus is enclosed by a double capsule of tubular tissue, the glomerular capsule (Bowman's capsule) (**Figure 15**). The inner visceral layer of the capsule is closely applied to the blood vessels of the glomerulus and is separated from the outer parietal layer by the lumen or capsular space; at the arterial pole, or point of entrance of the blood vessels, the two layers are continuous. Fluid from the blood is filtered directly into the capsular space without first passing into the coelomic fluid. The filter consists of the endothelium of the capillary, the visceral layer of the glomerular capsule, and their combined basal laminas (**Figure 16**).

The blood vessels of the glomerulus are large capillaries that are interposed in the course of an arteriole; as such, they form a rete mirabile (**Figure 17**). Blood enters the glomerulus by way of an afferent arteriole and leaves by way of an efferent arteriole. From the efferent arteriole, it breaks up into true capillaries that twine around the tubules (**Figure 9**).

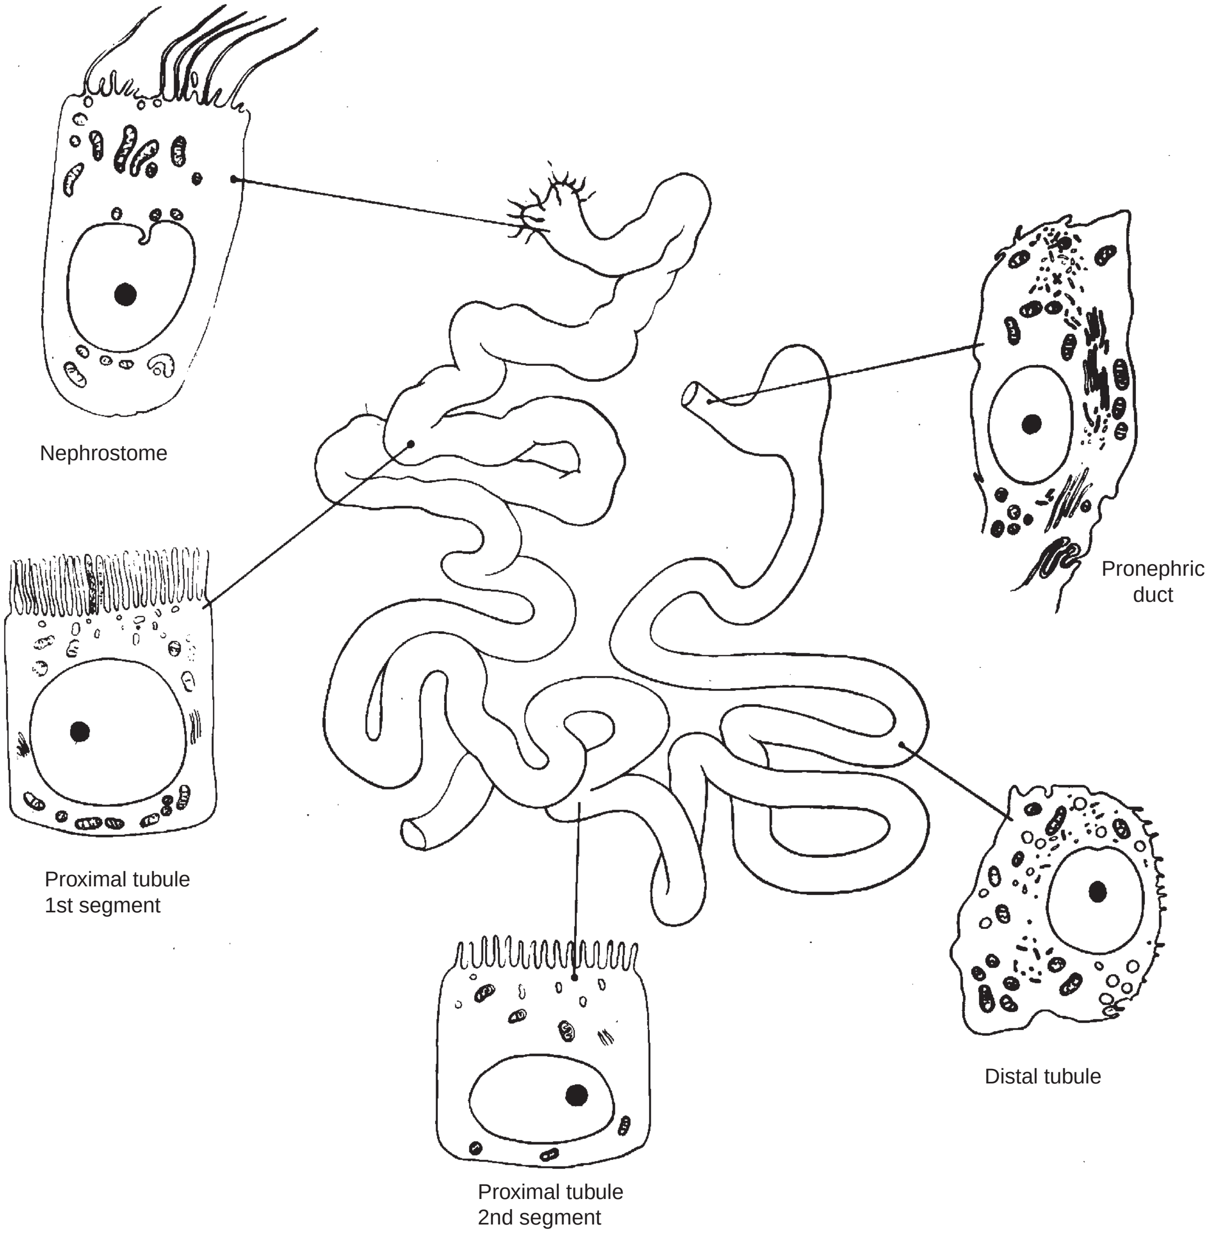

Figure 14 Diagram of a single pronephric tubule from a first-year ammocoete. The various regions of the tubule and their constituent cell types are shown. From Bowen PC (1969) The Cytology of the Pronephros of Lampreys, PhD Thesis, University of Oxford, text – figure 2.

Granules occur within epithelioid cells in the wall of the afferent arterioles in the glomeruli of elasmobranchs and teleosts (**Figure 18**). These cells have much in common with the juxtaglomerular cells of higher vertebrates and are presumed to release renin which is involved in the control of glomerular filtration rate (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange).

The visceral epithelium of the glomerular capsule is made up of elaborate cells, the podocytes, whose processes embrace the capillary loops (**Figure 19**). The extreme complexity of these cells, which resemble a basket starfish, can be best appreciated in scanning electron micrographs. The cell body or perikaryon has several branching arms fringed with foot-like processes, the pedicels; these interdigitate with pedicels from other podocytes to surround the glomerular capillaries. A single podocyte may extend processes to embrace several adjacent capillaries. The relationship of podocytes to the glomerular endothelium is seen in transmission electron micrographs (**Figure 16**). The endothelium is thin and pierced by many large fenestrations. It is sheathed by a well-defined, continuous basal lamina on which

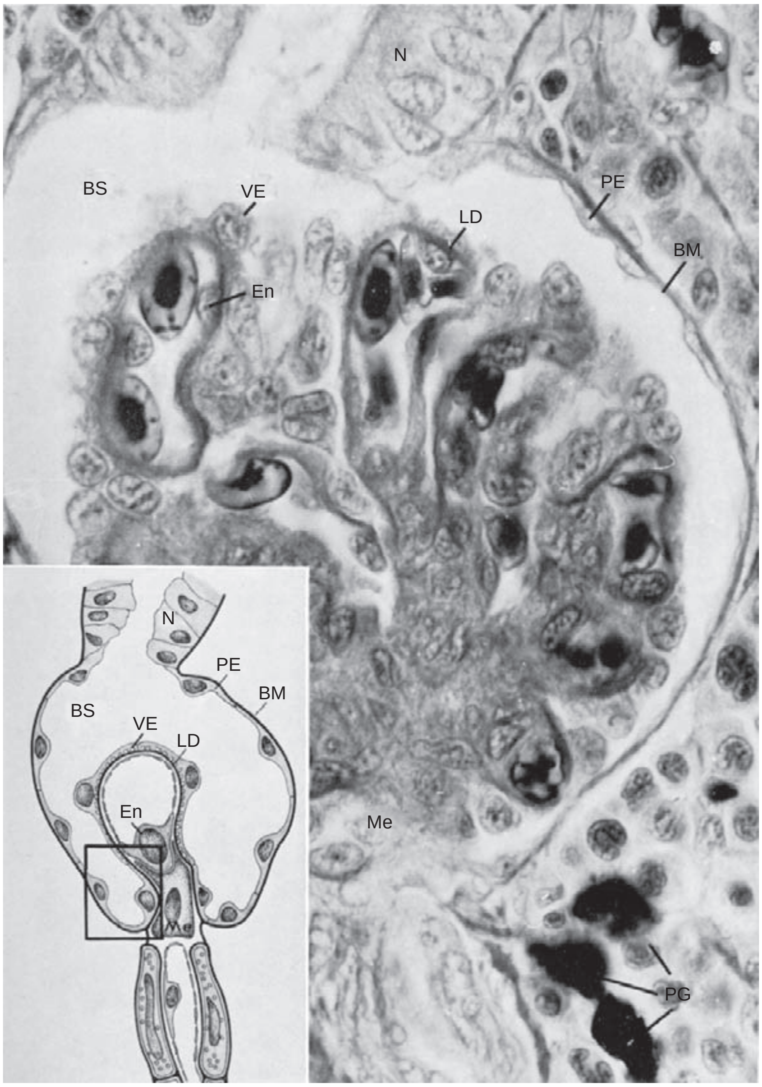

Figure 15 Photomicrograph of a section of the renal corpuscle of a trout. 1540×. Inset: Schematic drawing of the glomerulus of a freshwater trout. Abbreviations: BM, basal lamina of the parietal epithelium; BS, nephric space; En, endothelial cell of a glomerular capillary; Me, mesangial cell; N, neck segment; PE and VE, parietal and visceral epithelium of the nephric capsule; LD, basal lamina between the endothelium of the capillary and the visceral epithelium; PG, pigment granules. From Anderson BG and Loewen RD (1975) Renal morphology of freshwater trout. *American Journal of Anatomy* 143: 93–114 figures 2 and 3.

are implanted the pedicels of the podocytes. Filtration slits between adjacent pedicels open into the capsular space. A thin slit membrane spans the slit and joins adjacent pedicels, probably functioning as a spacer. Podocytes reinforce the delicate filter against the pressure of blood within the capillaries. Occasional stellate mesangial cells may be seen between the endothelial cells and the basal lamina, especially where the capillaries branch (**Figure 15**). These wandering cells likely remove fragments of degenerating materials.

The glomerular capsule is lined with a simple squamous epithelium and empties into a long, tortuous tubule that can be divided into four parts (**Figure 20**): a short ciliated neck segment; the proximal convoluted tubule of cells with a brush border; the intermediate segment, often ciliated; and the distal convoluted tubule, smaller than the proximal tubules and with a larger lumen. Each distal convoluted tubule empties directly into the archinephric duct (Wolffian duct).

The epithelial cells of the kidney tubule use energy in moving substances across a biological gradient and salvage valuable substances that have leaked into the nephric capsule; this is active transport. These epithelial cells demonstrate several characteristic morphological features: a brush border (**Figure 21**),

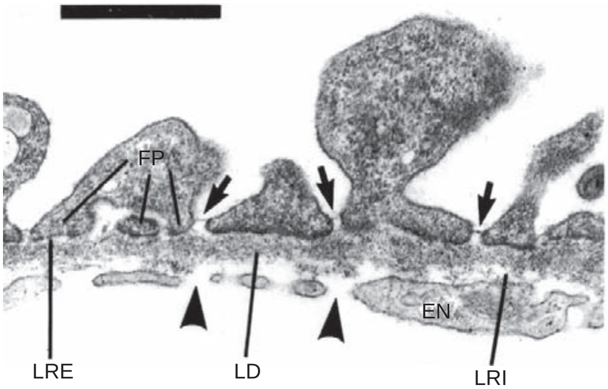

Figure 16 Transmission electron micrograph of a section through the filtration barrier in the glomerulus of a rainbow trout (*Salmo gairdneri*). The basal lamina occurs in three layers: the lamina densa (LD) between the lamina rara externa and lamina rara interna (LRE, LRI). Foot processes (FP) from podocytes reinforce the delicate filter by embracing the basal lamina. The endothelium (EN) of the capillaries is perforated by fenestrations (arrowheads). Note that the spaces between the pedicels (arrows) are spanned by delicate membranes that probably act as spacers. Scale = 500 nm; 46 000×. Figure 21 Transmission electron micrograph of a section through the proximal tubule of an adolescent dogfish (*Scyliorhinus caniculus*). The epithelial cells have a high brush border consisting of densely packed, long microvilli (MV). A large number of densely staining mitochondria occupy the perinuclear region. The apical cytoplasm is filled with numerous small clear vesicles (CVs). Cilia (CI) from other epithelial cells lie in the lumen. A distal tubule (arrowheads) is shown at the right bottom. Scale = 1 μm. From Hentschel H (1991) Developing nephrons in adolescent dogfish, *Scyliorhinus caniculus* (L.), with reference to ultrastructure of early stages, histogenesis of the renal countercurrent systems, and nephron segmentation in marine elasmobranchs. *American Journal of Anatomy* 190: 309–333, figure 14.

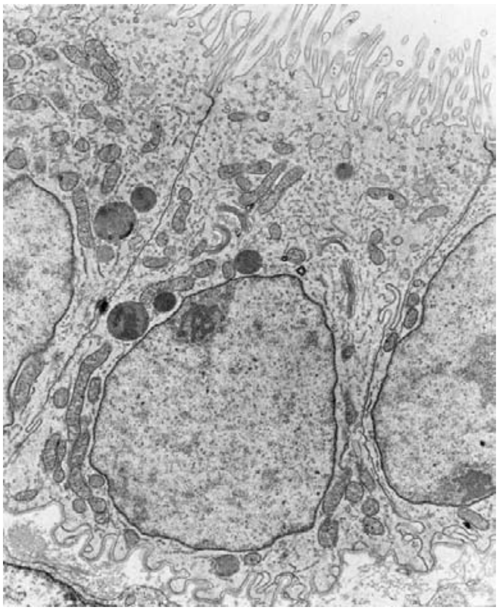

Figure 22 Transmission electron micrograph of a section of a proximal convoluted tubule of a skate (*Raja erinacea*). Tight junctions seal the apical borders between these epithelial cells. 12 000×. From Lacy ER and Reale E (1991) Fine structure of the elasmobranch renal tubule: Neck and proximal segments of the little skate. *American Journal of Anatomy* 190: 118–132, figure 5.

capsules are not invaginated to form the usual egg cup-shaped structure but are compressed between these glomeruli so that their simple squamous epithelium envelops the loops of capillaries. The capsules are drained by conspicuous, ciliated neck segments (**Figure 27**). The glomus is surrounded by tubules of the nephron that are basically similar to those seen in other kidneys.

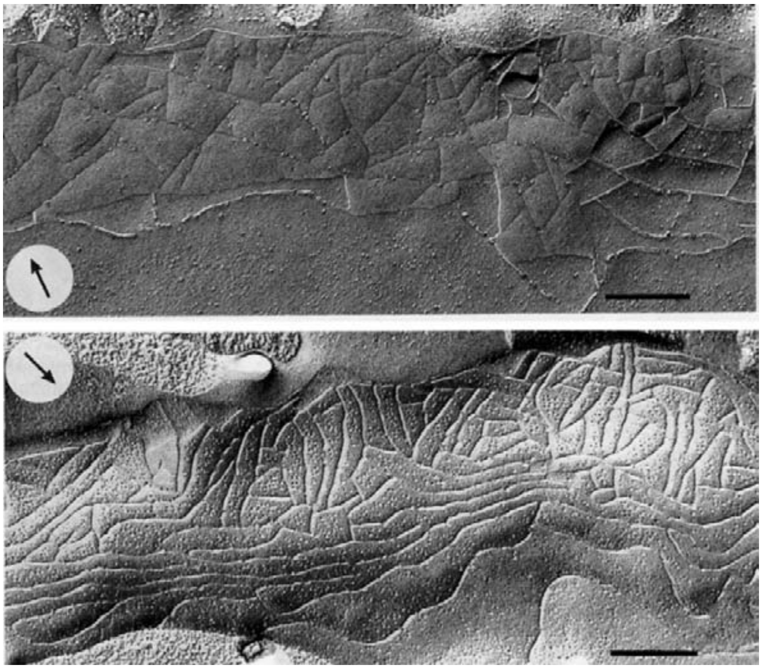

Figure 23 Electron micrographs of freeze-fracture replicas demonstrating apical tight junctions between membranes of adjacent epithelial cells of the proximal tubule (top) and distal tubule (bottom) of the dogfish (*Scyliorhinus caniculus*). The junction is much more elaborate between the cells of the distal tubule, probably indicating that fluids are transported against a steeper gradient than in the proximal tubule. From Hentschel H, *et al.* (1993) Renal tubule of dogfish, *Scyliorhinus caniculus*: A comprehensive study of structure with emphasis on intramembrane particles and immunoreactivity for H^+–K^+-aenosine triphosphatase. *Anatomical Record* 235: 511–532, figure 7.

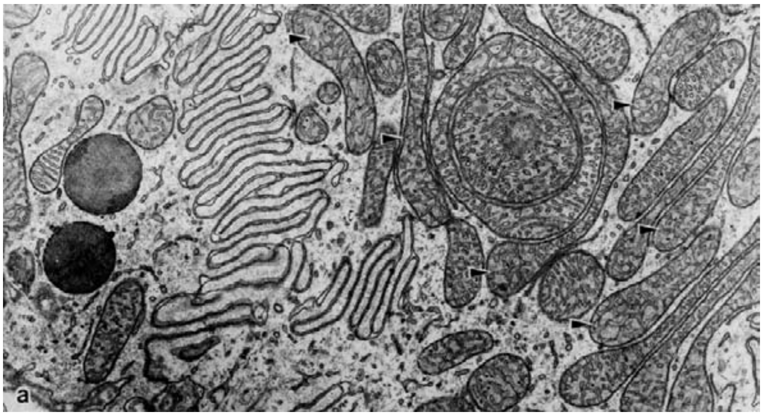

Figure 24 Transmission electron micrograph of a section through the intermediate segment of the renal tubule in the kidney of the skate (*Raja erinacea*). Elaborate infoldings occur between adjacent epithelial cells. Mitochondria (arrowheads) are abundant. From Lacy ER and Reale E (1991) The fine structure of the elasmobranch renal tubule: Intermediate, distal, and collecting duct segments of the little skate. *American Journal of Anatomy* 192: 478–497, figure 5a.

The kidney of the hagfish is an opisthonephros of almost diagrammatic simplicity (**Figure 28**). Each of the segmentally arranged nephrons consists of a renal corpuscle, comprising a glomerulus and glomerular capsule, and a short tubule that drains into the archinephric duct. Each renal corpuscle is supplied with blood from

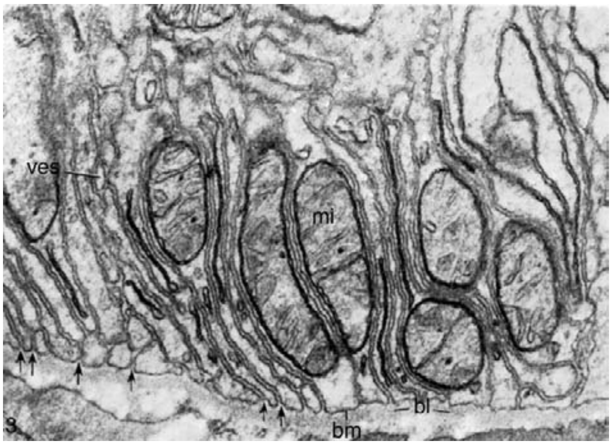

Figure 25 Transmission electron micrograph of a proximal tubule in the kidney of the stickleback (*Gasterosteus aculeatus*) showing the infoldings of the basal plasma membrane (bm) that constitute the basal labyrinth. Most of the folds of membrane are continuous with the outer cell membrane (arrows). bl, basal lamina; mi, mitochondrion; ves, vesicular membrane structure confined within the folds of membrane. 60 000×. From Wendelaar Bonga SE and Veenhuis M (1974) The membranes of the basal labyrinth in kidney cells of the stickleback, *Gasterosteus aculeatus*, studied in ultrathin sections and freeze-etch replicas. *Journal of Cell Science* 14: 587–609, figure 3.

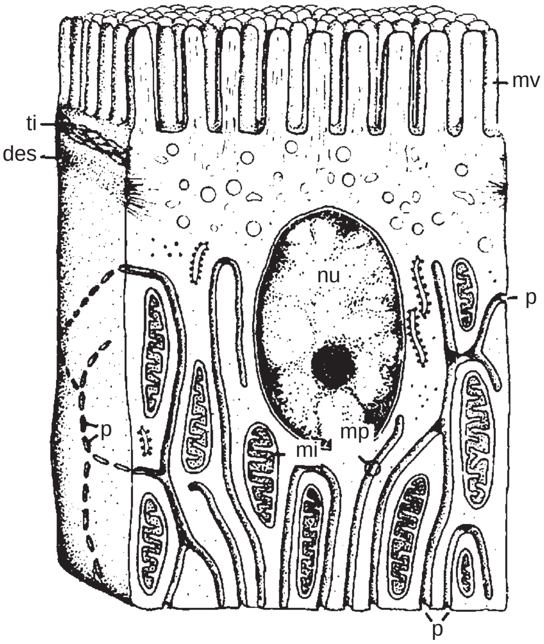

Figure 26 Diagram of a cell from the proximal tubule of the stickleback to illustrate the basal labyrinth. The interiors of the folds are continuous with the extracellular space by slit-like pores (p). des, desmosome; mi, mitochondrion; mp, membrane pairs of an infolding; mv, microvilli; tj, tight junction. From Wendelaar Bonga SE and Veenhuis M (1974) The membranes of the basal labyrinth in kidney cells of the stickleback, *Gasterosteus aculeatus*, studied in ultrathin sections and freeze-etch replicas. *Journal of Cell Science* 14: 587–609, figure 2B.

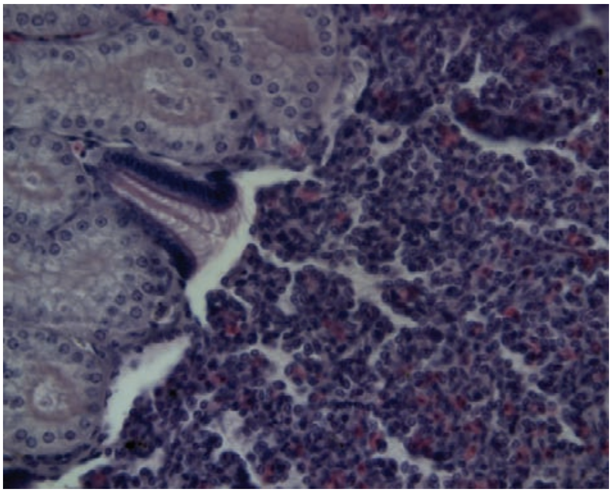

Figure 27 Photomicrograph of a section through the opisthonephros of a larval lamprey (ammocoete, *Petromyzon marinus*). All of the glomeruli are grouped together to form one large glomus (right); the bright pink flashes are erythrocytes in its capillaries. At the left is a mass of kidney tubules; a ciliated neck segment is interposed between individual glomeruli and draws fluid from the renal capsule and delivers it to the tubules. The epithelium of the ciliated neck segment is continuous with the simple squamous epithelium of the renal corpuscle investing the loops of blood vessels of each glomerulus. Capillaries invade the loose connective tissue between the tubules; pink erythrocytes can be seen in the capillary at the extreme upper left. 40×.

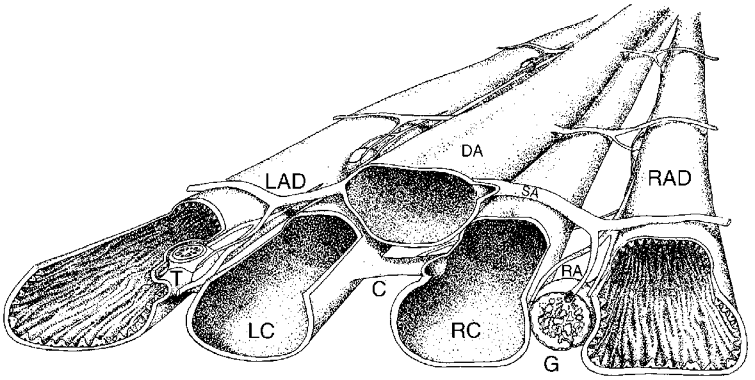

Figure 28 Schematic drawing of a portion of the corpuscular region of the hagfish kidney (*Myxine glutinosa*). The dorsal aorta (DA) gives off segmental arteries (SAs) that give rise to renal arteries (RAs). Glomeruli (G), located within each segment, receive blood from the renal arteries. The glomeruli are closely associated with the archinephric ducts on each side (LAD and RAD). C, cardinal anastomosis; LC and RC, left and right posterior cardinal veins; T, tubule. Glossary

Acid–base balance The regulation of constant pH in the body compartments usually achieved by adjustments of PCO_2 and/or HCO_3^- levels.

Glomerular ultrafiltration The process whereby blood plasma is filtered at the glomerulus to produce the primary urine which is subsequently modified by secretion and reabsorption.

Glucosuria The presence of abnormally elevated levels of glucose in the urine.

Hypercapnia High levels of carbon dioxide in blood.

Mesangial cell A renal cell type that contacts the endothelial cells of the glomerulus and thus constitutes a portion of the filtration barrier.

Pedicel The extended projections arising from podocytes that interdigitate to form filtration slits.

Podocyte Cells of the renal visceral epithelium that form a critical component of the glomerular filtration barrier, contributing size selectivity and maintaining a large filtration surface.

Tubular transport maximum The maximal rate at which a substance can be reabsorbed (or secreted) by the kidney.

Introduction

The predominant function of the kidney is excretion, which is broadly defined as the removal of materials from the body. The broad category of excretion can be subdivided into several more well-defined physiological processes including nitrogenous waste elimination, ionic and osmotic regulation, acid–base balance, and the control of extracellular fluid volume.

The excretory process, while universal among fish, can vary tremendously with respect to the volume and chemical composition of the excretory fluid (urine) produced, as well as the mechanisms leading to urine formation. For example, fish inhabiting a freshwater (FW) environment produce large volumes of dilute urine to rid the body of water absorbed at the gill without unduly exacerbating net salt loss. On the other hand, seawater (SW) teleost fish produce small quantities of isosmotic urine to conserve water and to eliminate salts in the face of continual branchial passive water loss and salt gain. In most fish, urine formation is the net result of glomerular filtration, fluid and solute reabsorption, and secretion. However, a number of SW species possess aglomerular kidneys and thus produce urine exclusively by tubular secretion. This is but one example of the enormous functional and phenotypic diversity surrounding the fish kidney that make it such an excellent model for studying structure–function relationships in piscine physiological systems.

Kidney Structure

Aglomerular Kidneys

Only 30 species of fish are known to possess aglomerular (lacking glomeruli) kidneys representing a mere 0.1% of extant fish species. Three distinct lineages evolved from glomerular ancestors on separate occasions 120, 65, and 23 million years ago. Examples of fish with aglomerular kidneys are toadfish (family Batrachoididae), goosefish and anglerfish (family Lophiidae), pipefish and seahorses (family Syngnathidae), and some pufferfish (family Tetraodontidae). Not only do the kidneys of these fish lack glomeruli, they also do not possess distal tubules. Thus, the basic structure of the aglomerular nephron consists of a proximal portion resembling the second proximal segment of the teleost glomerular kidney (see below) and a collecting duct system. As the distal tubule is crucial for the production of dilute urine, the aglomerular kidney is limited in its capacity to accommodate fluid loads because the lower limit of urine osmolarity is believed to be approximately 200 mOsm L^{-1}. Thus, the renal excretion of a large fluid load would also be accompanied by significant loss of salt. It is probably for this reason, rather than the absence of glomeruli, *per se*, that aglomerular fish are restricted to the SW or estuarine environment.

Glomerular Kidneys

Majority of fishes have what is termed a glomerular kidney. Glomerular kidneys share the common function of producing urine through a first step of ultrafiltration at the glomerulus (a network of capillaries contained within Bowman's capsule). Beyond this one common feature, however, glomerular kidneys exhibit substantial anatomical variation among the fish groups (**see also Role of the Kidneys**: Histology of the Kidney). Adult hagfish possess two discrete kidneys (pronephric and mesonephric); however, only the posterior mesonephric kidney, a paired elongated structure lying on either side of the midline, is believed to be functional. Each side of the hagfish mesonephric kidney contains about 40 nephrons that drain into paired mesonephric ducts (ureters). The ultrafiltrate produced by glomerular filtration within Bowman's capsule enters a short neck segment prior to delivery into the mesonephric duct. The epithelial cells lining the mesonephric duct resemble the cells of the first proximal segment of the teleost nephron (see below).

The kidney of cyclostomes (lampreys), as in hagfish, is a paired, elongated structure. However, in most other respects, the cyclostome kidney bears little resemblance to the hagfish nephron but more closely resembles the kidneys of the more advanced teleosts. Thus, the glomerulus is followed by a short neck segment, a proximal tubule, an intermediate segment, a distal tubule, and a collecting duct which empties into a mesonephric duct.

The elasmobranch nephron is by far the most elaborate within the various fish taxa and, in some respects, is similar to the mammalian kidney because of the occurrence of countercurrent tubular flow. The tubules form two loops with limbs that descend and ascend in countercurrent parallel pathways through two discrete zones, a bundle zone and a sinus zone. The bundle zone is encapsulated by a peritubular sheath that may allow control over the chemical composition of the interstitial fluid and possibly assist urea and trimethylamine oxide (TMAO) reabsorption via countercurrent multiplication.

The teleost kidney contains two sections: a head kidney, which comprises about 20% of the anterior portion of the kidney and the trunk kidney which comprises the other 80% and extends along the dorsal wall of the body cavity. The head kidney is largely composed of steroidogenic interrenal cells, chromaffin cells, and hematopoietic tissue while the trunk kidney contains the vast majority of filtering nephrons in addition to hematopoietic and pigmented cells.

The teleost kidney is typically grouped into three functional categories (FW, SW, and euryhaline) and into five anatomical classes (types I–V). The distinction of the five classes is based largely on the extent of separation between the trunk and head kidney and the degree of fusion of the left and right kidneys. For example, nearly all marine species are grouped within category III in which only the posterior portion of the kidney is fused and the anterior region is composed of two slender branches. There are relatively few anatomical differences in the tubular composition of FW, SW, and euryhaline fishes with all of them possessing a neck segment exiting Bowman's capsule, two segments of proximal tubule, and a collecting duct. The collecting ducts drain into two mesonephric ducts, which fuse to form a common archinephric duct (bladder). The FW nephron, which is designed to produce large volumes of dilute urine, has large glomeruli and a distal tubule which is essential for NaCl reabsorption and the production of dilute urine. The FW nephron also contains an intermediate segment positioned between the proximal and distal tubules; the function of the intermediate segment is unknown. The nephron of euryhaline species also contains a distal tubule, but its role in NaCl reabsorption varies according to salinity. The marine nephron which is designed for water conservation possesses smaller glomeruli and lacks the diluting distal tubule (**Figure 1**).

Urine Formation

In the glomerular kidney, urine is formed through the interactive effects of ultrafiltration, water and solute reabsorption, and secretion. This strategy allows great flexibility in the chemical composition of the final urine that is excreted because the primary urine (ultrafiltrate) can be extensively and variably modified by reabsorption and secretion (**Figure 2**).

Ultrafiltration

Ultrafiltration is the process whereby blood plasma is selectively filtered at the glomerulus to produce the primary urine in an epithelial-lined tubule. The process of glomerular ultrafiltration is driven by pressure gradients across a filtration barrier within the glomerulus, which is composed of the capillary endothelium, a matrix of mesangial cells, a basement membrane, and a visceral epithelium. The visceral epithelium is composed of podocytes that give rise to cellular projections termed pedicels, which can be arranged to form slits through which filtration occurs. Unlike in mammals, the glomerular capillaries of fish lack fenestrations (pores) and this difference presumably reduces hydraulic conductivity of the filtration barrier in fish, all other things being equal.

As in other kidneys, two types of pressure determine the net filtration pressure (**see also Design and Physiology of Capillaries and Secondary Circulation**: Circulatory Fluid Balance and Transcapillary Exchange). A positive

hydrostatic pressure difference between glomerular capillaries and the lumen of Bowman's capsule generates filtration across the filtration barrier. A counteracting negative colloid osmotic pressure difference opposes filtration. The hydrostatic pressure in the glomerular capillaries is largely dictated by the blood pressure in the glomerular capillaries, which is greatly influenced by variations in cardiac output and the vascular resistance in the afferent and efferent renal arterioles. The colloid osmotic pressure difference arises because the filtrate formed within Bowman's capsule is largely devoid of protein. Net filtration along the length of glomerular capillaries persists as long as hydrostatic pressure exceeds plasma colloid osmotic pressure. However, as fluid is lost from glomerular capillaries by filtration, colloid osmotic pressure increases and hydrostatic pressure decreases (very slightly) until net filtration pressure falls to zero. Consequently, the process of ultrafiltration produces primary urine which, except for its lack of protein, has a chemical composition similar to plasma (**Figure 3**).

Within any given nephron, the rate at which the ultrafiltrate is formed is termed the single nephron glomerular filtration rate (SNGFR), which is determined by pressure gradients, hydraulic conductivity, and the surface area over which filtration is occurring. The glomerular filtration rate (GFR) for the entire kidney is set by the number

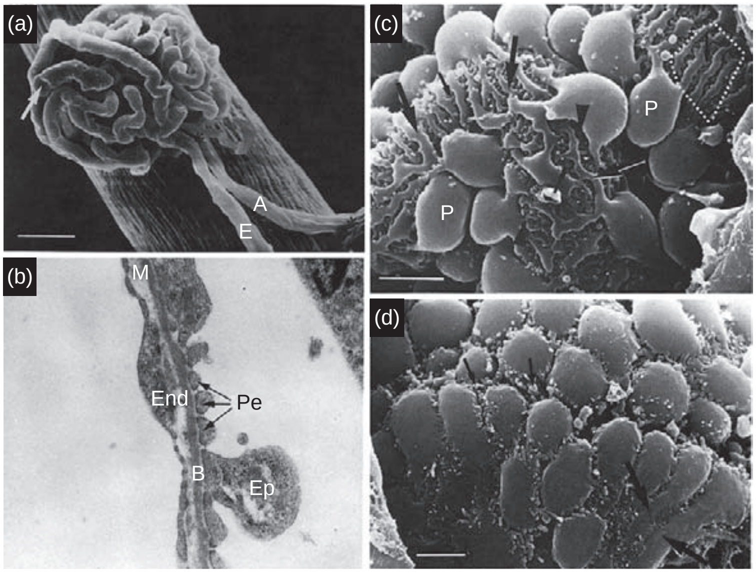

Figure 3 Structure of the teleost glomerular kidney. (a) A corrosion cast of a glomerulus with single afferent (A) and efferent (E) arterioles. Arrow indicates endothelial cell indentations. Asterisks show positions of origin and end of afferent arteriole used to measure the length of the vessel. (b) A transmission electron micrograph of the glomerular capillary wall in an FW trout; capillary endothelium (End), mesangial matrix (M), basement membrane (B), visceral epithelium (Ep). Epithelial pedicels (Pe) are connected by slit diaphragms. (c) Visceral epithelium of glomerulus of an FW trout showing rounded epithelial podocytes (P) with primary processes, sometimes branching into secondary and tertiary processes(large arrows) and terminating in pedicels (small arrows). An area of regular interdigitation of pedicels is enclosed by dotted outline. Some pedicels arise directly from podocytes (arrowheads). Few cytoplasmic microprojections present on podocyte and its processes. (d) Seawater adapted fish. Flattened podocytes and broad, flat primary processes (large arrows) with little visible interdigitation of pedicels. Many cytoplasmic microprojections (small arrows). Bar = (a) 20 μm; (b) ~ 1 μm; (c) ~ 4 μm; and (d) 4 μm. (a) Reproduced from Brown JA (1985) Renal microvasculature of the rainbow trout, *Salmo gairdneri* – scanning electron-microscopy of corrosion casts of glomeruli. *Anatomical Record* 213(4): 505–513. (b)–(d) Reproduced from Brown JA, Taylor SM, and Gray CJ (1983) Glomerular ultrastructure of the trout, *Salmo gairdneri* – glomerular capillary epithelium and the effects of environmental salinity. *Cell and Tissue Research* 230(1): 205–218.

of filtering nephrons and their SNGFRs. Urine flow rate, which can be highly variable in FW fish, is always less than GFR because of tubular reabsorption; but since fractional tubular reabsorption tends to be held constant, GFR and urine flow rate tend to be proportional. Typically, a small fraction of nephrons are unperfused and thus do not contribute to urine formation. Moreover, not all of the perfused nephrons are actually filtering at any given time. Thus, GFR can be rapidly modified by glomerular recruitment (or de-recruitment), whereby the numbers of filtering nephrons are adjusted.

The principal factors contributing to glomerular recruitment are changes in arterial blood pressure and renal blood flow. Factors contributing to increased systemic arterial blood pressure, such as circulating catecholamines or activation of sympathetic nerve fibers, will promote glomerular recruitment, besides increasing SNGFR (assuming no changes in renal blood-flow patterns). Angiotensin II, the product of the renin–angiotensin-system (RAS), while promoting an elevation of systemic blood pressure (**see also Design and Physiology of Arteries and Veins**: Physiology of Resistance Vessels), actually acts as an antidiuretic (reduces urine formation) in fish because of its vasoconstrictory actions on the afferent renal vasculature.

The lower urine flow rates in SW fish or in euryhaline fish experiencing increasing environmental salinity are predominantly related to marked reductions in GFR. In SW fish, the reduced GFR primarily reflects anatomical changes – fewer and smaller glomeruli as well as alterations in their morphology that promote a reduced hydraulic permeability. For example, the pedicels, which are arranged to form leaky filtration slits in FW fish, are either poorly developed or tightly packed together to limit filtration. In addition, the podocytes overlying the glomerular capillaries are more sparsely distributed in FW fish, while they tend to be more abundant and flattened in SW fish to further limit filtration.

Reabsorption

Depending on species and environmental salinity, fractional reabsorption may be entirely absent (hagfish) or as high as 97% (FW teleosts). While impressive in FW teleosts, the capacity of the fish kidney to reabsorb filtered NaCl remains considerably less than in the mammalian nephron where ~99% of the filtered NaCl is reabsorbed. Moreover, unlike in mammals where the bulk of NaCl reabsorption occurs at the proximal tubule, fish appear to rely at least equally on segments distal to the proximal tubule. For example, in the lamprey (*Lampreta fluviatilis*) only 10% of filtered NaCl is reabsorbed at the proximal tubule, while 80% is reabsorbed at the collecting duct.

In teleosts, the predominant solutes reabsorbed from the primary urine are Na^+, Cl^-, Ca^{2+}, and glucose. For NaCl, the greatest rates of reabsorption are found in FW species because of their need to produce dilute urine (i.e., retain salt but lose excess water). Correspondingly, relatively little water is reabsorbed. Typically, less than 50% and occasionally as little as 5% of the filtered water is reabsorbed.

The mechanisms of Na^+ and Cl^- reabsorption are not well understood. Na^+ uptake from the filtrate probably involves electroneutral Na^+/H^+ exchange via one or more members of the SLC9 family of Na^+/H^+ exchangers (e.g., NHE3 or NHE2), while Cl^- uptake may be achieved by members of the SLC4 (e.g., SLC4A2) or SLC26 (e.g., SLC26A4 and SLC26A6) anion transporter gene families. An essential driving force for trans-tubular Na^+ uptake is basolateral Na^+/K^+-ATPase (NKA), which facilitates the final re-entry step of Na^+ into the blood. The tubular reabsorption of Ca^{2+} is thought to involve its passive entry across the luminal (mucosal) membrane through an epithelial Ca^{2+} channel (ECaC) followed by active transport across the serosal membrane via Ca^{2+}-ATPase (PMCA).

The teleost nephron, like the mammalian kidney, has an excellent capacity to reabsorb dissolved glucose lost to the filtrate; virtually all glucose is removed from the filtrate under normal conditions. In rainbow trout, the predominant mechanism of glucose reabsorption is via coupled Na^+–glucose transporters. The tubular transport maximum for glucose (TmG) in the trout kidney is about $150\,\mu mol\ kg^{-1}\ h^{-1}$, which corresponds to plasma glucose levels exceeding 20 mM. Thus, it is unlikely that significant glucose will be lost in the urine (a condition termed glucosuria) except after acute dietary carbohydrate loading.

Secretion

In addition to ultrafiltration, solutes can be removed from the blood and they can enter the urine by secretion; examples of secreted solutes include Ca^{2+}, Mg^{2+}, NH_4^+, H^+, K^+, SO_4^{2-}, and PO_4^{2-}. To determine whether or not a solute is undergoing net secretion, the renal clearance ratio (RCR) for that solute must be determined. The RCR is the ratio of the amount of solute excreted in the urine (UFR × urine [solute]) to the amount filtered (GFR × plasma [solute]). If the RCR exceeds 1 (excretion exceeds filtration), this indicates net secretion into the urine whereas a RCR less than 1 indicates net reabsorption. It is important to emphasize that the RCR provides data only on the net tubular processes. RCR only reveals which processes dominate in cases where solutes are reabsorbed as well as secreted (e.g., K^+ and Ca^{2+}).

In FW fish, the extent of tubular secretion for any given secreted ion essentially reflects the blood chemistry, which in turn is largely controlled by dietary loading and acid–base status. For example, dietary ingestion of Mg^{2+} and SO_4^{2-} will promote increased secretion of these solutes, while catabolism of ingested protein to ammonia will promote NH_4^+ secretion. Acidification of the blood may be associated with increased secretion of H^+ (see below), which in turn may be associated with markedly increased secretion rates of PO_4^{2-} and NH_4^+. SW fish secrete significant quantities of divalent ions which are largely derived from ingested seawater (**see also Role of the Gut**: Gut Ion, Osmotic and Acid-Base Regulation). The nature of divalent ion secretion is poorly understood but may involve Mg^{2+}/Na^+ exchange, Mg^{2+}/H^+ exchange, and anion/SO_4^{2-} exchanges (possibly via SLC26A1).

Acid–Base Balance by the Kidney

Although the gill is the predominant site of acid–base regulation in fish, the kidney also plays an essential role that should not be underestimated. Fish regulate blood pH through modulations of plasma HCO_3^- levels, which in turn are dictated by adjustments of branchial acid excretion (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Gill Salt Secretion in Marine Teleosts and Mechanisms of Ion Transport in Freshwater Fishes). For example, the regulation of respiratory acidosis is associated with marked increases in plasma HCO_3^- levels which may routinely exceed 20 mM and even reach values exceeding 70 mM (e.g., in European eel, (*Anguilla anguilla*) exposed to an external P_{CO_2} of 45 mmHg). Under such conditions, it is essential that the kidney is able to reabsorb the filtered HCO_3^-. Essentially, branchial acid excretion would become a futile exercise in the absence of a renal mechanism for the retention of accumulated HCO_3^- ions. Thus, for every additional mol of HCO_3^- appearing in the glomerular filtrate, the kidney must secrete an additional mol of H^+ to ensure complete HCO_3^- reabsorption. As increases in renal acid secretion are effectively used to reabsorb excess filtered HCO_3^-, it is rare that net acid excretion by the kidney will ever match the markedly elevated rates of acid excretion occurring at the gill during compensation of acidosis. On the other hand, the rates of renal acid secretion required to sustain a condition of fully compensated respiratory acidosis (i.e., elevated HCO_3^- to achieve normal pH at high P_{CO_2}) are likely to approach the rates of peak acid excretion at the gill. It is important to emphasize that under conditions of chronic hypercapnia, high rates of renal acid secretion must be sustained whereas the elevation of branchial acid excretion need last only as long as it takes to accumulate sufficient HCO_3^- to raise pH back to normal.

The potential for renal mechanisms to contribute to acid–base regulation appears to be highest in FW fish, where large volumes of urine are produced (see above). In SW fishes, the pH-regulating capacity of the kidney is limited by low urine flow rates and an apparent lack of responsiveness to systemic acid–base disturbances. By contrast, the responses of the FW teleost kidney to acid–base disturbances are comparable in pattern and flexibility to those of the mammalian kidney, although quantitatively subservient to those of the gill (although see above).

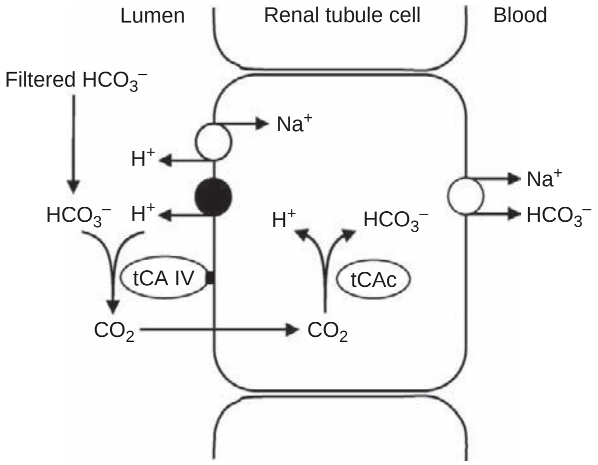

Figure 4 A model depicting the proposed mechanism of renal HCO_3^- reabsorption in fish. Acid added to the filtrate by the V-type H^+-ATPase and NHE3 titrate-filtered HCO_3^- in the tubule lumen in a reaction catalyzed by membrane-bound CA IV. The resultant CO_2 enters the renal epithelial cell by diffusion and is hydrated to H^+ and HCO_3^- in the presence of a high activity cytoplasmic CA isoform (tCAc). Finally, HCO_3^- ions are moved across the basolateral membrane by NBC1, while protons are recycled into the tubule lumen. Energy-consuming transporters are indicated by filled circles.Reproduced from Perry SF and Gilmour KM (2006) Acid–base balance and CO_2 excretion in fish: Unanswered questions and emerging models. *Respiratory Physiology and Neurobiology* 154:199–215.

Recent work suggests that the mechanism of renal HCO_3^- reabsorption in rainbow trout in many ways parallels that of the mammalian proximal tubule, the site responsible for 80–90% of renal HCO_3^- reabsorption in mammals (**Figure 4**).

Acid secretion into the filtrate across the luminal membrane is achieved via two mechanisms: electroneutral Na^+/H^+ exchange and active H^+ pumping by V-type H^+-ATPase. In rainbow trout, the specific Na^+/H^+ exchanger thought to be involved in renal acid secretion is NHE3 or SLC9A3. H^+ ions secreted into the filtrate combine with HCO_3^- to form CO_2, a reaction catalyzed by membrane-associated carbonic anhydrase isoform IV (tCA IV). The CO_2 diffuses into the tubule cells where it is dehydrated to HCO_3^- and H^+ in the presence of cytosolic carbonic anhydrase (tCAc). The H^+ ions thus formed re-enter the filtrate via NHE3 or H^+-ATPase while the HCO_3^- is reabsorbed into the plasma via $Na^+-HCO_3^-$ co-transporter isoform 1 (NBC1) (**Figures 5–7**).

Nitrogen Excretion by the Kidney

The two predominant forms of nitrogenous waste excreted in the urine are ammonia and urea with negligible contributions from other N_2-containing substances such as uric acid, creatine, and creatinine. It is important to point out that the rates of renal ammonia and/or urea excretion, while substantial, comprise only a small fraction (<5%) of whole-body nitrogen excretion. Although increasing the rates of renal ammonia excretion will not markedly affect whole-body N_2 balance, it can have a significant consequence on renal acid–base balance

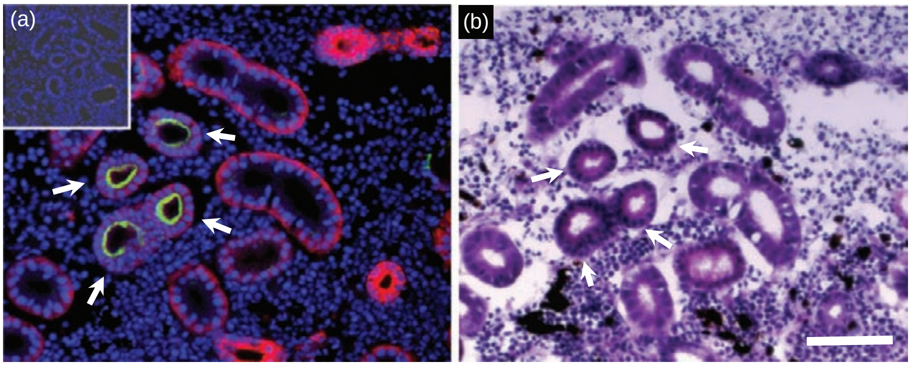

Figure 5 Localization of NHE3 protein to apical regions of proximal renal tubules in rainbow trout (*Oncorhynchus mykiss*) kidney using immunocytochemistry. (a) Apical NHE3 (stained green; indicated by white arrows) was localized to cells containing basolateral $Na^+–K^+$-ATPase (stained red); nuclei are stained blue (4,6-diamidino-2-phenylindole). (b) Periodic acid Schiff (PAS) staining of the same section demonstrated that NHE3 was specifically localized to the brush border of proximal tubule cells. The NHE3 and $Na^+–K^+$-ATPase immunofluorescence were absent with omission of primary antibodies (inset in (a)) when image was acquired under the same exposure as in (a). Bar = 50 μm. Reproduced from Ivanis G, Braun M, and Perry SF (2008) Renal expression and localization of SLC9A3 sodium hydrogen exchanger (NHE3) and its possible role in acid–base regulation in freshwater rainbow trout *(Oncorhynchus mykiss). American Journal of Physiology* 295: R971–R978.

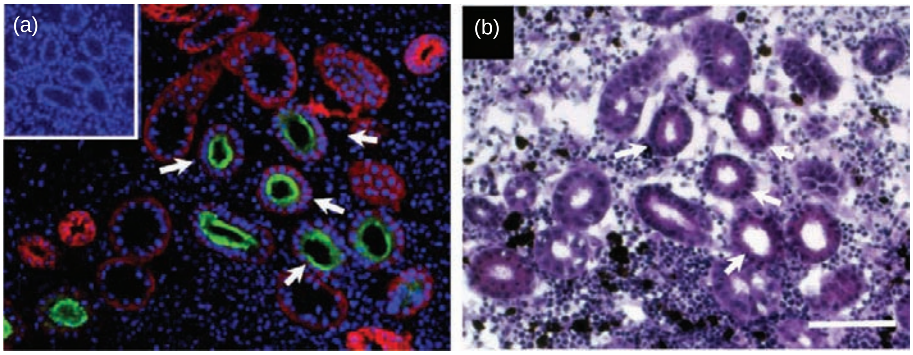

Figure 6 Localization of vacuolar-type H$^+$-ATPase (V-ATPase) protein to apical regions of proximal renal tubules in rainbow trout (*Oncorhynchus mykiss*) kidney using immunocytochemistry. (a) Apical V-ATPase (stained green) was localized in cells containing basolateral Na$^+$–K$^+$-ATPase (stained red). (b) The identity of the V-ATPase-enriched tubules (white arrows) as proximal tubules was based on the presence of a prominent brush border (stained pink using PAS on the same section). The V-ATPase and Na$^+$–K$^+$-ATPase immunofluorescence were absent with omission of primary antibodies (inset in (a)) when image was acquired under the same exposure as in (a). Bar = 40 μm. Reproduced from Ivanis G, Braun M, and Perry SF (2008) Renal expression and localization of SLC9A3 sodium hydrogen exchanger (NHE3) and its possible role in acid–base regulation in freshwater rainbow trout (Oncorhynchus mykiss). *American Journal of Physiology* 295: R971–R978.

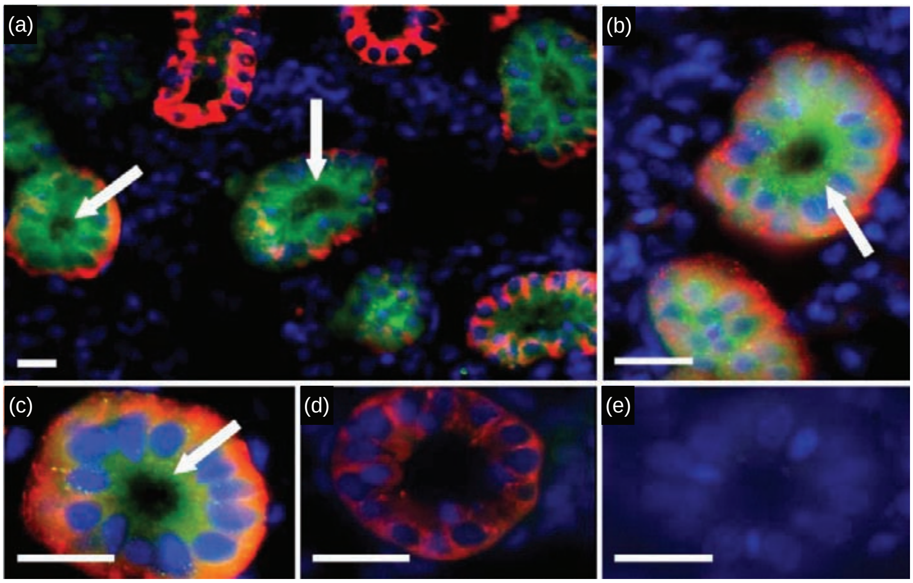

Figure 7 Representative fluorescence micrographs revealing the presence of CA IV protein in rainbow trout (*Oncorhynchus mykiss*) renal tubules by immunocytochemistry. Green color indicates CA IV, red color indicates Na$^+$–K$^+$-ATPase, and nuclei are stained blue (DAPI). (a–c) Different tubules viewed at ×40, 63, and 100 magnifications, respectively. In cells co-expressing the two proteins, CA IV was localized to the apical regions of tubules (arrows) or co-localized with Na$^+$–K$^+$-ATPase (yellow/orange) in basolateral regions. In some tubules not expressing CA IV, Na$^+$–K$^+$-ATPase was broadly distributed. Specific fluorescence was prevented by pre-absorption of the CA IV antibody with immunizing peptide (d) or omission of both primary antibodies (e). Scale bars = 25 μm. Reproduced from Georgalis T, Yorston J, Gilmour KM, and Perry SF (2006) The roles of cytosolic and membrane bound carbonic anhydrase in the renal control of acid–base balance in rainbow trout, *Oncorhynchus mykiss. American Journal of Physiology* 291: F407–F421. (2005).

because ammonia is an important urinary buffer. Ultimately, the capacity of the urine to excrete acid is related to the presence of buffers such as ammonia and phosphate. In the ureogenic marine elasmobranchs that accumulate high levels of urea in the blood as an osmolyte, the role of the kidney is to ensure that filtered urea is effectively reabsorbed. The mechanism of reabsorption of urea by the elasmobranch kidney likely involves a facilitated urea transporter which has been cloned and characterized in dogfish.

Glossary

Aquaporins Membrane proteins that act as water channels (discovered by Peter Agre for which he won the Nobel prize in 2003).

Metabolon A structural–functional relationship between enzymes or membrane transporters that have linked functions.

Paracellular Refers to the route between cells of an epithelium, usually through tight junctions.

Serosal Refers to the side of an epithelium normally bathed by blood or extracellular fluid.

Transcellular transport Refers to the transfer of substances through the cell, i.e., across both the basolateral and apical membranes.

Introduction

The gut (**see also The Gut**: The Gastrointestinal Tract: An Introduction) is well known for processing the dissolution products from the digestion of food, which obviously includes large quantities of organic and inorganic ions. However, the majority of our knowledge of the ionic and osmoregulatory roles of the gut in fish comes from nonfeeding animals and, in particular, the central role the gut plays in the hypoosmoregulatory strategy of marine teleosts. This article therefore begins by describing the ion and water transport processes involved in the gut of fish under nonfeeding conditions, followed by the lesser-known ionoregulatory responses of the gut to feeding. In both cases, the discussion includes some of the inevitable interactions with acid–base regulation. This is not only because acid–base relevant ions (e.g., H^+, HCO_3^-, and NH_4^+) are often involved in ion transport processes generally, but particularly in the gut where conspicuously high rates of gastric acid secretion and pancreatic bicarbonate base secretion are well known in all vertebrates. Furthermore, very high rates of net base secretion occur in the intestine of marine fish as part of their osmoregulatory strategy.

Gut Anatomy

The gut of all animals is best known for its role in feeding, digestion, and assimilation of nutrients. However, within fish the gut plays a number of alternative roles, including respiratory gas exchange, ion and osmotic regulation, nitrogenous waste excretion, and acid–base balance. Not surprisingly, this multi-functionality is associated with highly varied gut morphology within the fish world (**see also The Gut**: The Gastrointestinal Tract: An Introduction and **Food Acquisition and Digestion**: Digestive Efficiency). However, for the purposes of the present article, it is sufficient to appreciate three main features of the gastro-intestinal tracts in fish.

First, within genetically related species, quality of diet influences relative gut length (in order from longest to shortest; detritivores and coralivores, herbivores, omnivores, and carnivores). Second, many fish (~25% of known taxa) are completely agastric (no stomach), and others can have a stomach but lack typical gastric acid secretion (**see also Integrated Function and Control of the Gut**: Barrier Function of the Gut and Intestinal Absorption, **Gut Anatomy and Morphology**: Development of Fish Gut). Third, many fish species have pyloric ceca, blind-ended sacs at the anterior end of the intestine, but the number can vary from zero to several hundred. The function of these pyloric ceca is still debated but they certainly enhance the intestinal surface area and are involved in the secretion of some digestive enzymes and bicarbonate, as well as absorption of nutrients and water.

Ion and Osmotic Regulation Functions of the Gut in Nonfeeding Teleost Fish

Much more is known about ion regulation in the gut of marine fish than freshwater fish, and more about teleosts than either elasmobranchs (**see also Chondrichthyes**: Physiology of Sharks, Skates, and Rays) or agnathans (**see also Hagfishes and Lamprey**: Hagfishes, Lampreys: Energetics and Development, and Lampreys: Environmental Physiology). For this reason, we first describe our current knowledge for marine teleost fish.

Like most vertebrates, marine teleosts have body fluids with an osmolality and Na$^+$ and Cl$^-$ concentrations that are roughly one-third of seawater (~1050 mOsm kg^{-1} and ~150 mM, respectively; **see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Osmoregulation in Fishes: An Introduction). This generates a strongly dehydrating osmotic driving force for water loss and salt gain across their outer body surface (mainly via the large area and thin diffusion distance of the gills). To compensate for the osmotic loss, marine teleosts therefore are obliged to continuously drink large amounts of the external medium equivalent to 2.5–12% of their body mass per day (1–5 ml kg^{-1} h^{-1}).

Drinking of seawater occurs steadily in marine teleosts, with small volumes being ingested very regularly. The imbibed seawater is 3 times more concentrated than blood and is dominated by the monovalent Na$^+$ and Cl$^-$ ions (**Table 1**). Yet, by the time the remaining fluid reaches the distal end of the intestine, it has been reduced greatly in volume (50–85% of the water has been absorbed) and its chemistry is very different from the original ingested seawater, instead being dominated by Mg^{2+}, SO$_4^{2-}$, and HCO$_3^-$ ions (**Table 1**)

During passage through the gut, most of the imbibed Na$^+$ and Cl$^-$ are absorbed in order to drive the essential uptake of water that compensates for living in the dehydrating marine environment. The Mg^{2+} and SO$_4^{2-}$ become more concentrated mainly due to the low permeability of

Table 1 The chemistry of blood plasma and rectal fluid in teleost fish, and in seawater and different types of freshwater.

	Seawater,	*Plasma*	*Rectal fluid*	*Typical freshwater*	*Ion-poor freshwater*
Osm	1050	320	~300	<10	<1
Na$^+$	470	140–180	40–100	0.35	0.009
Mg^{2+}	53	1	100–150	0.21	0.002
Ca^{2+}	10	2	2–5	0.75	0.001
K$^+$	10	2–4	5	0.08	0.004
Cl$^-$	548	130–170	30–100	0.23	0.031
SO$_4^{2-}$	28	<1	~100	0.21	-
HCO$_3^-$	2	5–10	50–100	1.11	0.036

Ion concentrations are in mmol l^{-1} and osmolality is in mOsm kg^{-1}.

Typical freshwater values represent averages for worldwide rivers (Bayly and Williams, 1973). Ion-poor freshwater values represent averages for forest streams in the Amazon (Furch, 1984). Seawater values represent those for a salinity of 34 (Barnes, 1954)

the intestine for these ions and the progressive absorption of water. By contrast, the high levels of bicarbonate arise from its net secretion from enterocytes (intestinal epithelial cells). In turn, this causes further modification of the gut fluid chemistry through the chemical precipitation of most of the imbibed calcium and some magnesium as their insoluble carbonates ($CaCO_3$ and $MgCO_3$). The production of these chalky precipitates is now acknowledged to play an important role in offsetting the potentially detrimental accumulation of unabsorbed divalent cations (see later). Details of the precise mechanisms involved in the above processing of imbibed seawater within each section of the gut are given in the following.

Esophagus and Stomach

Relatively few studies have focused on the role of the esophagus, but it is clearly important in marine teleosts for large absorptive fluxes of Na^+ and Cl^-. The imbibed fluid entering the stomach therefore is somewhat desalinated and much closer to the osmolality of blood than the original seawater ingested. This ion transport role of the esophagus is very specific to Na^+ and Cl^-, with little permeability to other ions or water. The NaCl absorption is thought to be driven by both active and passive mechanisms, with basolateral Na^+K^+-ATPase (NKA) providing the driving force. The stomach may be the site of some further changes, including slight dilution of luminal fluid due to net secretion of water, but generally the modified seawater enters the intestine slightly hyperosmotic to blood and still dominated by Na^+ and Cl^- ions.

Intestinal NaCl Co-Transport and Water Absorption

Upon entering the intestine, active absorption of Na^+ and Cl^- is essential to drive the uptake of water into the blood. The co-transport of Na^+ and Cl^-, and the fluid absorption this generates, is ultimately driven by the electrogenic basolateral NKA (**Figure 1**). It is noteworthy that the activity of this key-energizing, ion-transporting enzyme is higher in the intestine than in the other two major ionoregulatory organs in fish (the gills and kidney). For every two K^+ ions pumped into the cell by the NKA, three Na^+ ions are pumped out of the basolateral side of the cell and into the lateral intercellular space (LIS). This generates a low intracellular Na^+ concentration, as well as a negative membrane potential (intracellular relative to extracellular). Collectively, these provide an electrochemical Na^+ gradient that facilitates coupled uptake of both Na^+ and Cl^- across the apical membrane via two transport mechanisms: Na^+:Cl^-

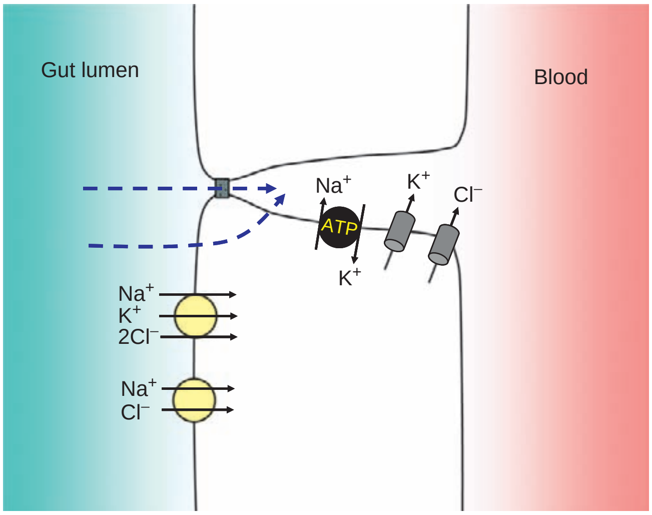

Figure 1 The mechanism of NaCl co-transport and solute-linked water transport in the intestine of marine teleosts. Basolateral NKA uses the energy in ATP to pump K^+ into the cell and Na^+ into the LIS. The latter generates a low intracellular Na^+ concentration which in turn provides the electrochemical gradient for apical Na^+ uptake from the gut lumen into the cell. This apical Na^+ uptake occurs via co-transporters, which use the prevailing Na^+ gradient to simultaneously drag Cl^- ions (NC) or Cl^- and K^+ ions (NKCC2) into the cell. Chloride ions subsequently exit the cell on the basolateral membrane via chloride channels, down their electrochemical gradient. Potassium ions accumulating in the cell from both basolateral NKA and apical NKCC then recycle out of the cell via K^+ channels. Blue dashed arrows represent potential routes for water movement that follow the net transport of solutes (primarily Na^+ and Cl^-) in the apical-to-basolateral direction. The accumulation of both Na^+ and Cl^- in the LIS generates a slightly hyper-osmotic environment which will draw water by osmosis from the gut lumen. The pathway for this osmotic flow of water is not yet known, but could involve paracellular movement via the tight junction, or transcellular via water channels (aquaporins) on the apical and basolateral membrane. Water and NaCl ultimately enter the gut vasculature, and the excess Na^+ and Cl^- ions are then actively excreted via mitochondria-rich cells in the gills.

(NC) and Na^+:K^+:2Cl^- (NKCC) co-transporters. Note that the apical entry of Cl^- is uphill (i.e., against the prevailing electrochemical gradient for Cl^-) and driven by the downhill electrochemical gradient for Na^+ ions. The apical co-transport of Na^+ and Cl^- ions therefore is secondary active transport, ultimately dependent on the energy consumed by the primary active NKA on the basolateral membrane. Subsequently, the apical entry of $Cl^-$is followed by Cl^- exit at the basolateral membrane, via either electrochemical diffusion through channels or K^+Cl^- co-transport. For all these processes to continue, it is essential that K^+ ions are recycled via channels to prevent its intracellular accumulation.

All of the above transport processes ultimately serve to drive the net absorption of both Na^+ and Cl^- (the main solutes in seawater), which subsequently provides an appropriate transepithelial osmotic gradient to drive net water absorption by the gut. This is often described as solute-linked or solute-coupled water flow, which is clearly secondary to salt transfer in the same direction. However, despite decades of research, the precise mechanism and route of the water absorption is still uncertain.

Although a number of aquaporins (water channels; **see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Water Balance and Aquaporin) have been identified for potentially osmoregulatory roles in the marine teleosts intestine (in particular, AQP-8b), there is no direct evidence that transepithelial water absorption actually occurs via such channels. Indeed, it is not even certain that net transepithelial water movement is transcellular (i.e., through both the apical and basolateral membranes). Most favored models explain net water absorption as occurring via the paracellular pathway in the gut, drawn by osmosis across the tight junctions into a slightly hyperosmotic LIS environment (**Figure 1**). Further intrigue on the issue of water absorption arises from the concept of the simultaneous translocation of a fixed number of water molecules within the tertiary structure of various ion co-transporters (termed 'molecular water pumps' by Zeuthen and co-workers). For example, the Na^+/glucose co-transporter (SGLT1) is proposed to carry two Na^+, one glucose, and 264 water molecules simultaneously. Despite our recent advances in molecular physiology, precise details of the mechanism of water transport across the gut remain elusive and continue to be a topic of important research activity.

Intestinal Cl^- and Water Absorption Directly Linked to HCO_3^- Secretion

The principles behind apical NaCl co-transport, fueled by basolateral NKA, ultimately providing the driving force for water absorption in the gut are well established. However, this is not the only major driving force for water absorption in the marine teleosts intestine in particular. A hint of this is indicated by the fact that the rate of Cl^- ion absorption is always much higher than Na^+ ion absorption. Some of this can be accounted for by NaCl co-transport being at least partially mediated via the NKCC (i.e., two Cl^- ions for each Na^+ ion and K^+ ion). However, the early work of Homer Smith (1930) demonstrated that the intestinal fluid of marine teleosts differs greatly from other vertebrates in being very alkaline pH (8.2–9.2) and having high levels of bicarbonate (typically 50–100 mM; **Table 1**). This unusual gut fluid chemistry results from apical anion exchange that involves the net secretion of HCO_3^- ions in return for uptake of Cl^- ions. In some cases, apical Cl^-/HCO_3^- exchange can account for up to 70% of the total Cl^- absorption in the marine teleost intestine. The molecular identity of this apical anion exchanger (AE) is likely to be SLC26a6 (one of a large family of solute carrier group of membrane transport proteins), which is electrogenic exporting more than one HCO_3^- ion for each Cl^- ion imported (although the precise ratio is uncertain, hence it is denoted as $n\mathrm{HCO}_3^-/\mathrm{Cl}^-$ exchange). This is important because it means that the uphill Cl^- absorption mechanism is part of a net export of negative charge, which is supported by the apical membrane potential (i.e., inside negative by about −100 mV relative to outside).

The source of intracellular bicarbonate ions in most species is probably a flexible combination of the hydration of metabolic CO_2 (catalyzed by intracellular carbonic anhydrase; **see also Detection and Generation of Electric Signals**: Physiology of Tuberous Electrosensory Systems) and basolateral uptake of HCO_3^- from the blood via a Na^+:HCO_3^- co-transporter (NBC1) (**Figure 2**). In the latter case, basolateral uptake of bicarbonate from the blood simply provides the intracellular bicarbonate for subsequent apical secretion via Cl^-/HCO_3^- exchange. However, in the former situation, hydration of CO_2 generates intracellular protons as well as bicarbonate ions. Therefore, to maintain cellular pH balance and to ensure a continued supply of bicarbonate for apical exchange with chloride, these protons must be readily extruded from the basolateral side of enterocytes.

The precise molecular identity of this acid export is not yet known, but there is functional evidence for basolateral Na^+/H^+ exchanger (NHE) in toadfish and molecular evidence for abundant basolateral proton pumps (H^+-V-type ATPase) in rainbow trout. Whatever transporters are involved, and whether bicarbonate secretion is transepithelial or is fueled by intracellular CO_2 hydration, the net effect is the same: net base secretion to the gut lumen and net acid absorption into the blood (because bicarbonate uptake into the cell from the blood is equivalent to acid moving in the opposite direction in acid–base terms). Therefore, this has acid–base repercussions for the whole animal, which are discussed later.

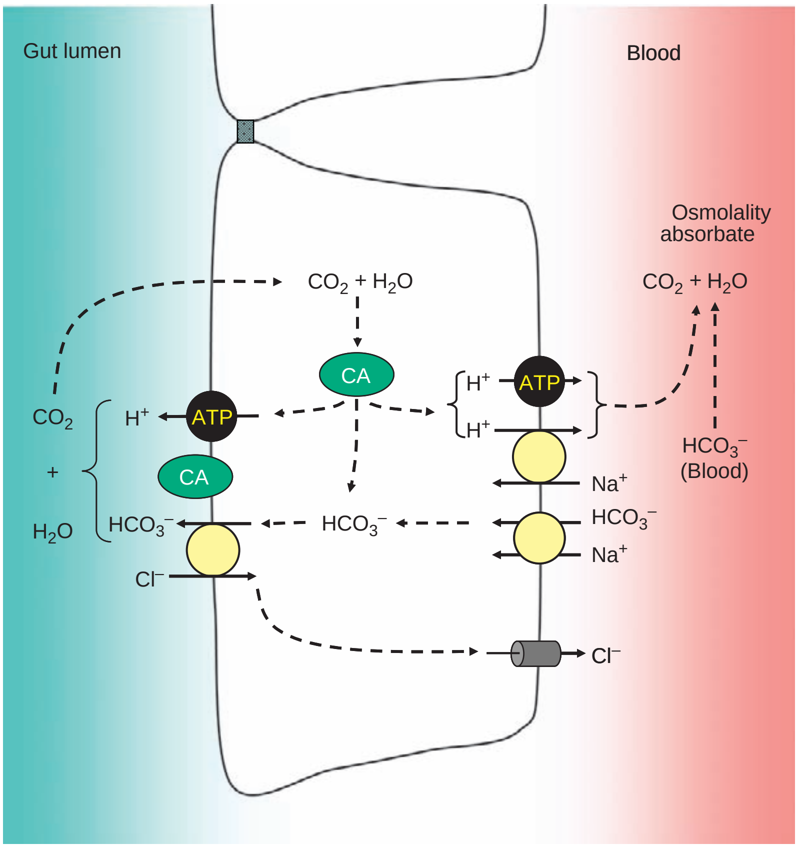

Figure 2 Direct role of HCO_3^- secretion in water absorption by the intestine of marine teleosts. The figure combines elements of models presented by both Grosell et al. (2009) and Whittamore et al. (2010) that relate to the role of epithelial bicarbonate secretion and the associated mechanisms that generate a driving force to support net water absorption. Bicarbonate ions are generated inside the enterocyte either from the hydration of metabolic CO_2 (catalyzed by cytosolic carbonic anhydrase) or from the basolateral uptake from the blood side via Na^+:HCO_3^- co-transporters (NBC1). The HCO_3^- ions are then exported into the gut lumen via apical Cl^-/HCO_3^- exchangers (SLC26a6). Chloride ions taken up across the apical membrane ultimately reach the blood side of the cell via basolateral Cl^- channels (the same as proposed in **Figure 1**). The intracellular hydration of CO_2 also generates protons (H^+). To maintain cellular pH balance, these H^+ ions are normally removed by basolateral proton pumps and/or NHEs. Basolaterally absorbed protons ultimately are buffered by blood-derived HCO_3^- in the subepithelial space, producing gaseous CO_2 from these dissolved ions. This conversion helps in reducing the osmolality of basolateral fluid which would otherwise become hyperosmotic as a result of the net absorption of HCl and NaCl. When luminal Ca^{2+} concentrations are low, this limits the potential for apical HCO_3^- removal via $CaCO_3$ precipitation in the gut lumen. Under these circumstances, a second mechanism operates whereby apical proton pumps export some of the intracellular H^+ ions. This appears to be coupled to the apical anion exchange of Cl^-/HCO_3^- in a functional metabolon. Co-localized carbonic anhydrase enzymes present on the apical membrane (CA-IV) promote the rapid conversion of the luminal osmolytes (HCO_3^- and H^+) to CO_2 gas. This reduces the luminal osmolality, thus promoting apical water absorption. It also encourages further apical Cl^-/HCO_3^- exchange by enhancing the apical HCO_3^- ion gradient. The resulting Cl^- absorption also helps drive water absorption. Intriguingly, the apically generated molecular CO_2 probably diffuses back into the cell, thus regenerating the intracellular source of HCO_3^- ions.

So how is water transport linked to this process of bicarbonate secretion? At face value, the apical exchange of intracellular HCO_3^- for luminal Cl^- should at best be neutral in terms of osmolyte movement (if the exchange ratio is 1:1). However, if the intracellular bicarbonate is derived from CO_2, then effectively the whole process results in a CO_2 gas molecule (which is osmotically neutral at cellular CO_2 concentrations) being replaced by a Cl^- ion, which is a strong osmolyte. This effect alone will tend to draw water across the apical membrane and, provided the Cl^- ultimately is absorbed in the blood, an osmotic movement of water across the whole epithelium will result. Thus, bicarbonate secretion can be directly responsible for a portion of water absorption in the intestine. The entire length of the intestine (anterior, mid-, and posterior sections) is capable of substantial bicarbonate secretion, which should support this mechanism of water absorption. It is also worth noting that for the fish species that have pyloric ceca, these are capable of strong bicarbonate secretion and water absorption, and these anatomical features clearly offer additional functional area for these processes.

A further aspect of bicarbonate secretion may be important in water absorption, especially when luminal Ca^{2+} concentrations are low (**see** section Intestinal Water

Absorption Indirectly Linked to HCO_3^- Secretion via Alkaline $CaCO_3$ Precipitation). This involves the combined action of Cl^-/HCO_3^- exchange and proton pumps on the apical membrane, in a functional metabolon, whose simultaneous action at first seems counter-intuitive for a base-secreting epithelium (**Figure 2**). However, the rate of apical acid secretion is much less than the rate of apical bicarbonate secretion, so net base secretion still ensues. The benefit of this metabolon for Cl^- ion and water absorption works in three ways. First, the limiting factor within the cell is provision of HCO_3^- ions to the Cl^-/HCO_3^- exchanger (identified as SLC26a6 in toadfish). Intracellular accumulation of protons near this site would reverse the CO_2 hydration reaction and inhibit further HCO_3^- ion secretion, so co-localized proton pumps offer an effective way to remove the accumulating protons and maintain the local supply of HCO_3^- ions. Second, the resulting supply of protons to the mucosal boundary layer will titrate a portion of the secreted HCO_3^- to CO_2, thus locally reducing the outward HCO_3^- gradient. This has the double benefit of (1) assisting uphill Cl^- uptake via Cl^-/HCO_3^- exchange (thus promoting solute-linked water absorption) and (2) reducing the osmolality within the mucosal boundary layer due to the conversion of osmotically active HCO_3^- and H^+ ions to osmotically inert CO_2 gas, thus further promoting the transmembrane osmotic gradient for water absorption. Third, the gaseous CO_2 may be recycled (by simple diffusion across the apical membrane) back into the cell to help fuel a continued supply of H^+ and HCO_3^- for further apical export. Thus, many processes involved in HCO_3^- ion secretion are directly involved in driving water absorption, which is a vital role of the intestine in marine teleosts fish.

One puzzling aspect of water absorption driven by the HCO_3^- ion secretion mechanism is that numerous studies and models indicate that the associated fluid absorbed (absorbate) must be strongly hyperosmotic to the blood, as well as being highly acidic containing predominantly HCl. In contrast, studies in which intestinal bicarbonate secretion is experimentally enhanced show that blood plasma osmolality is actually reduced compared to normal, and any blood pH disturbances are small. The gills (**see also Role of the Gills**: Morphology of Branchial Ionocytes) and kidney (**see also Role of the Kidneys**: The Kidney) undoubtedly act in concert with the gut for osmoregulation in marine fish, and may well remove most of the excess salts from any hyperosmotic intestinal absorbates. However, a model has also been proposed which involves only the intestine and helps explain this discrepancy. The absorbate should not be considered as an isolated volume of fluid absorbed by the intestine. In reality, it rapidly becomes mixed with a supply of extracellular fluid within the subepithelial space. Here the acidic absorbate will almost immediately be buffered by the continuous supply of HCO_3^- ions from the blood, which will neutralize the pH and increase the circulating level of CO_2. In addition, the neutralization reaction will simultaneously reduce the osmolality by converting osmotically active HCO_3^- and H^+ ions to CO_2 gas. This neutralization within the gut vasculature is estimated to effectively make the absorbate hypoosmotic to blood, which is the ideal scenario for marine teleosts living in the dehydrating seawater environment.

Intestinal Water Absorption Indirectly Linked to HCO_3^- Secretion via Alkaline $CaCO_3$ Precipitation

Besides the direct roles in water absorption described above, bicarbonate secretion plays a highly novel and indirect role in water absorption. The high pH (8.2–9.2) and bicarbonate concentrations (50–100 mM) reached in the intestinal fluids are far above those resulting from pancreatic secretions in mammals, and occur whether post-prandial or inter-digestive. So they do not serve purely to neutralize the acidic stomach contents that enter the intestine, and they are clearly associated with the particular osmoregulatory needs of marine teleosts. It is this unusual gut fluid chemistry that contributes a further important driving force for water absorption. The alkaline, HCO_3^--rich conditions cause unabsorbed Ca^{2+} from imbibed seawater to precipitate as insoluble calcium carbonate ($CaCO_3$, and, to a lesser extent, Mg^{2+} as $MgCO_3$). The resulting solid carbonate crystals become wrapped in mucus and are periodically excreted along with rectal fluids. Remarkably, the amount of $CaCO_3$ excreted by marine teleosts has recently been shown to make a significant and previously unrecognized contribution to the global inorganic carbon cycle. In teleosts, the secretion of HCO_3^- and subsequent precipitation of $CaCO_3$ in the intestine is dependent upon ambient salinity and the requirement to drink and thus a fundamental role in osmotic regulation has been proposed.

Water absorption by any mechanism means that imbibed solutes that are not absorbed become increasingly concentrated along the intestine. The divalent ions Ca^{2+}, Mg^{2+}, and SO_4^{2-} are quite abundant in seawater (10, 53, and 28 mM, respectively) and are generally poorly absorbed compared to monovalent ions. This may simply be due to a very low permeability of the epithelium to these divalent ions. Conversely, there is some evidence of a very effective active secretion mechanism (at least for SO_4^{2-} ions in exchange for Cl^- uptake), which serves to counteract most of the passive absorption that occurs. Regardless of the explanation for the impermeance of these divalent ions, if 85% of the imbibed fluid is absorbed (as for seawater rainbow trout), any unabsorbed ions that remain in solution would be left behind in 15% of the original fluid volume (i.e., concentrated by 6.7-fold). For Ca^{2+}, Mg^{2+}, and SO_4^{2-}, this would result in their accumulation to over 67, 353, and 187 mM, respectively. Collectively, these represent >600 mM of unabsorbed solutes in the fluid of the distal intestine, which would massively oppose water absorption. Despite low permeation of the intestine by these divalent ions, a small portion is inevitably absorbed given the large gradients (and these divalent ions are subsequently excreted by the kidney in marine fish). However, the chemical precipitation of Ca^{2+} and Mg^{2+} by reaction with the secreted bicarbonate removes a large portion of these ions from solution, thus avoiding a detrimental accumulation (**Figure 3**). The carbonate precipitation reduces luminal (mucosal) osmolality and enhances the transepithelial osmotic gradient for water absorption, providing a further important mechanism of facilitating water transport. The importance of this mechanism to osmoregulation is highlighted by the acute sensitivity of intestinal bicarbonate secretion to the luminal calcium concentration both *in vivo* and *in vitro*. The intestinal epithelium appears to be highly tuned to remove imbibed calcium (and to a lesser extent Mg^{2+}) at whatever rate it enters the intestine.

Ion Regulation in the Gut of Freshwater Fish

Freshwater fish face the opposite osmotic problem to marine fish (**see also Osmotic, Ionic and Nitrogenous-Waste Balance**: Mechanisms of Ion Transport in Freshwater Fishes); rather than continually combating dehydration, they suffer from a continual osmotic gain of water. This is mainly via the large surface area and thin diffusion distance of the gills. Freshwater fish therefore have little need to drink for osmoregulatory purposes, and typically have drinking rates 10- to 50-fold lower than marine teleosts. In addition, any fresh water that is imbibed typically has very low ion concentrations compared

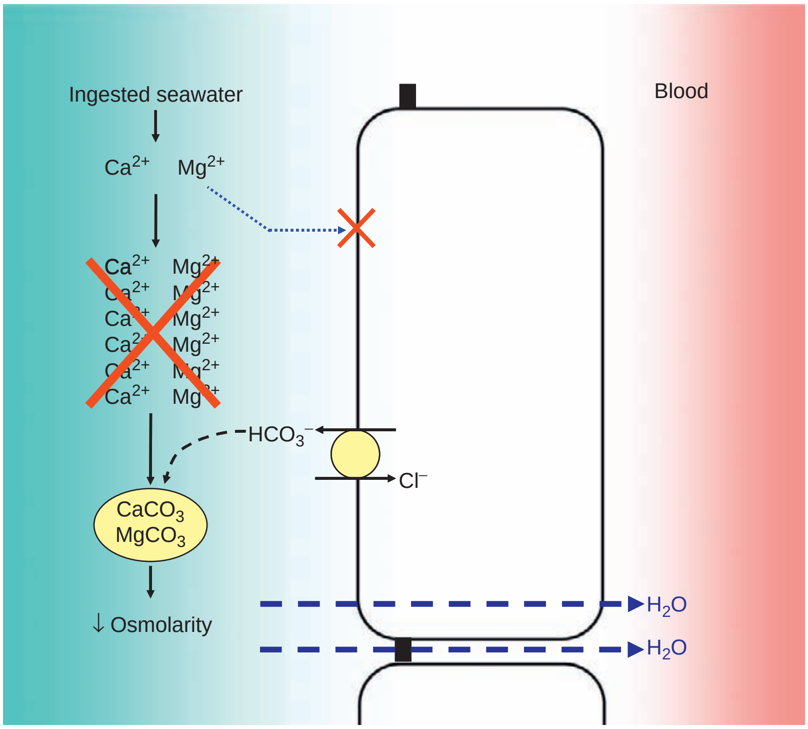

Figure 3 Indirect role of alkaline precipitation of calcium and magnesium carbonates in water absorption by the intestine of marine teleosts. Ingested seawater contains relatively high concentrations of Ca^{2+} (10 mM) and Mg^{2+} (53 mM). These divalent cations are poorly absorbed during their passage along the intestine and so theoretically their concentrations will increase as water is absorbed via the direct mechanisms described in **Figures 1** and **2**. For example, if 85% of the ingested fluid volume is absorbed, this would leave behind 67 and 353 mM of Ca^{2+} and Mg^{2+}, respectively. If allowed to occur unchecked, this would represent a substantial increase in the osmolality of fluid in the gut lumen, which in turn would retard net water absorption. However, the net secretion of bicarbonate ions (see **Figure 2**) results in the removal of almost all of the accumulated Ca^{2+} and a smaller fraction of the accumulated Mg^{2+}, by precipitating them as their insoluble carbonate salts ($CaCO_3$ and $MgCO_3$). The resulting removal of these dissolved solutes reduces the osmolality of fluid in the gut lumen which improves the apical to basolateral osmotic gradient to facilitate further net water absorption.

to either body fluids or seawater. As a result, there is little scope for the gut to play a major role in ion regulation in freshwater fish under nonfeeding conditions. However, in freshwater fish in particular, the diet can provide a vital source of many ions, as well as a net sink for endogenous water.

Ion and Osmotic Regulation by the Gut of Feeding Freshwater Teleost Fish

For many freshwater fish, at least for the best-studied ions Na^+, Cl^-, and Ca^{2+}, the active transport processes in the gills are capable of satisfying the ion uptake requirements. In other words, the gill is sufficient to balance any obligatory ion losses via urine flow and skin or gill diffusion. In these examples, stable whole-body ion balance can be achieved for long periods in the absence of feeding and involvement of the gut. However, for other species gill ion uptake may be insufficient to maintain whole-body ion balance in the absence of dietary intake. Examples include Amazonian fish that live in extremely ion-poor water that limits uptake ability, and also a range of species such as eels, killifish, and bluegill that have minimal capacity for active gill Cl^- transport. For these fish, therefore, the gut is an essential ionoregulatory organ. In most cases though, the need to understand gut ion regulation during feeding comes from an aquaculture perspective, that is, appreciating the limiting and loading factors in commercial diets, and the influence that the ion content of food has on various aspects of the physiology of fish. In what follows, we describe our limited current knowledge on the handling of ions and water by the gut of freshwater fish.

During feeding some water is gained as part of the diet itself (animals and plants contain generally 60–80% water). Furthermore, when farmed fish are fed on commercial feeds, which are typically very dry pellets (~10% water; **see also Energetic Models**: Bioenergetics in Aquaculture Settings), the dietary water can be supplemented by larger amounts of imbibed water (e.g., 1.6 ml water for every 1 g of food), which is important to improve the motility of ingested food within the gut. Nevertheless, the gut is actually the site of net water loss during feeding in freshwater fish for two separate reasons. First, the active secretion of digestive juices in the stomach and intestine contributes to net fluid export. Second, even if the fluid component of the undigested meal begins as relatively iso-osmotic to fish blood, the digestion process results in dissolution of cellular and hard materials (e.g., bone) that yields very high salt concentrations and therefore high osmolality in the digested contents of the stomach (called chyme) and anterior intestine, which induces a net osmotic movement of water from the body fluids into the gut. Although the more distal sections of the intestine may be the sites of water absorption, as a whole the gut is responsible for net fluid loss during feeding.

For monogastric animals, like humans, the stomach is usually considered to be purely an organ of secretion and digestion. However, a surprising discovery from the limited studies on freshwater fish is that the stomach performs substantial absorption of many ions. Indeed, the stomach of trout absorbs the majority of Na^+, K^+, and Mg^{2+}, and 50% of the Ca^{2+} present in a commercial pellet diet. As expected, the trout stomach is the site of net secretion of H^+ and Cl^-. However, this simple summary obscures some interesting temporal changes in the fluxes of these various ions. Almost all the Cl^- secretion occurs during the first half of the food's residence within the stomach, whereas almost all the K^+ absorption occurs during the second half of this gastric digestion phase. This probably reflects the established mechanism of gastric acid secretion in vertebrates generally, and putitatively in teleosts, which involves an apical H^+/K^+-ATPase. During stimulation of net acid secretion, ATP is consumed to drive the secretion of H^+ and uptake of K^+, but to maintain the functioning of this pump the K^+ ions must be recycled back to the stomach lumen via K^+ channels. Presumably, only once gastric acidity has reached its target pH and acid secretion is downregulated will the K^+ recycling pathway also be shutdown allowing net K^+ absorption to proceed. However, the actual transport mechanisms for gastric absorption of K^+ (and Na^+, Ca^{2+}, and Mg^{2+}), and their molecular identities, remain unknown in fish.

Although the stomach is capable of surprisingly high rates of absorption of these four ions, it would appear that the intestine is responsible for substantial net secretion, at least for Na^+, Ca^{2+}, and Mg^{2+}. Whereas virtually 100% of the dietary K^+ is assimilated by the gut as a whole, for dietary Ca^{2+} and Mg^{2+} the overall assimilation is only ~30% and ~60%, and for Na^+ the common situation seems to be zero net absorption or secretion by the gut overall due to intestinal secretion exactly counterbalancing gastric uptake.

Ion and Osmotic Regulation by the Gut of Feeding Marine Teleost Fish

In seawater trout fed on a similar commercial diet, the gut processing of the meal results in a similar net loss of water as that found in freshwater fish. However, this obviously compounds the existing osmoregulatory problems experienced under nonfeeding conditions, representing a significant additional physiological challenge for digestion in marine teleosts. Unlike freshwater fish, most of the dietary ions are not assimilated by the gut as a whole, which is appropriate given the additional salt load it would create on top of the diffusive influx caused by breathing seawater.

The Role of the Gut in Acid–Base Regulation

There has been surprisingly little study of the possible role of the gastro-intestinal tract of fish in acid–base regulation. This is despite its good candidacy given the well-known capacity for acid secretion by the stomach, and base secretion by the pancreatic tissue and intestine itself (for marine teleosts at least, see above). Despite this potential, the gut is generally considered to be a minor player relative to the gills and kidney. Although the gills are typically considered to perform the vast majority of any acid–base regulatory work in fish, the kidney has recently been re-evaluated for its energetic importance in maintaining blood acid–base status in fish, in particular the high re-absorption rates for filtered HCO_3^- ions (**see also Role of the Kidneys**: The Kidney). We will now discuss some of the more recent work on the role of the gut in acid–base regulation.

It was clear from the early work on intestinal bicarbonate secretion in marine teleosts that the continual production of alkaline- and HCO_3^--rich gut fluid together with carbonate precipitates represented a significant route of base excretion from the body. The majority of this base stems from the HCO_3^--rich rectal fluids rather than the carbonate precipitates, and although the release of rectal fluid is quite intermittent, it occurs at sufficiently high rates overall (0.5–1.1 ml kg^{-1} h^{-1}) to generate base excretion rates in the range of 100–150 μEq kg^{-1} h^{-1}. Under resting conditions, this clearly contributes to the whole animal acid–base balance when compared against the acids and bases excreted via the gills and kidney, that is, roughly one-half to one-third of the combined ammonia or bicarbonate excreted by these other organs. Thus, there appears to be a degree of anatomical separation for net base fluxes (a large fraction via gut) and acid fluxes (primarily via the gills) in resting marine teleosts. However, the importance of the intestine in true acid–base regulation following an acid–base disturbance is less clear.

The most natural situation for the intestine to assist whole-body acid–base regulation would be during the post-prandial metabolic alkalosis commonly known as the alkaline tide. It is well known that following a meal, the stomach of vertebrates secretes large quantities of isotonic HCl for gastric digestion (**see also Integrated Function and Control of the Gut**: Gut Secretion and Digestion). It is less well known that for every molecule of acid secreted by the gastric oxyntic cells in mammals (or oxyntopeptic cells in nonmammalian vertebrates), an equal amount of bicarbonate base must be exported into the blood to maintain cellular acid–base neutrality. This compensatory transport generates the alkaline tide phenomenon – a rapid increase in blood HCO_3^- concentration and pH in the minutes/hours after a meal. This is well characterized in mammals and ectothermic terrestrial vertebrates in which the initial blood alkalosis is rapidly compensated by reduced ventilation (by raising internal levels of CO_2) which helps by offsetting the initial rise in blood pH, followed by a more gradually excretion of the excess plasma HCO_3^- via the kidney. The alkaline tide has now been demonstrated in both freshwater and seawater fish. Unlike air-breathing vertebrates, fish do not compensate the initial alkalosis by any hypoventilatory rise in blood CO_2. However, the intestinal mechanism for bicarbonate secretion (which already functions in osmoregulation within marine teleosts) appears to play a secondary role in sequestering at least some of the excess plasma HCO_3^- arising from the alkaline tide. Interestingly, this seems to be more prevalent in freshwater rather than seawater trout, even though the latter should be better prepared with respect to the intestinal HCO_3^- transport mechanism. This suggests that freshwater trout already have the cellular machinery present to carry out effective intestinal HCO_3^- secretion and can use this to help offload some of the excess HCO_3^- accumulated in the blood after a meal. By contrast, seawater trout appear to excrete most of the excess plasma HCO_3^- via the gills. This surprising difference between freshwater and seawater trout may reflect the availability of counter-ions to the gills for driving these ion-transport mechanisms in the two media.

Under less natural conditions, when seawater teleosts were subjected to a metabolic alkalosis (due intra-vascular infusion of excess $NaHCO_3$ at ~500 μEq kg^{-1} h^{-1}), this treatment failed to produce any upregulation of rectal fluid base excretion. Instead, the nonintestinal sites (gills, skin, and kidney) excreted almost all of the exogenous base load. By contrast, a respiratory acidosis induced by exposure to hypercapnia (raised ambient CO_2) causes a twofold increase both in intestinal $CaCO_3$ excretion rate, and in the rectal fluid concentration of dissolved HCO_3^-. Therefore, under certain exogenous acid–base disturbances, the intestine can respond to alter its base excretion rates. However, it is worth noting that the response to hypercapnic acidosis is actually counter-productive in terms of restoring normal internal acid–base balance, as the enhancement of rectal base excretion would simply exacerbate the blood acidosis, providing the gills and kidney with even more acid–base regulatory work.

So although the intestine is a relatively important factor when considering acid–base homeostasis under nonfeeding conditions, it appears to play little positive role in true acid–base regulation during recovery from either metabolic alkalosis or respiratory acidosis.

Glossary

Active ion transport The process of using cellular energy (usually in the form of ATP) to move ions across a membrane, typically against their concentration gradient. This process can be further divided into primary (direct action of an ion transporter that hydrolyzes ATP) and secondary (ions move down an electrochemical gradient created by other primary processes) active transport. The rectal gland Na^+/K^+-ATPase moves Na^+ and K^+ ions across the cell membrane in an example of primary active transport. Secretion of Cl^- by the gland qualifies as secondary active transport because it relies on the Na^+ gradient established by Na^+/K^+-ATPase.

Alkaline tide The systemic increase in blood pH (reduced H^+ ion concentration or alkalosis) that follows a meal. As acid (HCl) is secreted into the stomach for digestion of a meal, the blood plasma is left with an excess of base (bicarbonate ion, HCO_3^-), leading to a systemic rise in pH.

Apical membrane The side of an epithelial cell facing the outer world; for the gut and rectal gland, this is the lumen.

Basolateral membrane In rectal gland secretory cells, the basolateral membrane faces the interior of the animal and is exposed to humoral factors. It is extensively infolded and is separated from the apical membrane region by tight junctions between adjacent cells.

Concentration gradient A difference in the concentration of a substance (e.g., ions in the body fluids) across some spatial scale. In the context of rectal gland, concentration gradients most often refer to differences in ion concentrations across the cell membrane or across the secretory epithelium.

Cytoskeleton A network of tubules and filaments that provides structural support to cells. Major cytoskeletal proteins include tubulins (in microtubules), actins, and myosins. These cytoskeletal elements also provide anchor points or scaffolding for cellular organelles, membranes, and proteins. Changes in cytoskeletal composition and structure, known as cytoskeletal reorganization, lead to changes in cell morphology.

Endocrine/paracrine/autocrine factors A diverse class of molecules that exert specific downstream effects on target tissues and cells, including activation or inhibition of specific pathways or processes. Depending on the point of origin, these molecules are classified as endocrine (usually originating from one or more glands remote from the point of action and circulating in the blood), paracrine (originating from tissues or cells neighboring the point of action on a different cell type), or autocrine (originating from and acting on the same tissue or cell type).

Euryhaline Animals that physiologically adjust to a wide range of water salinity are considered euryhaline (*eury*, broad; *haline*, salt) in contrast to stenohaline animals.

Secretagog Collective term for substances that can stimulate secretion; for the rectal gland these include forskolin, CNP, VIP, and theophylline.

Stenohaline Describes an organism that cannot live in environments that undergo large changes in salinity (steno 'narrow').

Introduction

Regulation of the body's salt and water content is a central physiological challenge for all animals. Marine fishes, including the elasmobranchs (the sharks, skates, and rays), maintain their body fluid ionic (especially Na^+ and Cl^-) concentrations below that of the surrounding seawater (**Table 1**). Elasmobranchs exhibit a peculiar osmoregulatory strategy, in which they retain large quantities of the nitrogenous waste product urea as an organic

osmolyte; they also accumulate trimethylamine oxide (TMAO), which counteracts urea's destabilizing effects on proteins. This urea-based strategy maintains elasmobranch body fluids slightly hyperosmotic to seawater, eliminating the need for constant water absorption via drinking. However, elasmobranchs still face a constant influx of salts, driven by the inwardly directed ion gradients. Furthermore, the act of feeding expands the intravascular fluid volume and introduces salts into the body fluids both directly by ingestion of seawater and food items, and indirectly as a consequence of acid–base adjustments associated with digestion.

While the gill handles regulation of the major monovalent ions (Na^+ and Cl^-) in bony fishes, the elasmobranchs (and coelacanth) possess a small, highly specialized structure known as the rectal gland (also known as the digitiform gland) that carries out the majority of salt secretion. This gland, located near the posterior section of the intestine, secretes a concentrated solution of NaCl (~500 mM) that is twice the ionic concentration of the plasma, but that is nearly iso-osmotic with seawater and the body fluids. Although the rectal gland was described by scientists as early as in the 1600s, its salt-secreting function was not demonstrated until the 1950s, by Burger. In addition to its role in ion regulation, the gland also functions to regulate intravascular volume because water follows osmotically into the secretion fluid. In fact, several authors have suggested that vascular fluid volume regulation is the gland's primary function, but the distinction seems unnecessary given the intimate relationship between water and salt movements in the gland, the kidney's major role in elasmobranch volume regulation, and the likely co-occurrence of salt and volume loading after a meal in the whole organism. The bulk of available evidence indicates that the rectal gland acts as a fine-tuning mechanism for regulating both intravascular volume and body salt content, necessitated by the elasmobranch kidney's inability to secrete urine with a higher salt concentration than the vascular fluid. Interestingly, some elasmobranchs can maintain their body-fluid ion concentrations when the rectal gland is removed or ligated.

The rectal gland has for decades been a productive model for studying both the mechanisms and the controls of salt secretion in vertebrates due to its highly specialized function, its cells rich in the enzymes and transporters that drive salt transport, and its experimentally convenient anatomical features. The long history of rectal gland studies at multiple levels of organization – from molecular biology to individual cells to the *in vivo* gland – also clearly demonstrates the iterative path of scientific inquiry. These studies have revealed the surprisingly complex and dynamic anatomy and physiology of what at first glance appears to be a simple tissue.

Anatomy

The anatomy of the rectal gland has been thoroughly studied, and it is only described briefly here. Readers are referred to Olson's work (see section 'Further reading') and references therein for an excellent, detailed review.

Gross Morphology

The rectal gland's name derives from its location in the dorsal mesentery above the posterior end of the spiral intestine (i.e., near the rectum) (**Figure 1**(**a**)). Rectal gland weights per unit of body mass range from 100–600 mg kg^{-1} body mass in marine and brackish species to 15–60 mg kg^{-1} body mass in euryhaline and freshwater species. The smallest and least complex (fewest tubules) rectal glands are found in Amazonian freshwater stingrays of the family Potamotrygonidae, in which the need for salt secretion is negligible in an ion-poor habitat.

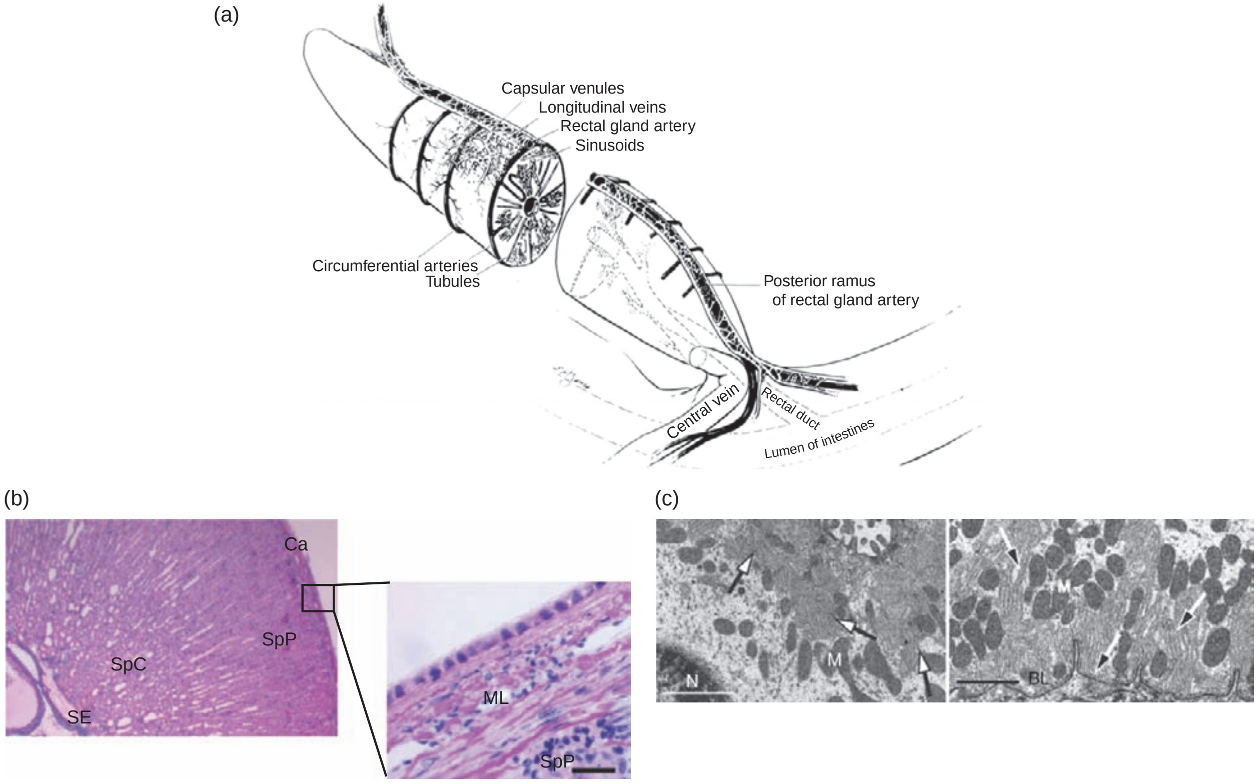

Figure 1 (a) Diagram of the gross morphology and vascular circulation of the rectal gland. (b) Histological cross section of the rectal gland of *Squalus acanthias*, demonstrating the three layers: outer capsule (Ca), middle secretory parenchyma (peripheral SpP and central SpC zones), and stratified epithelium (SE). The rectal gland lumen appears at the bottom left. The inset magnifies the outer capsule and reveals the ring of smooth muscle layer (ML); Scale bar = 20 μm. The gland consists of three tissue layers: an outer muscular capsule, a middle secretory parenchyma, and an inner stratified epithelium that lines a central lumen (**Figure 1**(**b**)). The capsular, smooth muscle ring that surrounds the entire gland contracts in response to secretagogs and appears to play a role in changing the gland's overall morphology during intermittent gland secretion. The central lumen is fed by a radiating network of densely packed, blind secretory tubules that come in small and large diameters and that extend through the parenchyma. Nerve fibers, which contain the secretagog vasoactive intestinal peptide (VIP), are interspersed among the tubular secretory cells.

Vasculature

The rectal gland is a heavily vascularized tissue (**Figure 1**(**a**)). A single devoted vessel, the posterior mesenteric artery (PMA), supplies the gland with blood and the humoral factors that regulate gland activity (see below). The anterior branch of the PMA divides first into circumferential arteries, followed by a capsular web of arterioles, and then into an extensive network of radial capillaries that associate closely with the secretory cells of the tubules in the parenchyma. In the middle parenchyma, larger venous sinuses are sometimes associated with the secretory tubules. Downstream, these vessels coalesce into luminal veins, and ultimately into a single central vein that drains into the vasculature of the intestine. The posterior branch of the PMA runs along the dorsal surface of the gland and bypasses its circulation altogether. A third vascular pathway functions as a shunt, allowing blood to bypass the tubular capillaries while circulating through the capsule. Constrictions in the arteriovenous anastomoses that lead to this bypass system, as well as rectal gland vasoconstriction in response to norepinephrine treatment (which is abolished by the secretagog VIP), suggest that blood perfusion through the gland is dynamically regulated. However, definitive studies of the regulation and function of these two bypass pathways are yet to be performed. Notably, perfusion and secretory activity of the rectal gland are both highly variable in time, although a direct correlation between perfusion rate and salt secretion is not always found.

Secretory Cell Morphology

The mechanisms of salt transport in the rectal gland are intimately tied to its epithelial and cellular morphology. The rectal gland tubule walls are composed almost entirely of a single layer of columnar secretory cells. These secretory cells exhibit highly infolded basolateral membranes, which enhance the cell-membrane surface area to accommodate the numerous and varied ion transporters that reside there. Dense aggregations of mitochondria are closely associated with the basolateral – but less so with the apical – membrane regions of the cell, supplying aerobically derived adenosine triphospate (ATP) to fuel active ion transport (**Figure 1**(**c**)). The apical membrane includes a number of microvilli extending into the tubule lumen. Neighboring secretory cells also exhibit extensive lateral interdigitation that has been referred to as jigsaw-puzzle-like and that enhances the extent of the paracellular pathway for sodium exit (see below). Shallow (~20–60 nm compared to hundreds of nm in other epithelia), leaky tight junctions that selectively permit Na^+ efflux join these interdigitated cell membranes.

Studying Rectal Gland Secretory Function

The fluid secreted in the rectal gland lumen drains via a single duct into the intestine, from where it is excreted with the feces. This feature, in concert with the simple vascular-supply structure, makes the intact gland an almost ideal study system for controlled perfusion studies. By cannulating the rectal gland duct, PMA, and central vein (but not the posterior bypass of the PMA, as noted by Olson), researchers can manipulate the ionic concentrations, hormone levels, pH, perfusion pressure, and other variables of the perfusing humoral fluid and then analyze the excurrent humoral fluid as well as the quantity and composition of the fluid secreted by the gland. Such studies may be performed *in vivo* (within the anesthetized or unrestrained animal), *in situ* (within pithed animals, where the central nervous system is destroyed), or *in vitro* (outside of the animal; literally, in glass). Researchers have also isolated individual rectal gland tubules and cultured the secretory epithelium of a single tubule for more focused biochemical and physiological studies. Different experimental preparations have their advantages and disadvantages. Isolated gland or tubule preparations, in particular, have allowed for the experimental manipulation of individual variables and have led to many of the major advances in rectal gland physiology. Building on these successes, recent *in vivo* studies have refocused on the rectal gland as a dynamic tissue with important organismal function(s) particularly in the context of feeding and the associated physiological perturbations. The *in vivo* preparation using unrestrained animals allows for perhaps the most physiologically realistic measurements; however, this comes at the cost of limited ability to manipulate the experimental parameters. Finally, the availability of secretagogs, specific activators and inhibitors of the various constituents of the secretory apparatus, and, more recently, cloned sequences for these constituents, has allowed for detailed characterization of the mechanisms and controls of rectal gland function.

Mechanism of Salt Transport

The molecular mechanisms of NaCl transport in the rectal gland are very similar to those used in other salt-transporting epithelia, including bony fish gills and the human kidney. In fact, many of the details of ion transport in these other tissues were first worked out in the spiny dogfish (*Squalus acanthias*) rectal gland.

Transcellular, Secondary Active Transport of Cl^- is Coupled to Paracellular Na^+ Efflux

The current model for ion transport in the rectal gland is summarized in **Figure 2**(**a**). The energizing step for transcellular, secondary active chloride-ion transport occurs at the basolateral membrane of secretory cells, where high densities of Na^+/K^+-ATPase pump three Na^+ ions out of the cell for every two K^+ ions that are pumped in. This pump creates both a strong inwardly directed gradient for Na^+ and a net negative charge inside the cells (i.e., an electrochemical gradient for Na^+ to reenter the cells). The Na^+ ions move down this electrochemical gradient into the cell via the passive transporter sodium–potassium two-chloride cotransporter (NKCC), bringing along two Cl^- ions (against the transmembrane Cl^- gradient) and a K^+ ion. K^+ ions pass back out of the cell through a passive K^+ channel to avoid an intracellular excess. The Na^+ ions are then actively re-transported out of the cells via the Na^+/K^+-ATPase pump. This process yields an intracellular Cl^- ion excess relative to the tubule lumen. The Cl^- ions then follow their transmembrane gradient into the tubule lumen via an apical passive chloride channel, which shares structural and biochemical properties with the human cystic fibrosis transmembrane conductance regulator (CFTR). The Na^+ ions enter the tubule lumen via a paracellular route through the leaky tight junctions between secretory cells; efflux of Na^+ is driven

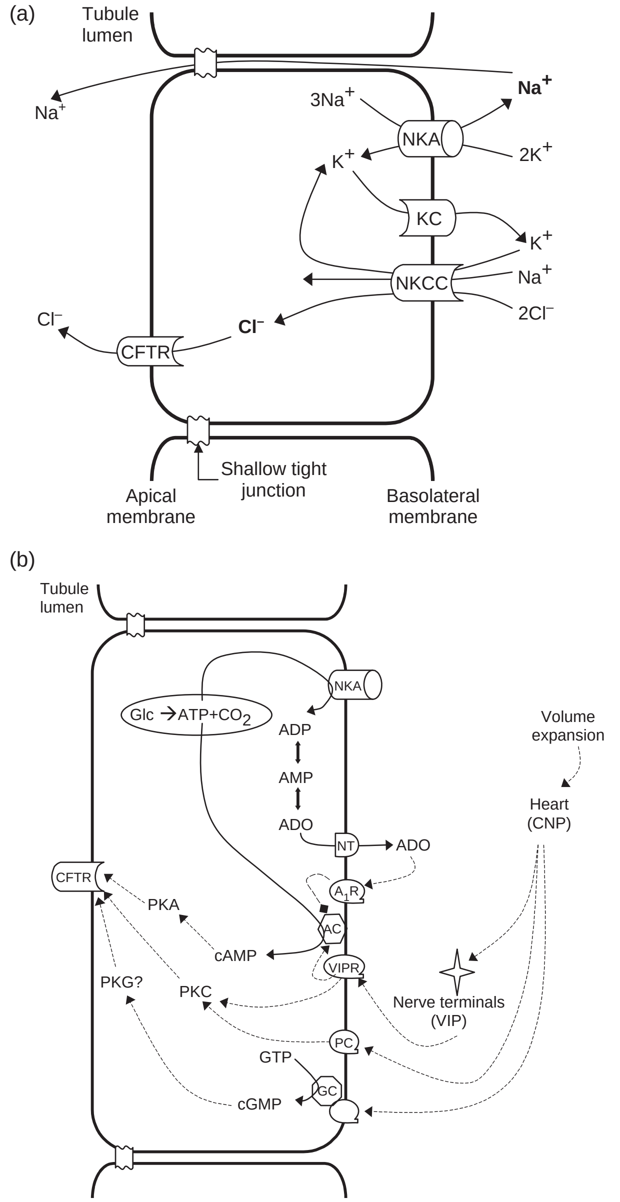

Figure 2 (a) Schematic of the current model of sodium (Na$^+$) and chloride (Cl$^-$) ion transport in secretory cells of rectal gland tubules. Bold symbols indicate intracellular and extracellular accumulations of chloride and sodium, respectively. NKA, Na$^+$/K$^+$-ATPase; KC, potassium channel; CFTR, cystic fibrosis transmembrane conductance regulator chloride channel; NKCC, sodium–potassium two-chloride cotransporter. (b) Schematic of some of the consensus controls of rectal gland salt secretion, including volume expansion via the effects of CNP and negative feedback via endogenous production of adenosine. Other proposed control mechanisms are described in the text. Dashed lines with arrowheads indicate activation; long-dashed lines with diamond heads indicate inhibition. by the net electrical gradient established by the buildup of Cl$^-$ in the lumen. Thus, neither Cl$^-$ nor Na$^+$ secretion into the tubule lumen is achieved directly by primary active transport processes.

Water follows the secreted ions into the tubule lumen down an osmotic gradient, either across the secretory cells or through the tight junctions between cells. The secreted rectal gland fluid drains into the central lumen and subsequently exits via a lone duct into the posterior intestine. Although it was proposed by Burger in the 1960s that the inner stratified epithelium of the central lumen further modifies the secreted fluid, definitive studies of this function have not been conducted.

Energetic Requirements for Salt Transport

The high density and activity of Na$^+$/K$^+$-ATPase in the basolateral membrane of secretory cells means that these cells have high energetic (i.e., ATP) requirements. Dense aggregations of mitochondria, the aerobic power plants of cells, reside in close proximity to the basolateral membrane and supply ATP for active ion transport. Consequently, the rectal gland has an extremely high aerobic metabolic rate, and it extracts ~95% of the blood oxygen that enters its circulation in both the basal and stimulated states. The enzyme carbonic anhydrase, probably located in the extracellular space, converts the aerobic end product CO$_2$ to carbonic acid. This reaction prevents buildup of CO$_2$ in metabolically active secretory cells and thus facilitates their continued activity.

What are the metabolic fuels that support the secretory activity of the rectal gland? In many elasmobranch tissues, ketone bodies appear to be the dominant aerobic metabolic fuels. Somewhat surprisingly, recent work demonstrated that glucose is necessary to support rectal gland salt transport in the spiny dogfish and that ketones only supplement glucose-fueled secretion. Notably, these and other studies are yet to study the role of fatty-acid fuels in rectal gland function.

Several observations suggest that vascular oxygen supply and/or aerobic ATP production cannot always support secretion in the gland. First, biochemical measures indicate a high glycolytic (anaerobic) capacity in the rectal gland, suggesting that gland activity may be intermittently driven by less efficient anaerobic pathways. Consistent with this theory, volume loading enhances activity of the anaerobic pathway enzyme lactate dehydrogenase in the gland. Intermittent reliance on glycolytic pathways may help to explain the absolute requirement in the rectal gland for glucose as a metabolic fuel. Second, another enzyme, creatine kinase, is spatially tightly coupled to Na$^+$/K$^+$-ATPase. Creatine kinase transfers phosphate groups between the phosphagen creatine and adenosine diphosphate (ADP), allowing for rapid restoration of localized ATP levels for cellular work and also possibly buffering secretory cells against variations in metabolic fuel or oxygen availability. Third, several authors have noted that low perfusion rates *in vivo* may limit the delivery of oxygen and/or the export of CO_2 from active secretory cells, and this, in turn, would necessitate a switch to anaerobic metabolism. Thus, anaerobic support of rectal gland secretion may be more important in the intact animal than previously thought, although this remains to be experimentally demonstrated.

Other Rectal Gland Functions

Given the urea-based osmoregulatory strategy of the elasmobranchs, it is striking that rectal gland fluid contains very little urea (~20 mM in the rectal gland fluid vs. ~400 mM in vascular fluid, **Table 1**). Recent work showed that the basolateral and, especially, the apical membrane of rectal gland secretory cells both exhibit low permeabilities to urea. Consistent with this idea, a shark-specific facilitated urea transporter has been putatively identified in the rectal gland, although its location within the cell and its function remain to be demonstrated.

Another set of experiments revealed xenobiotic transport function in the rectal gland via multidrug-resistance proteins, but the physiological significance of this function is unclear.

Controls of Rectal Gland Function

Temporal variation in the rate of rectal gland secretion has been recognized for a long time. Baseline secretion rates are low or negligible; in fact, some *in vitro* preparations require pharmacologic or hormonal stimulation just to establish a baseline rate for comparison with the experimental conditions. Numerous studies, many of them conducted on *Squalus acanthias*, have demonstrated a large and interacting suite of factors that stimulate or inhibit rectal gland secretion. Early studies of rectal gland secretion demonstrated that it was activated by injecting into the animal, solutions of salt and sugar, or just water alone. A series of experiments by Solomon and colleagues suggested that intravascular volume expansion is the dominant stimulus, at least in *Squalus acanthias*. Recent studies on the gland *in vivo* offer further insight, suggesting that gland activation is a graded and temporally dynamic process, with salt transport (and activation of associated enzymes and transporters) peaking ~6–20 h after a meal/infusion. Importantly, the act of feeding and its associated physiological consequences (including, but not limited to, the alkaline tide and intravascular volume loading) elicit biochemical and morphological changes in the gland that cannot be reproduced entirely by modification of intravascular volume, pH, or salt alone. Thus, the *in vivo* control of rectal gland physiology appears extraordinarily complex (see the section 'Further reading' for details)

Endocrine, Paracrine, and Autocrine Regulation of Secretion

The search for the humoral (i.e., hormonal) factor(s) that stimulate rectal gland secretion resulted from the early discovery that adenosine 3,5-cyclic monophosphate (cAMP) (or activation of adenylyl cyclase, the enzyme that produces cAMP) is a potent stimulus for secretion; cAMP is an important second messenger in receptor-mediated hormone signaling cascades. The first hormone shown to stimulate rectal gland secretion was VIP, although blood levels of this peptide did not change coincident with gland activation. The recent consensus model posits that blood-volume expansion (e.g., after feeding) causes release of the hormone C-type natriuretic peptide (CNP) from the elasmobranch heart. At the rectal gland, CNP exerts its effects directly on secretory cells through a protein kinase C (PKC)-dependent pathway and indirectly through stimulation of VIP release from nerve terminals within the gland. Thus, VIP functions as a neurotransmitter in this scenario, at least in *S. acanthias*, and it activates adenylyl cyclase and PKC, complementing and magnifying the direct effect of CNP on secretory cells. CNP also contributes to vasodilation in the gland and thus regulates its perfusion. Overall, it appears that this CNP pathway functions in a negative feedback loop to fine-tune intravascular volume by enhancing rectal gland secretion. The related hormones atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) may also play a more limited role.

Other hormones may also contribute to the control of rectal gland secretion. Of particular relevance in the context of feeding is a gut hormone known as rectin (also known as scyliorhinin II). Rectin has a stimulatory effect on the secretion rate, possibly representing a communication link between digestive activity and the rectal gland. The parenchyma also hosts binding sites for the unique elasmobranch hormone 1α-hydroxycorticosterone, but its physiological significance remains unexplored in this context.

Further complicating the picture, the rectal gland is also subject to autocrine regulation. Specifically, adenosine, a product of ATP hydrolysis, accumulates in stimulated rectal gland cells. After moving across the basolateral membrane, adenosine at nanomolar concentrations inhibits rectal gland activity by binding to an inhibitory adenosine A_1 receptor.

Nervous Control of Secretion

Studies of the hormonal control of rectal gland secretion have dominated much of the literature. However, given the extensive innervation of the rectal gland and the known role for nerve-derived VIP in gland activation in *S. acanthias*, it is not surprising that other neurotransmitters also affect secretion rate. In particular, neuropeptide Y (downstream of cAMP formation) and somatostatin (upstream of cAMP formation) both inhibit rectal gland secretion. Somatostatin has been localized to nerve terminals that also contain VIP. Thus, regulation of these and other nervous signals appears quite complex, and their *in vivo* physiological significance remains elusive, at least in part due to the heavy reliance on *in vitro* experimental rectal gland preparations that have severed the nerve connections.

Extracellular pH and Ionic Strength Affect Secretion

In addition to the hormonal and the nervous controls of rectal gland secretion, changes in the hydrogen ion concentration (i.e., pH) and ionic strength of the vascular and extracellular fluids directly influence rectal gland activity. The act of digestion involves the secretion of acid into the gut lumen, culminating in an increase in pH (i.e., an alkalosis) of the vascular fluids. This alkaline tide has been the subject of much recent attention with reference to its impact on the rectal gland, again largely in *S. acanthias*. These studies demonstrate that extracellular pH, rather than either the partial pressure of CO_2 or the concentration of bicarbonate base, is the dominant signal of the alkaline tide involved in rectal gland activation. Accordingly, alkalosis stimulates Na^+/K^+-ATPase activity more than volume expansion alone. The recent characterization of the basolateral K^+ conductance in *S. acanthias* as a two-pore-domain K^+ channel (TASK-1) that is sensitive to pH offers one possible mechanism for the effect of pH on rectal gland activity, but other pathways are likely to be involved.

The presence of a calcium-sensing receptor (CaSR, a G-protein-coupled receptor) in rectal gland artery and tubules supports a direct link between the ionic strength of the vascular fluids and rectal gland secretion. The CaSR's activity decreases in response to increased ionic strength. A recent model proposes that the CaSR constitutively inhibits cAMP formation under basal conditions, while increased ionic strength (e.g., following a meal) releases cAMP formation from the inhibitory effects of CaSR and leads to the activation of ion transport. CaSR also influences cAMP formation in the rectal gland artery, suggesting a complementary role in control of rectal gland perfusion.

Molecular Mechanisms of Secretion Control

Downstream of hormonal or other modes of stimulation or inhibition, salt-transport processes in the rectal gland are modulated at the molecular level. Many of the enzymes and transporters involved in salt secretion are subject to post-translational modifications, including (de)phosphorylation, that either activate or inhibit their activity. For example, upon stimulation by factors that increase intracellular cAMP, protein kinase A phosphorylates the R domain of CFTR, leading to opening of this apical Cl^- channel. Activation of basolateral NKCC by phosphorylation lags behind CFTR; this event coincides with decreases in intracellular Cl^- as it leaves through the apical CFTR, but it appears to be triggered by transient cell shrinkage. Other modes of regulation have been postulated, including the possible existence of discrete pools of Na^+/K^+-ATPase with different sensitivities to cAMP-dependent stimulation.

Given the dramatic difference in salt-transport rate between basal and activated states in the gland, it is not surprising that recent biochemical and proteomics studies also demonstrate regulation of the activities and abundances of energy-producing enzymes following feeding (increase) or dilution of the surrounding seawater medium (decrease). However, the underlying molecular-signaling mechanisms are yet to be determined.

Morphological Contributions to Rectal Gland Activation

The rectal gland's morphology was recently shown to be highly plastic at both the gland and cellular levels, particularly in response to feeding. Shortly following a meal, the diameters of rectal gland tubules increase, while the smooth muscle ring surrounding the gland becomes compressed. The morphology of individual secretory cells also shifts after a meal, including expansion of the apical surface area via disaggregation of the apical microvilli (**Figure 3**). Actin filaments and actin-bundling proteins, such as transgelin, probably play a significant role in rectal gland activation, although the specific mechanism and the stimulus for cytoskeletal reorganization following feeding both are yet to be defined. In accord with this actin hypothesis, rectal gland activation by CNP (but not VIP) can be reversed by inhibitors of actin cytoskeleton organization, and the actin cytoskeleton reorganizes following K^+ manipulation or hypotonic exposure of rectal gland secretory cells. Whether these cytoskeletal events somehow regulate the localization and/or activity of the molecular constituents of the salt-transport apparatus remains to be seen. For example, cytoskeletal elements may play a role in sensing cell shrinkage and activating NKCC.

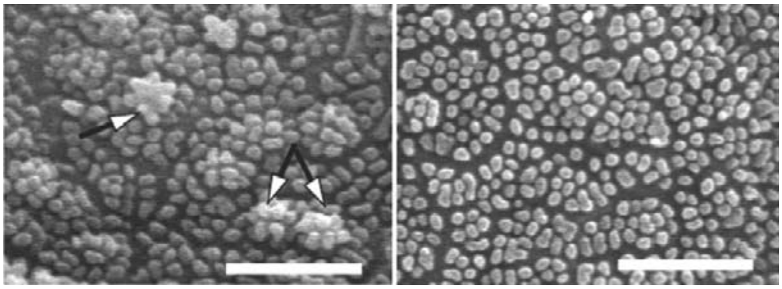

Figure 3 Scanning electron micrograph of the apical (luminal) surface of rectal gland tubular secretory cells of the spiny dogfish (*Squalus acanthias*) before (left) and 6 h after (right) a meal. Note the fusion of apical microvilli into flower-like structures in the fasted gland. These structures disaggregate at 6 h after feeding, when the microvilli are regularly spaced. Scale bars = 2 μm. Conclusion

Few animal tissues have received as much attention in the physiological and biomedical literature as the elasmobranch rectal gland. Despite decades of research and numerous advances at the molecular, cellular, and tissue levels, a comprehensive picture of the *in vivo* controls of rectal gland function is yet to be elucidated. In particular, it remains extremely challenging to assess the spatial and temporal integration of the numerous signals (endocrine, paracrine, autocrine, neural, etc.) that are known to influence gland secretion. Significantly, there are exceedingly few studies of how the controls of rectal gland function vary among species (e.g., in euryhaline vs. stenohaline species), in different environmental conditions (e.g., in low vs. high salinity), or across life-history stages. Therefore, a number of opportunities exist for researchers to analyze this intriguing and complex gland from new perspectives.

Glossary

Ammoniotelic An animal that predominantly excretes ammonia.

Deamination The release of amino groups ($-NH_2$) from amino acids.

Diffusion limited Transfer limited by diffusion processes at an exchange site.

Lipophilic Having an affinity for lipids.

Na^+/K^+-ATPase This is a major ATP-consuming ion pump that, directly or indirectly, drives many ion-regulatory processes, including maintaining sodium and ion gradients across cell plasma membranes and being present at high levels in ionocytes.

NE-2 A plasma protein that is an electrically neutral Na^+/H^+ antiporter.

NMDA receptor *N*-methyl-D-aspartate receptor in the vertebrate brain.

Ornithine–urea cycle Cyclic succession of reactions that produce urea from ammonia in livers of ureotelic animals.

Perfusion limited Transfer limited by rate of perfusion of an exchange site.

Rhesus (Rh) glycoprotein Membrane protein that facilitates ammonia transfer.

Transamination The transfer of amino groups ($-NH_2$) between amino acids.

Ureotelic An animal that predominantly excretes urea.

Uricolysis The breakdown of uric acid producing urea.

V-type proton ATPase Vacuolar-type ATPase that hydrolyzes ATP to generate a H^+ gradient.

Introduction

When amino acids are catabolized, the amino group ($-NH_2$) is released (deamination) or transferred (transammination) to another molecule for removal or reuse. If amino groups are not salvaged for resynthesis of amino acids, they must be dissolved in water and excreted to avoid a toxic rise in the plasma concentration of nitrogenous wastes. Elevated levels of these wastes can cause convulsions, coma, and eventually death. Excess nitrogenous wastes are excreted by teleost fish as ammonia, whereas elasmobranchs and a few teleosts also produce and excrete urea. Lesser quantities of nitrogen are excreted in the form of other compounds, such as creatinine, creatine, or trimethylamine oxide, and, in very small quantities, amino acids, purines, and

pyrimidines. Rates of ammonia excretion vary with diet and the condition of the fish, and are between 5% and 30% of that for CO_2. In fact, about 40–60% of the nitrogen intake from fish food is excreted as ammonia within 24 h. In fasting fish, muscle proteins are broken down for energy, producing ammonia waste. In addition, ammonia can be produced through the deamination of adenosine monophosphate (AMP) in skeletal muscle during violent exercise. Some fish have been shown to reduce the rate of ammonia production from amino acid catabolism in response to an ammonium load to slow down the buildup of ammonia internally (**Figure 1**).

Ammonia Gas, Ammonium Ions, and pH

Ammonia gas (NH_3) in solution combines with a proton to form ammonium ions (NH_4^+), the pK of the reaction varying between 9 and 9.5. When pH is equal to pK, then the ratio of NH_3 to NH_4^+ is one to one, but at the more physiological pH of 7.5 the ratio is around 1:100, that is, most of the ammonia in fish is in the form of NH_4^+. As pH falls, such as following intense exercises and during severe hypoxia, the proportion of NH_3 will decrease further such that the NH_3 to NH_4^+ ratio will approach 1:1000, that is, most ammonia is present in the fish body is as NH_4^+, with only a small proportion as NH_3.

The pH of living tissues, including those of fish, is such that it is midway between the pK of the ammonia/ammonium reaction and the apparent pK of the CO_2/bicarbonate reaction. As a result, there are adequate levels of both CO_2 and NH_3 for removal by diffusion of the gaseous form of these metabolic products. Ammonia moves between compartments largely as NH_3. If ammonium chloride (NH_4Cl) levels in the extracellular fluid increase, NH_3 enters the cell and the ratio of NH_3 to NH_4^+ within the cell increases. NH_3 combines with hydrogen ions to form NH_4^+ within the cell, thus raising intracellular pH. During NH_4Cl exposure, intracellular pH quickly reaches a maximum and then starts to fall because of the action of somewhat slower acid–base regulating mechanisms in the membrane. A subsequent return of the external NH_4Cl level to the original value results in a sharp fall in intracellular pH as NH_3 diffuses out of the cell leaving behind a proton. Cell pH falls below the initial level and slowly returns to the original value as NH_4^+ ions and protons slowly move out of the cell. Protons and NH_4^+ can be transported across plasma membranes by a variety of passive and active mechanisms that vary from cell to cell and are discussed later.

Ammonia Excretion and pH

Acid waters enhance ammonia excretion, whereas fish have difficulty excreting ammonia in alkaline waters. NH_3 diffusing into an acid environment will combine with a proton and be trapped as NH_4^+, unable to diffuse back into the cell or animal (**Figure 2**). The excretion of protons or acidification due to either CO_2 excretion or bicarbonate uptake will enhance ammonia movement due to NH_4^+ trapping, maintaining the gradient for NH_3 across the gill epithelium. Thus, diffusion of ammonia gas across the gills is enhanced by simultaneous CO_2 and proton excretion. The proton excretion is due to V-type H^+-ATPase activity (ATP, adenosine triphosphate) in the apical membrane, which increases membrane potential; this enhances sodium influx through sodium channels in the gill membrane. There is also sodium/proton exchange across the gills, and the exchange protein (NHE-2) has been located in the gills of several freshwater fish and shown to be involved in sodium uptake. The overall result is that there is often a correlation between sodium uptake and ammonia excretion across the gills.

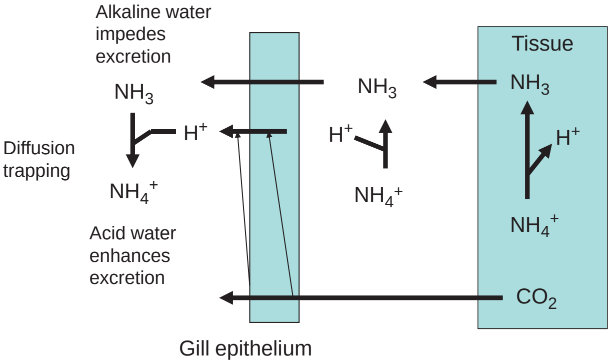

Figure 2 NH_3 excretion acidifies the tissues and is enhanced by diffusion trapping due to the conversion of NH_3 to NH_4^+ in the gill water boundary layer. Proton flux across the apical gill membrane and carbon dioxide excretion enhances this process.

Fish can be trapped in puddles of water for many hours or days; continual excretion of endogenous ammonia into a small volume of external media can lead to high external ammonia concentrations. The associated excretion of CO_2 will reduce water pH. This lowering of environmental pH has advantages for dealing with elevations in environmental ammonia levels by reducing the concentration of NH_3 in the water and, therefore, ammonia levels in the fish constituting environmental ammonia detoxification. Mudskippers build and lay eggs in water-filled burrows in the tidal mud flats. It has been reported that the giant mudskipper (*Periophthalmodon schlosseri*) can decrease the pH of the burrow water by acid, in addition to CO_2 excretion, presumably to protect their embryos against ammonia toxicity. Because ammonia excretion is usually as NH_3, alkaline waters are much more toxic to fish than acid waters as there is no acid trapping of excreted NH_3. Fish accumulate ammonia in waters higher than pH 9 and few fish can survive in such waters. The Lake Magadi tilapia is unusual in that it converts ammonia to urea via the ornithine–urea cycle (OUC) and can survive in these extremely alkaline waters.

Ammonia Transfer across Cell Membranes

Biological membranes are usually much more permeable to NH_3 than NH_4^+. Although NH_3 has a high solubility in water, it is only weakly soluble in lipids. In this respect, NH_3 contrasts strongly with lipophilic molecules such as CO_2; the permeability to NH_3 of nearly all cell membranes is much less than their permeability to other respiratory gases such as CO_2 and O_2. Unlike freshwater fish, seawater fish have shallow tight junctions between mitochondria-rich cells, which increase cation permeability. A significant portion of total ammonia can be excreted by NH_4^+ diffusion through this paracellular route in seawater fish.

Ammonia diffusion across many membranes is enhanced by the presence of Rhesus (Rh) glycoproteins. It has been shown in zebrafish that the transfer of ammonia is correlated to the expression of Rh genes. There are several types of Rh proteins found in a variety of tissues on both baso-lateral and apical regions of cells. These channels have been found in fish gills and a number of other tissues. The overall process is the diffusion of NH_3 through an Rh protein channel in the membrane. The isoforms Rhcg1 and Rhcg2 have been reported to be present and play a role in the transfer of ammonia across the fish gills.

A small amount of NH_4^+ can permeate biomembranes through K^+ channels. Most of the values for P_{NH4}/P_K through K^+ channels in a wide range of animals, including vertebrates and invertebrates, range between 0.1 and 0.3, that is, K^+ channels are more permeable to K^+ than NH_4^+. The hearts of some fish have K^+ channels with a very low NH_4^+ permeability, important in preventing heart attacks following feeding as discussed later. In addition, NH_4^+ can also be actively transported through membranes by substituting for potassium on Na/K-ATPase on the baso-lateral membrane of the gills. The mudskipper (*P. schlosseri*) uses this mechanism to actively excrete ammonium ions, which contributes to its ability to survive concentrations of ambient ammonia that would be toxic to other fishes.

Active excretion of NH_4^+ would be costly if associated with high membrane NH_3 permeability and would result in ammonia recycling and the transfer of protons across the membrane. If the membrane is permeable to NH_4^+ then its distribution will be determined by membrane potential, whereas the NH_3 level in each compartment will be determined by pH. Under certain conditions, an efflux of NH_4^+ will be associated with an influx of NH_3 which will short-circuit membrane potential and the pH gradient and require energy to maintain cell pH and the membrane potential. The mudskipper (*P. schlosseri*) reduces NH_3 membrane permeability by modifying the phospholipid and cholesterol compositions of membranes to reduce such recycling.

Ammonia and Gill Ventilation

Under most conditions, ammonia excretion is probably diffusion rather than perfusion limited. Ammonia transfer across the gill epithelium of rainbow trout has been shown to be linearly related to the NH_3 partial pressure gradient and there are a number of mechanisms to augment ammonia transport across membranes in the face of a relatively low NH_3 membrane permeability.

Ventilation is regulated to meet the requirements for oxygen transfer and will normally be more than sufficient to meet the requirements for the much lower flux of ammonia. Nevertheless, elevated ammonia levels are associated with increases in gill ventilation that are independent of changes in water pH. These increases in gill ventilation, however, have negligible effect on ammonia excretion and probably represent a nonphysiological response on the part of the fish in regard to ammonia excretion. There are large increases in blood ammonia levels following a meal which last several hours. An interesting possibility is that the postprandial increase in ventilation to deliver the increased oxygen uptake required for food intake and digestion is mediated by ammonia-induced increases in ventilation.

Neuroepithelial cells in the fish gill are similar in structure to mammalian oxygen chemoreceptors and are probably involved in the increases in ventilation associated with hypoxia in fish. If the K^+ channels in fish gill neuroepithelial cells are permeable to NH_4^+, then these cells would be depolarized by elevated NH_4^+ levels and the response would be an increase in gill ventilation. Thus, the increase in gill ventilation associated with elevated ammonia may be due to activation of the chemoreceptors in the gills of fish but this probably has little effect on ammonia excretion but does facilitate increased oxygen uptake in the postprandial fish.

Ammonia Volatilization

Many blennies (*Blennius pholis; Alticus kirki*), mangrove killifish (*Rivulus marmoratus*), and the oriental weatherloach (*Misgurnus anguillicaudatus*) are capable of volatilizing significant amounts of ammonia during aerial exposure. High temperatures and humidity, as well as high body ammonia levels, increase the likelihood of the ammonia being volatilized from the film of water covering the body of tropical fishes. These fish are able to tolerate very high tissue ammonia levels, which is an essential prerequisite for high rates of volatilization to occur. In *M. anguillicaudatus*, there appears to be at least two sites of NH_3 volatilization, that is, the skin and the digestive tract, under terrestrial conditions. During emersion, the surface of the skin and the mucosal surface of the anterior portion of the digestive tract become significantly more alkaline. Since the fraction of NH_3 present is strongly influenced by the pH of the medium, the skin and digestive tract of *M. anguillicaudatus* could be a site of NH_3 volatilization. Although both the skin and the digestive tract may be involved in NH_3 volatilization when the fish is moving on land, excretion of ammonia through the skin would be inhibited when the fish burrows into the mud. When the fish is surrounded by mud, the digestive tract (either through the mouth or through the cloaca) becomes the only avenue for NH_3 volatilization.

Ammonia Toxicity

Release and breakdown of sewage from humans and other animals into water and the subsequent increase of ammonia levels is a particular problem. Elevated levels of ammonia in the environment can reduce excretion or lead to ammonia uptake by the animal. Although low levels of ammonia in the environment can be beneficial and have been shown to promote growth in fish, elevated ammonia levels in the environment can decrease exercise performance, growth, and feeding, and inflict gill damage. Acute ammonia toxicity results in excessive activation of brain *N*-methyl-D-aspartate (NMDA) receptors, leading to convulsions and death in all vertebrates.

While ammonia can be converted to less toxic urea, urea synthesis consumes ATP (see below) and energy can be saved if enough water is available to support the excretion of nitrogenous waste as dilute ammonia. When ammonia cannot be excreted effectively, fish may reduce ammonia production. In addition, some fish species prevent the buildup of internal ammonia by converting ammonia to less toxic forms, namely glutamine and urea. A number of fish species convert ammonia to glutamine for storage until the ammonia levels in the body have returned to normal, for example, following feeding (see below). Glutamine is much less toxic than ammonia but is not normally excreted in significant quantities. The brains of many fish are protected, to a certain extent, by detoxifying ammonia to glutamine. Increased levels of cellular glutamine, however, can increase cell osmolarity, and the subsequent water influx could cause cell swelling. This swelling can create severe problems in the mammalian brain which is tightly constrained in the skull but seems to be less of a problem in fish with brains in a cavity larger than the brain itself. An increase in Gulf toadfish brain glutamine levels is not associated with any change in brain water content indicating that glutamine formation was not causing cerebral swelling in toadfish. In addition, the brain is more loosely held in the brain case of many fish, and inhibition of glutamine synthetase (GS) is not protective in fish. Thus, unlike mammals, glutamine synthesis and accumulation in the brain does not appear to be a major cause of death following ammonia intoxication in fish. In fact, ammonia tolerance in fish may be related to the capacity for producing glutamine to detoxify ammonia in the brain.

Glutamine is produced from glutamate and NH_4^+, the reaction catalyzed by GS. Glutamate may, in turn, be produced from either α-ketoglutarate (α-KG) and NH_4^+ catalyzed by glutamate dehydrogenase (GDH) in the mitochondrial matrix, or α-KG and other amino acids catalyzed by various transaminases (**Figure 3**). Whether the synthesis of glutamine begins with glutamate or α-KG is determined by the distribution of GS within the cell,

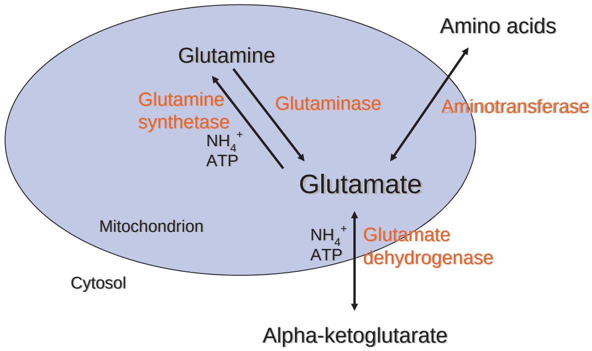

Figure 3 The conversion of alpha-ketogluterate to glutamine removes two NH_4^+ ions.

and multiple GS genes have been reported for the rainbow trout and the Gulf toadfish.

The blood–brain barrier of fish is apparently permeable to NH_3, because the brain ammonia content of some fish species can build up to very high levels. The mechanisms involved in ammonia tolerance in the brain cells of these ammonia-tolerant fish are presently uncertain. The brain is often the organ undergoing the largest increase in glutamine content following elevations of blood ammonia levels and it appears that fish brains detoxify the permeated ammonia to glutamine. Although glutamine accumulation and the consequent astrocyte swelling is known to be one of the reasons behind hepatic encephalopathy in mammals, it does not seem to be a problem in fish. The GS inhibitor methionine sulfoximine (MSOX), at a dosage protective for mammals, does not protect mudskippers or the oriental weather loach against acute ammonia toxicity. It has been demonstrated that the increase in brain glutamine was not associated with any changes in brain water in the Gulf toadfish, *Opsanus beta*, indicating that glutamine formation was not causing cerebral swelling in toadfish. This suggests that detoxification of ammonia to glutamine may be important to ammonia tolerance but, unlike mammals, glutamine synthesis and accumulation in the brain does not appear to be a major cause of death following ammonia intoxication in fish. Some tropical air-breathing fishes can detoxify endogenous ammonia to glutamine in noncerebral tissues as well as the brain. Sleepers (the marble goby, *Oxyeleostris marmoratus*, and four-eyed sleeper, *Bostrichthys sinensis*) and the swamp eel, *Monopterus albus*, are exceptional because they can detoxify ammonia to glutamine in their livers and muscles during aerial exposure and ammonia loading. The Gulf toadfish *O. beta* detoxifies endogenous ammonia to glutamine to suppress ammonia excretion during confinement stress.

Excessive activation of NMDA receptors is a key event in the mechanism of ammonia toxicity in mammals. It was thought that high extracellular glutamate levels caused excessive NMDA receptor activation, but it was observed that activation of NMDA receptor precedes elevation of extracellular glutamate upon ammonia intoxication. Depolarization of postsynaptic neurons will increase the possibility of glutamate activation of NMDA receptors, even in the absence of high levels of glutamate. It is possible that ammonia activates NMDA receptors by depolarization of neuron cell membranes through the background K^+ channels, resulting in excessive activation of NMDA receptors and eventual neuronal death. Ammonia is known to cause depolarization of cell membranes activating NMDA receptors. Injection of the NMDA receptor antagonist (5R, 10S)-(+)-methyl-10,11-dihydro-5H-dibenzo[a, d]cyclohepten-5, 10-imine hydrogen maleate (MK-801) at a dosage of $2\,\mu g\ g^{-1}$ fish prior to ammonium acetate injection significantly reduced mortality rate in the weatherloach, but had no protective effect on either *P. schlosseri* or *Baleophthalmus boddaerti*. Interestingly, fish that are hypoxia tolerant also seem to be ammonia tolerant. The exact nature of ammonia toxicity in fish is not known.

Ureogenesis

In ureogenic fishes, the OUC consists of the enzyme CPS III and four other enzymes (plus GS) located in the matrix of liver mitochondria, utilizing glutamine as a substrate. Thus, ureogenic fishes possess high levels of GS in liver mitochondria. Because ammonia is already detoxified to glutamine, which is proton neutral and will not disrupt oxidative phosphorylation, the formation of carbamoyl phosphate via CPS III from glutamine in the liver mitochondrial matrix cannot be regarded as an ammonia-detoxifying system. This is different from terrestrial vertebrates, whose OUC involves carbamoyl phosphate synthetase I which utilizes NH_3 directly as a substrate. In the case of ureogenic and ureotelic marine elasmobranchs, two GS isozymes exist separately in the brain and the liver, localized in the cytosol and the mitochondria, respectively. GS has also been detected from mitochondria of the elasmobranch kidney, which may function as part of a substrate cycle for ammonia excretion during acidosis.

Urea is accumulated as an osmolyte in elasmobranchs, holocephans, and coelacanths. Marine elasmobranchs are ureogenic and they possess a functional OUC in mitochondria of their livers and muscles. They are also ureotelic, that is, urea is the primary product (>50%) of nitrogen excretion. Elasmobranchs have high concentrations of urea in their bodies, which is prevented from leaking into the environment by the very low permeability to urea of their gill epithelia. This low permeability is due to the high cholesterol composition of the gill membrane, coupled to a urea/sodium antiporter in the basolateral membrane that transports urea back into the blood. The elasmobranch kidney also functions to conserve urea but this pathway is less significant because of low rates of urine flow in elasmobranchs.

For those fishes that are ureogenic but nonureosmotic, the OUC in the liver can apparently detoxify ammonia, which is produced at high rates mainly in the mitochondrial matrix through catabolism of excess amino acids from food. There are increases in rates of urea synthesis and excretion in the giant mudskipper *P. schlosseri* and the slender lungfish *Protopterus dolloi* within 24 h after feeding. Recent work on marine sharks and freshwater stingray confirms that ureogenic elasmobranchs also increase the rate of urea synthesis upon feeding, but urea can be retained for

Table 1 Ammonia toxicity in resting and swimming rainbow trout: USA Environmental Protection Agency (EPA) criteria protect resting but not swimming fish

the purpose of osmoregulation, instead of being excreted.

Only a few teleosts are ureotelic in water (e.g., the gulf toadfish) or able to detoxify a minor quantity of ammonia to urea during ammonia loading (*Mugilogobius abei*). The majority of tropical teleosts studied so far does not use ureogenesis as a major strategy to detoxify ammonia. Ureogenesis in fishes is energetically expensive. For teleosts and elasmobranchs, a total of 5 mol of ATP is hydrolyzed for each mole of urea synthesized, equivalent to 2.5 mol ATP used for each mole of nitrogen assimilated. It is probably because of this that ureogenesis is not commonly adopted as a single major strategy to handle ammonia toxicity when air-breathing tropical teleosts are exposed to terrestrial conditions or environmental ammonia.

To date, the only teleost for which unequivocal evidence is available for the OUC to function primarily for the purpose of ammonia detoxification is the tilapia *Alcolapia grahami* in highly alkaline lakes (pH 10) in Kenya. This fish has a high capacity to detoxify ammonia to urea via the OUC and is the first known example of complete ureotely in an entirely aquatic teleost fish. The majority of the urea synthesized in *A. grahami* is excreted through the gills. By contrast, African lungfishes synthesize and accumulate urea during emersion and estivation on land; they are ureogenic and possess a full complement of OUC enzymes.

Feeding and Exercise

Fish exhibit a postprandial elevation of blood ammonia levels lasting up to several hours. The increase in blood NH_4^+ levels could be expected to cause cardiac membrane depolarization and a heart attack, but the fish cardiac potassium channels have a very low permeability to NH_4^+ and the heart is protected. The postprandial ammonia levels in the blood, however, can be similar to those that kill fasting fish, presumably due to action on the brain. Why feeding fish are less sensitive to ammonia than fasting fish is not entirely clear. It appears that feeding fish increase GS activity in the brain, increasing brain glutamine production and protecting the brain against ammonia toxicity. Rhesus glycoprotein channels (Rhcg) are upregulated in the gills to augment ammonia excretion following feeding. Acid excretion is also enhanced by upregulation of sodium/proton and V-type H^+ATPase activity. The overall result is that fed fish can more readily excrete ammonia following feeding and have a greater capacity to produce glutamine. Similar responses have been documented following exposure to elevated environmental ammonia.

Exercising fish are very sensitive to environmental ammonia. Fish produce ammonia through the deamination of AMP in skeletal muscle during violent exercise but appear not to invoke protective mechanisms. As a result, swimming fish are much more sensitive to elevations in environmental ammonia than resting fish (**Table 1**).

In summary, ammonia is both a substrate and product of metabolism and, if allowed to accumulate in the body, is toxic. There are postprandial ammonia pulses that would kill a starving fish. Fish, however, have evolved mechanisms to deal with this situation some of which are useful in dealing with elevated levels of environmental ammonia. This is not the case for swimming salmonids who are very sensitive to increases in environmental ammonia.

Glossary

Ammoniotelic An animal that excretes predominantly ammonia.

Antiporter Membrane transporter where two molecules move in opposite directions across the membrane.

Aquaporins Membrane proteins that act as water channels (discovered by Peter Agre for which he won the Nobel prize in 2003).

Branchial Of the gills.

Chorion Proteinaceous coat or egg shell surrounding the embryo.

Convection Bulk movement of a medium, e.g, gas, water or blood.

Cutaneous Of the skin.

Estivation Dormancy in response to the danger of dehydration or high ambient temperatures.

Facilitated transporters Carrier-mediated membrane transporters that enhance the movement of molecules down the gradient.

Glomerulus Tuft of capillaries surrounded by the Bowman's capsule of the vertebrate kidney where blood is filtered to produce urine in the proximal tubule.

Nephron The morphological and functional unit of the vertebrate kidney involved in urine formation.

Osmoconformer An animal that matches its internal osmolarity to the external osmolarity.

Ureotelic An animal that excretes predominantly urea.

Uricolysis The breakdown of uric acid producing urea.

Introduction

In animals, waste products are formed when food is metabolized. Food in the form of protein is hydrolyzed releasing individual amino acids. Catabolism of excess amino acids results in the formation of the waste products, ammonia and carbon dioxide (CO_2). CO_2 can be eliminated by respiration, whereas ammonia must be excreted in solution or converted to other nitrogen products (e.g., urea and uric acid) prior to excretion.

Fish excrete two main nitrogenous end products (ammonia and/or urea) and some minor compounds (such as trimethylamine oxide (TMAO), creatine, creatinine, and amino acids). One major problem that all animals face is the fact that ammonia is a relatively toxic compound when concentrated in body tissues. Ammonia is a major neurotoxin that interferes with cellular and neurotransmitter metabolism, as well as nerve conduction. Therefore, nitrogen excretory strategies must be designed to avoid the toxic accumulation of ammonia. Most fish excrete the majority of their nitrogen wastes as ammonia (ammoniotelic). Ammonia is highly soluble in water, provided water is abundant, then eliminating ammonia is an energetically inexpensive mechanism (it requires $\sim$400 ml water to excrete 1 g of ammonia; but requires no adenosine triphosphate (ATP)). Some amphibious fish in water-restricted habitats, however, may repackage ammonia into urea, a relatively nontoxic end product. The trade-off is that synthesizing urea via the urea cycle is energetically expensive, requiring 5 ATPs per mole of urea produced. Consequently, other amphibious fish have opted for alternative strategies in water-restricted habitats. Some fish eliminate gaseous NH_3 across their skin or through the gut, whereas other species store ammonia in amino acids (e.g., glutamine (GLN)) or reduce ammonia production.

Although water availability is a key factor in the evolution of nitrogen excretion in animals, it is not the whole story. Some teleost fish living in highly alkaline water (pH) excrete no ammonia, only urea (ureotelic). Marine elasmobranch fishes (skates, sharks, and rays) synthesize and retain urea for osmoregulatory purposes. Finally, there is evidence that many teleost fish are ureotelic during early life stages, but switch to ammonotelism as adults. These examples are discussed in more detail in the following.

Synthesis of Urea

In fish there are three possible pathways for urea synthesis: the urea cycle (**Figure 1**), catabolism of dietary arginine by the enzyme arginase (ARG), and/or uricolysis. The urea cycle in fish starts with the fixation of ammonia and glutamate into GLN, catalyzed by the mitochondrial enzyme glutamine synthase (GS). Glutamine (GLN) and HCO_3 are combined to form carbamoyl phosphate, catalyzed by the enzyme carbamoyl phosphate synthetase type III (CPS III). Ornithine transcarbamylase (OTC) is the enzyme that catalyzes the conversion of carbamoyl phosphate to citrulline. In the cytosol, citrulline is converted into arginine in two steps, catalyzed by the enzymes argininosuccinate synthetase (ASS) and lyase (ASL). Finally, arginine is transported back into the mitochondria for final degradation to urea and ornithine, catalyzed by mitochondrial ARG.

When present, the location of urea synthesis is typically in the liver of fishes, where all the necessary enzymes are located. In fish that can complete the urea cycle in the liver, skeletal muscle may also be a secondary site of urea synthesis. Although a functional urea cycle is present also in adult amphibians and mammals, there are several differences in the intracellular location of the enzymes and substrate preferences of CPS.

Most fish have relatively high levels of ARG activity, even if they lack a functional urea cycle. The contribution of dietary arginine catabolism to overall urea excretion in fish is not well understood. In ammoniotelic fish, however, it is generally assumed that a significant portion of urea released is derived from uricolysis. The three enzymes involved in the degradation of uric acid (uricase, allantoinase, and allantoicase) are located in the peroxisomes of liver cells in fish (**Figure 2**). Therefore, in ammoniotelic fish lacking the urea cycle, some nitrogen wastes are excreted as urea and this urea is derived from arginolysis and/or uricolysis.

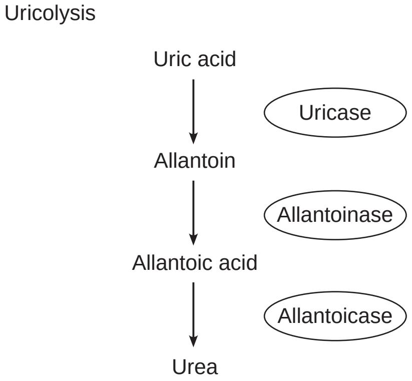

Figure 2 Uricolysis involves the breakdown of uric acid to urea in three steps, catalyzed by the enzymes uricase, allantoinase, and allantoicase.

Retention of Urea in Elasmobranchs and Coelacanths

Marine elasmobranch fishes are osmoconformers and retain urea as an osmolyte to balance internal osmolarity to

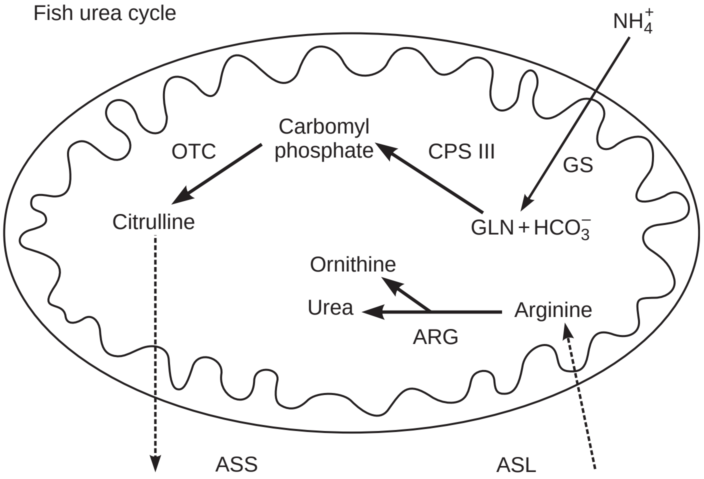

Figure 1 The fish urea cycle consists of five key enzymes (CPS III, carbamoyl phosphate synthetase; OTC, ornithine transcarbamylase; ASS, argininosuccinate synthase; ASL, argininosuccinate lyase; and ARG, arginase) and the accessory enzyme glutamine synthetase (GS) that combines glutamate and $NH4^+$ to produce glutamine (GLN). In fish, four of these six enzymes are positioned within the mitochondria of hepatic and/or skeletal muscle cells. Although elasmobranchs, coelacanths, and lungfish have a functional urea cycle, most teleost fish express the urea cycle during early life stages but not as adults.

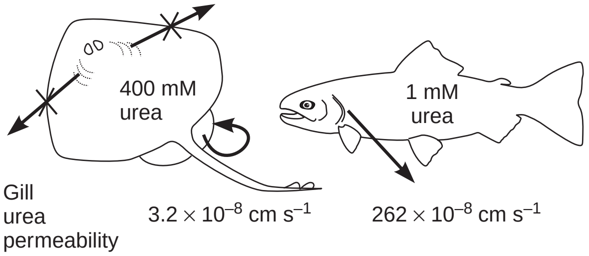

Figure 3 Elasmobranchs are osmoconformers and retain urea as an osmolyte. Elasmobranch gills are relatively impermeable to urea compared to a teleost, such as rainbow trout. Branchial urea permeability is ~80 times greater in a trout relative to an elasmobranch. Urea is reabsorbed by the elasmobranch kidney. These features of the elasmobranch gills and kidney prevent excessive loss of urea to the environment; however, some urea is excreted across the gills.

match the external osmolarity. Thus, urea concentrations are typically between 350 and 450 mM in elasmobranch plasma and tissues, whereas in other fishes urea is considerably lower, typically less than 1/100th of the concentration (**Figure 3**).

Urea at these relatively high concentrations impairs protein function. To combat this, stabilizing solutes (e.g., TMAO, betaine, and taurine) counteract the destabilizing effect of urea. Across many marine elasmobranch species the ratio of urea:stabilizing solutes is about 2:1. Even early embryos use this ureosmotic strategy. For example, urea concentrations are ~400 mM in marine skate embryos (*Raja erinacea*) when they hatch after ~9 months, and the ratio of urea:TMAO and other organic osmolytes is 2:1 as early as 4 months of age.

While elasmobranchs are ureotelic, urea is not a true waste product. Unlike other animals that want to rid themselves of urea, elasmobranchs have evolved mechanisms to prevent excessive urea loss. Why? Foremost, urea is energetically expensive to produce (see above) and excretion would represent a net loss of this energy investment. Second, they require high internal levels to maintain isosmotic balance. Therefore, sharks have evolved mechanisms to retain urea at potential sites for loss.

The two main sites of potential urea loss are the gills and kidney (**Figure 3**), and both have mechanisms to retain urea in the blood. In the kidney, plasma urea moves across the glomerulus into the filtrate, but urea is reabsorbed from the filtrate back into the plasma so that very little urea is lost in the urine. The elasmobranch nephron structure is very complex and the detailed mechanisms involved in renal urea reabsorption are not well understood. In euryhaline elasmobranchs, moving from seawater to dilute seawater initially increases the amount of urea lost in the urine and decreases the plasma osmolarity and urea concentration after a few days. Remarkably, freshwater elasmobranchs from the Amazon River (*Potamotrygon* sp.) lack the urea cycle enzymes, and plasma urea concentrations are as low as in ammonotelic teleosts.

Urea loss across the gills in elasmobranchs is much lower (~80 times lower) relative to teleost fish (**Figure 3**). Two factors help to explain this difference. First, there is an active urea transporter in the gills (see below) that returns urea back to the blood. In addition, the gill cell membranes have an exceptionally high cholesterol content inserted into the membrane phospholipids that impedes passive diffusion of small-molecular-weight solutes, such as urea. Therefore, although urea is lost to seawater at the gills down a diffusion gradient, much less urea is lost given the concentration gradient because of the transport protein and lipid composition of the gill cell membranes.

Compared with elasmobranchs, very little information exists for urea retention in coelacanths. The coelacanth *Latimeria* was first discovered in 1938 off the Comoro Islands, but very few live specimens have since been examined. Plasma and tissue urea levels appear to be similar to marine elasmobranchs (~350 mM) and they also retain TMAO. Presumably, their major nitrogen excretory product is urea and like elasmobranchs they likely have strategies to limit urea loss. This is just one of the many gaps in our knowledge of ureosmotic regulation in coelacanths.

Urea Excretion

In most fish, nitrogen excretion occurs primarily across the gills because of the high surface area for exchange between blood and water, and the relatively high permeability of the gill epithelium to small-molecular-weight solutes such as ammonia and urea. Branchial urea excretion depends on the blood-to-water urea concentration gradient, although water urea concentrations are usually negligible. On average, fully aquatic teleost fish excrete about ~15% of their nitrogen wastes as urea and ~85% as ammonia. A small percentage of urea is excreted in the urine or across the skin in water-breathing fish, but, in amphibious fish on land, more urea may be lost across the posterior end of the fish (i.e., skin and urine).

There are three fundamental ways in which urea may cross the epithelial cells that form the barrier between blood and water: through membrane protein transporters; by lipid-phase permeation; or between cells (paracellular pathway). Evidence suggests that in most cases urea is transported by membrane proteins, through either urea transporters (UTs) or, in some cases, water channels (aquaporins).

The first UT identified in fish was cloned from shark kidney and the gene sequence is similar to mammalian kidney-facilitated UTs. UTs are found in the gills of both marine and freshwater fishes. These UTs are facilitated bidirectional transporters that allow urea to diffuse down the concentration gradient (no ATP required), saturated at higher urea concentrations and inhibited by the drug phloretin. UTs are expressed during early fish development and have been shown in zebrafish larvae to be critical for maintaining urea excretion rates (see below).

Another class of UT proteins is found on the basolateral membrane of shark gill epithelium. These are secondary active urea transporters, where urea is transported against the gradient linked to the downhill movement of Na^+. In other words, some urea diffuses passively from the blood into the gill cell, but the urea/Na^+ antiporter moves urea back to the blood, recovering some of the lost urea. Low Na^+ concentrations are maintained by the Na^+K^+ATPase pump on the basolateral membrane (cost 0.5 ATP/Na^+). Therefore, to save one urea molecule that has cost 5 ATP to be synthesized, just 0.5 ATP are spent. The gene sequence for active UT has not been determined in fish (or mammals).

Environmental Impacts on Urea Excretion

Water availability has probably played an important role in the evolution of ureotelism in fishes. When lungfish (*Protopterus*, *Lepidosiren*) estivate, urea, not ammonia, accumulates in the tissues. Thus, urea synthesis via the urea cycle prevents ammonia accumulation over weeks or months out of water. Elevated urea levels occur only during estivation. When African lungfish (*Protopterus*) return to water after estivation, a large washout of urea occurs immediately during the first day, one that is correlated with the induction of UT messenger RNA (mRNA) levels. Once back in an aquatic habitat lungfish can easily excrete ammonia across the gills and again become ammoniotelic.

Most adult teleost fish do not have the capacity to synthesize urea at high rates. However, a few teleost species have a functional urea cycle that allows them to turn on urea production whenever water is limiting in the environment (e.g., *Heteropneustes fossilis*) or in response to elevated water ammonia levels (e.g., *Mugilogobius abei*). In other cases, fish are ureotelic because the chemical composition of the water prevents efficient ammonia elimination.

The tilapia (*Alcolapia grahami*) of Lake Magadi, Kenya top the list as the most ureotelic of teleosts. They thrive in waters of pH 10, 37 °C with high levels of carbonate salts. Ammonia is converted to urea via the urea cycle and they excrete 100% of their nitrogen wastes as urea, mostly across the gills. In other cases where teleost fishes inhabit somewhat less severe alkaline lakes, fish are primarily ammoniotelic but urea excretion is considerably elevated compared to fish in neutral pH waters. For example, the Lahontan cutthroat trout *Oncorhynchus clarki henshawi* found in Pyramid Lake, Nevada (pH 9.4, 10 °C) excrete ~34% of their nitrogen wastes as urea and the tarek *Chalcalburnus tarichi* of Lake Van, Turkey (pH 9.8, 18 °C) excrete 37% as urea. Thus, fish faced with a chronic high pH environment typically excrete more of their nitrogen wastes as urea. This is most simply explained by the fact that as blood pH increases, an increasing proportion of the total ammonia wastes in fishes exists as the more toxic form NH_3 rather than $NH_4{}^+$.

An interesting teleost that can switch between ammoniotelism and ureotelism and induce urea synthesis via a hepatic urea cycle is the marine gulf toadfish, *Opsanus beta*. Under laboratory conditions, toadfish rapidly switch from ammonia excretion to urea synthesis and excretion during stressful conditions, such as crowding, confinement, elevated environmental ammonia, or air exposure. Stressed toadfish eliminate urea across the gills in pulses over short time intervals (1–3 h) per day. So far, this pattern of pulsatile urea excretion has not been described for any other fish. Researchers were perplexed about the physiological value of excreting urea in pulses. Recent evidence suggests that this unusual pattern of urea excretion may have evolved as a predator-avoidance strategy. When toadfish excrete ammonia and urea together, the urea functions as a cloaking or masking molecule that prevents predators such as the gray snapper (*Lutjanus griseus*) from detecting the ammonia. Ammonia excreted alone may be a strong chemical attractant for some fish predators. These results in toadfish underline the importance of understanding the ecological connections of a particular fish in order to understand the possible adaptive value of ureotelism.

Early Life Stages

Nitrogen metabolism and excretion during early life stages in fish is not simply a replica of adult patterns on a smaller scale. There are three key differences. First, embryos feed endogenously, rapidly consuming yolk amino acids and proteins to provide fuel for growth and development. The potentially toxic ammonia molecule is continuously produced from amino acid catabolism. In adult fish, amino acids are generally spared from catabolic processes in favor of carbohydrates and fats.

Second, fish embryos and early larval stages rely on cutaneous excretion, whereas in most adult fish excretion is largely branchial. Cutaneous exchange is not supported by the convection of water over its surface, or by a dense capillary network to support blood convection. In addition, diffusion distances can be greater, slowing the rate of diffusion of nitrogeneous wastes at a time when they are being produced very fast.

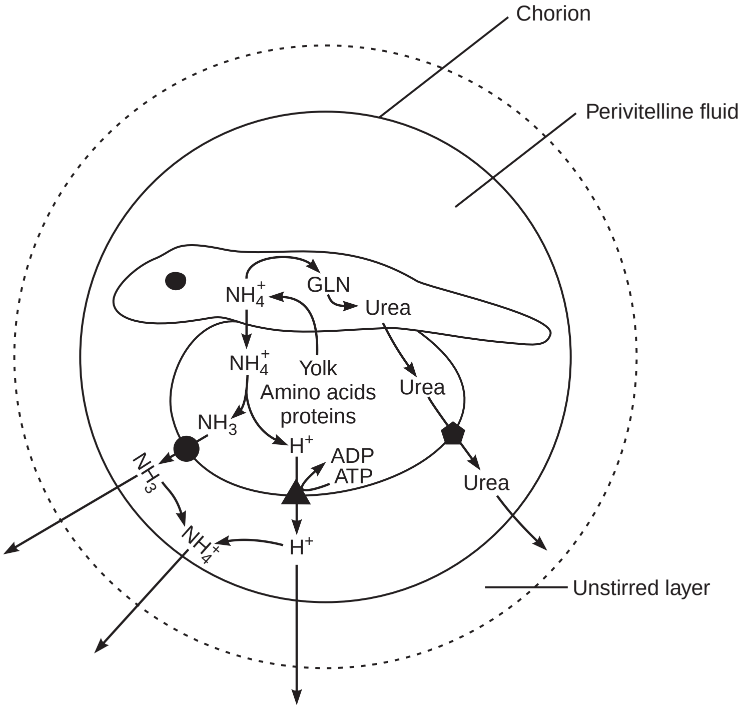

Figure 4 Ammonia is produced by the catabolism of yolk amino acids and proteins in fish embryos. Some ammonia is converted to glutamine (GLN) and urea via the urea cycle. Ammonia and urea are transported across the cutaneous surface by membrane proteins. The solid circle represents the Rhesus (Rh) glycoproteins that transport NH_3. The solid triangle represents the H^+ATPase pump that transports H^+s creating a slightly acidic environment that promotes NH_3 excretion. The solid pentagon represents facilitated urea transporters (UTs) that transport urea down the gradient from embryo to the perivitalline fluid. An unstirred or boundary water layer is present, adjacent to the chorion where molecules move only by diffusion.

Third, developing embryos are encapsulated within a shell or chorion, surrounded by the perivitelline fluid (**Figure 4**). This creates a stagnant layer of water both inside and outside the chorion, which further adds to the diffusion barrier. Nitrogen excretory products are present at a higher concentration in the perivitelline fluid and external unstirred layer compared to the surrounding environment. One might predict that ammonia elimination from the developing embryo would be more efficient in cases where embryos were exposed to high water flows that, in turn, reduce the thickness of the unstirred water layer. Fish embryos convert ammonia to GLN and/or urea via the urea cycle, which may be a strategy to prevent the accumulation of ammonia during critical stages of development.

Rainbow trout embryos provided with radiolabeled bicarbonate were shown to synthesize radiolabeled urea, experiments that provided the first evidence for a functional urea cycle in any teleost fish. Later experiments showed that embryos of several species of teleosts, both freshwater and marine, had the key urea cycle enzyme CPS III (**Figure 1**), as well as other required enzymes for the urea cycle. Overall, activities of the urea cycle enzymes are relatively high during early stages but may be low or absent in adult stages, except in the case of ureotelic species (see above).

The pattern of nitrogen excretion in embryos varies among species. Some embryos are ureotelic, for example, zebrafish *Danio rerio* and Atlantic cod *Gadus morhua* but as adults are ammoniotelic. Rainbow trout *O. mykiss*, on the other hand, are ammoniotelic during all life stages. These differences in relative urea excretion rates may be due to differences between rearing environments or the timing of development stages. In the viviparous blenny *Zoarces viviparous*, for example, synthesis and excretion of urea by embryos may be advantageous in protecting the mother and other embryos from exposure to toxic levels of ammonia.

Urea excretion in early stages depends on the facilitated UT protein, at least in freshwater rainbow trout and zebrafish. Ammonia transporters that belong to the Rhesus (Rh) glycoprotein family facilitate NH_3 diffusion from the embryo. Acid transport of H^+ ions via H^+ATPase ensures an external water environment close to the skin that is sufficiently acidic to maintain the embryo-to-environment NH_3 gradient by rapidly removing excreted NH_3 by converting NH_3 to $NH_4{}^+$ according to the pK for this reaction (**see also Nitrogenous-Waste Balance**: Excretion of Ammonia). Most of the urea and ammonia excreted probably exits in the yolk sac membrane where blood vessels lie just under the surface. In addition, the chorion has small pores that allow for the diffusion of small-molecular-weight wastes (urea, ammonia) into the environment. After hatching when the chorion is shed, early larvae still depend on cutaneous nitrogen excretion. However, whole body and pectoral fin movements probably enhance nitrogen excretion by disturbing the unstirred layers and increasing the convection of water over the surface.

In summary, urea is produced by all fish, but only those that excrete at least 50% of their nitrogenous wastes as urea are considered ureotelic. Elasmobranchs, coelacanths, and lungfish use the urea cycle to synthesize urea. Most adult teleost fishes lack a functional urea cycle, yet the pathway is complete in teleost embryos. Under some extreme environmental conditions, urea synthesis may occur in a few rare teleost fishes to prevent the toxic accumulation of ammonia. Urea is transported across cell membranes by UTs, either facilitated or secondary active transporters.

Glossary

Adrenocorticotropic hormone (ACTH) A protein hormone primarily produced by the corticotropic cells of the anterior pituitary that causes release of cortisol from the interregnal.

Corticotropin-releasing factor (CRF) A neuropeptide secreted by the paraventricular nucleus of the hypothalamus. CRF stimulates the corticotropic cells of the anterior pituitary to secrete ACTH.

Glucocorticoid and mineralocorticoid receptors (GR and MR, respectively) Ligand-activated, nuclear hormone receptors (subfamily 3, group C) that bind steroids such as cortisol. Upon activation, the receptors bind to glucocorticoid response elements in the genome, upstream of target genes.

Melanocortin receptor 2 (MC2R) A G-protein-coupled receptor belonging to the melanocortin family of receptors. MC2R specifically binds ACTH and is highly expressed in the cellular membrane of the interrenal cells.

Stress The disruption of homeostasis with exposure to a biotic or abiotic factor.

Whole genome duplication The duplication of the entire genome. It is thought that a genome duplication event 350 MYA in an ancient fish led to the massive expansion and diversification of the teleost group, and is also responsible for the 2000–3000 duplicate genes that exist in teleosts today.

Introduction

Stress is the disruption of homeostasis from exposure to a biotic or abiotic stressor. In vertebrates, a highly conserved response to stress is an elevation of plasma corticosteroid levels, which serve to restore homeostasis. The exact nature of this response is variable and dependent on a number of factors, including the type, duration, and intensity of the stressor. However, circulating corticosteroid concentrations have long been considered a reliable indicator of the activation of the stress response.

Cortisol is the primary corticosteroid in teleosts and has been implicated in a wide array of biochemical, physiological, and behavioral functions, including the release of glucose from stored glycogen to provide energy for the stress recovery process (**see also Hormonal Responses to Stress**: Hormone Response to Stress). Beyond metabolism, cortisol action also modulates feeding and growth (**see also Hormonal Responses to Stress**: Stress Effect on Growth and Metabolism), immune responses, osmoregulation (**see also Hormonal Control of Metabolism and Ionic Regulation**: The Hormonal Control of

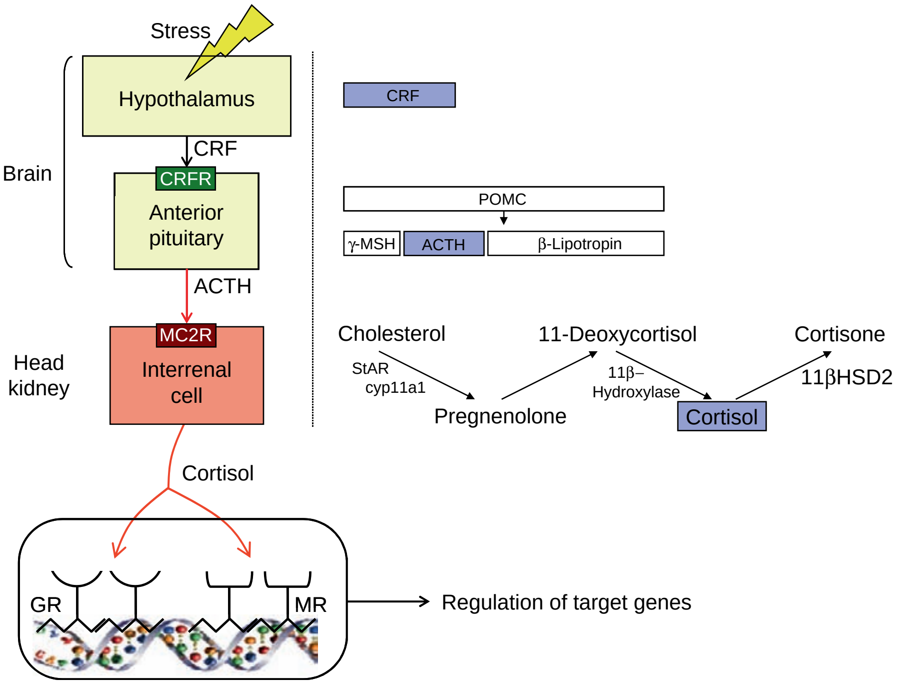

Figure 1 Overview of the hypothalamus–pituitary–interrenal (HPI)-axis anatomy and signaling pathways. Upon exposure to a stressor, the hypothalamus secrets corticotrophin-releasing factor (CRF), which stimulates the pituitary corticotropic cells to release adernocorticotropic hormone (ACTH) to the circulation. ACTH is one of many signaling molecules derived from the proopiomelanocortin (POMC) gene. Circulating ACTH binds specifically the melanocortin receptor type 2 (MC2R) expressed by the interrenal cells of the headkidney. MC2R induces cAMP signaling pathways that stimulate the cortisol synthesis from cholesterol and subsequent secretion to the bloodstream. In turn, circulating cortisol can enter a cell and bind to the glucocorticoid or mineralocorticoid receptors (GR and MR, respectively). These receptors bind to glucocorticoid response element upstream of target genes, thereby up- or downregulating their expression.

Osmoregulation in Teleost Fish) and reproduction (**see also Hormonal Responses to Stress**: Impact of Stress in Health and Reproduction). Cortisol signaling is not only critical in the recovery from stress, but also regulates many of these processes under unstressed conditions.

In teleosts, circulating cortisol levels are regulated by the functioning of the hypothalamus–pituitary–interrenal (HPI) axis (**Figure 1**), which is homologous to the mammalian hypothalamus–pituitary–adrenal (HPA) axis (**see also Hormonal Responses to Stress**: Hormone Response to Stress). While the pathways and functions of the stress axes are highly conserved among vertebrates, some differences do exist between fish and mammals. For instance, fish do not possess a discrete adrenal gland, but instead the steroidogenic cells (interrenal cells) are distributed throughout the head kidney region, primarily along the posterior cardinal veins and their branches. Also, the teleost genome underwent a whole genome duplication event 350 million years ago (MYA), resulting in two copies of a variety of stress axis genes (which have, in some cases, differentiated) compared to other jawed vertebrates. Another major difference is that only teleosts possess a caudal neurosecretory system (CNSS), which produces some of the same stress-related neuropeptides as the hypothalamus.

The functions of the HPI and HPA axes have been extensively studied in juvenile and adult animals, but little information exist on the ontogeny of the cortisol stress response. There is mounting evidence, primarily in birds and mammals, that stressful events occurring during the early life stages can predispose an organism to different pathological states as an adult. This has led to the paradigm "developmental origins of adult disease". For example, prenatal undernutrition in rats and sheep results in cardiovascular alterations such as hypertension. This is thought to be caused by decreased corticosteroid feedback control of the HPA axis that is programmed during fetal development. Very little is known about the long-term effects of stress axis modulation during embryonic and larval development in fish.

This article first reviews the HPI axis and cortisol signaling in teleosts, focusing primarily on molecular pathways. The second section describes the ontogeny of the stress axis, both the molecular pathways and the timing of the functional activation of the cortisol stress response. The subsequent section focuses on zebrafish

(*Danio rerio*), due to the popularity of this species in developmental and molecular studies. Development of the cortisol stress response in other teleosts, including common carp (*Cyprinus carpio*) yellow, perch (*Perca flavescens*) rainbow, trout (*Oncorhynchus mykiss*), and Atlantic salmon (*Salmo salar*), are also addressed.

Components of the HPI Axis

Hypothalamus

The hypothalamus receives inputs from various elements of the central (e.g., cerebral cortex and olfactory system) and peripheral (e.g., viscera) nervous systems. If the hypothalamus interprets an environmental or homeostatic cue as stressful, corticotrophin-releasing factor (CRF; **Figure 1**) is secreted from the nucleus preopticus (NPO) in the hypophysis and plays a key role in coordinating the neuroendocrine, autonomic, and behavioral responses to stress. Axons of the NPO CRF cells project directly into the anterior pituitary gland via synapses, or into the circulation via neurosecretion in the pars nervosa. In addition to CRF, CRF-binding protein (CRFBP) and CRF receptors (CRFR1 and R2) are involved in the regulation of the stress response by modulating CRF action. Several CRF-related neuropeptides such as urotensin I (UI) and urocortin 2 and 3 also control the HPI axis in teleosts through activation of urotensin and CRF receptors, similar to other vertebrates. CRF and UI are not only secreted by the hypothalamus, but are also secreted from the CNSS directly into the circulation in response to stressors to allow direct interaction with interrenal tissue and epithelial tissues.

Pituitary

CRF released to the anterior pituitary binds to CRF receptors (R1 and R2) in the membrane of the corticotropic cells. These are G-protein-coupled receptors and activation stimulates cAMP signaling pathways and the release of adrenocorticotropic hormone (ACTH) to the circulation. ACTH is derived from the proopiomelanocortin (POMC) gene, which is a precursor to a number of smaller signaling peptides (**Figure 1**). However, ACTH is the main product of POMC in the corticotropic cells. All POMC-derived peptides bind to and activate the G-protein-coupled melanocortin receptors in target tissues and ACTH specifically binds to the melanocortin 2 receptor (MC2R) located in target tissues.

Interrenal

ACTH binding to MC2R in the interrenal cells stimulates adenylate cyclase and cAMP-dependent signaling pathways such as protein kinase A, to stimulate cortisol synthesis. The increase in cAMP induced by MC2R is dependent upon receptor interactions with melanocortin receptor accessory proteins (MRAPs). Three of these proteins are found in zebrafish (MRAP1, 2a, and 2b), whereas two have been identified in mammals. MRAPs are also essential for the initial receptor protein folding, glycosylation, and translocation to the cell membrane.

In the interrenal cells, the initial step in steroidogenesis is the transport of cholesterol from the outer to inner mitochondrial membrane. Although the precise mechanism by which this cholesterol transport is accomplished is still uncertain, the steroidogenic acute regulatory protein (StAR) and the peripheral-type benzodiazepine receptor (PBR) are thought to play a key role in this mitochondrial intermembrane shuttling. The initial, rate-limiting enzymatic step is the conversion of cholesterol to pregnenolone, catalyzed by cyp11a1 (also known as cytochrome P450 side-chain cleavage (P450scc); **Figure 1**). Pregnenolone is further metabolized by a series of cytochrome P450 steroid hydroxylases and dehydrogenases leading to the production of cortisol. StAR, PBR, and cyp11a1 are particularly responsive to ACTH signaling (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids).

Nuclear Receptors and Cortisol Signaling

Cortisol signaling in target tissues is mediated by glucocorticoid and mineralocorticoid receptors (GR and MR, respectively), which belong to the nuclear receptor superfamily of ligand-bound transcription factors. GR is ubiquitously expressed, indicating a widespread adaptive role for cortisol. A primary target for cortisol is the GR in the liver, which plays a key metabolic role for providing energy while coping with stressors (**see also Hormonal Control of Metabolism and Ionic Regulation**: Corticosteroids). The stress-induced disturbance of homeostasis results in the upregulation of energy-demanding pathways, and in fish, cortisol enhances liver gluconeogenic capacity leading to elevated glucose liberation. This response is a key aspect of the stress recovery process, as glucose is the preferred fuel for tissues, in particular the gill and brain. GR activation by cortisol also regulates diverse processes such as osmoregulation, protein metabolism, the immune response, growth, reproduction, and behavior.

Cortisol is a very high affinity ligand for MR; however, 11βHSD2 is often co-expressed with MR in tissues such as the gill and kidney. This enzyme deactivates cortisol by metabolizing it to cortisone, which does not bind to MR. In mammals, this enzyme allows hormones such as aldosterone, which is at a much lower concentration than cortisol, access to MR. Aldosterone does not appear to be synthesized in fish, but 11-deoxycorticosterone (DOC) is instead the leading candidate as the teleost MR-specific ligand. However, a physiological role for DOC signaling via MR activation is still lacking in fish. The current thinking is that cortisol may be playing a key role in MR activation, while the specific effect associated with this receptor activation, including expression of MR-responsive genes, is unknown in fish.

Duplicated HPI Axis Genes

The whole genome duplication event in fish 350 MYA resulted in a number of duplicated genes in the HPI axis. For example, carp possess two genes for CRF, ACTH (POMC) and GR. However, zebrafish are unique among teleosts in that they have returned to single gene systems for CRF, ACTH, and GR (although zebrafish have two genes that encode POMC, the cleavage site for ACTH is mutated in one copy, resulting in ACTH derived from only one gene). Although this duplicate stress gene loss may have simplified studies on the development of the zebrafish stress axis, it also raises some very interesting questions regarding genome evolution and the functions of single versus duplicate gene systems.

Ontogeny of the HPI Axis

From early embryogenesis, components of the stress axis undergo dynamic changes in expression suggesting that they are functional at this time. However, aside from the well-defined role of cortisol and GR in fetal lung maturation in mammals, the specific stress- or basic developmental-related functions of the HPI/HPA components in the embryo are not well understood.

Embryos and larvae of oviparous teleosts have continuous access to cortisol because of a maternal deposit of cortisol in the oocyte. The temporal profile of this steroid during development has been documented in a variety of species (although similar cortisol profiles have yet to be characterized in viviparous and ovoviviparous fish). In all species examined, this deposited cortisol is depleted from the oocyte as embryonic development progresses, reaching a minimum level around hatch, after which time, the larva begins to synthesize cortisol and basal levels increase (**Figure 2**). However, when is the cortisol stress axis first responsive to stress? This section reviews the molecular ontogeny of the HPI axis with reference to the timing of basal and stress-induced cortisol production.

The majority of the work on the temporal expression of signaling molecules, receptors, and enzymes of the HPI axis during teleost development has been performed with zebrafish. The findings from this species are summarized first, followed by information that is available for salmonids, common carp, and yellow perch (primarily cortisol measurements).

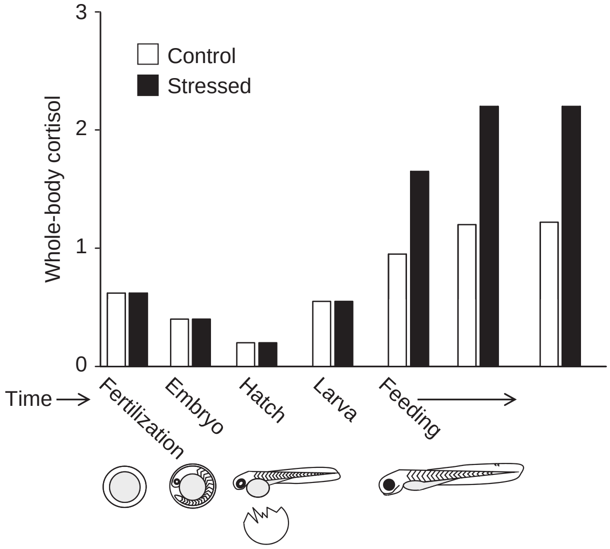

Figure 2 Representative whole-body cortisol levels (arbitrary units) in developing teleost embryos and larvae. Fish oocytes contain a maternal cortisol deposit, and after fertilization basal (open bars) cortisol levels decrease and reach a minimum around the time of hatching (approximately 2–3 dpf for zebrafish, 10 dpf for perch, and 4 wpf for salmonids). The newly hatched larva is able to synthesize cortisol and basal levels begin to rise. In contrast, cortisol levels after a handling stressor (black bars) do not increase above basal levels until after hatch, toward the onset of exogenous feeding. The exception is carp, which display an accelerated HPI-axis development.

HPI Axis Development in Zebrafish

The Mature Oocyte

Maternal factors are essential during early development as the initial steps of embryogenesis are driven solely by maternal mRNAs or proteins that were produced during oogenesis. In most animals, a substantial portion of embryogenesis occurs prior to the activation of zygotic transcription, which normally begins during the mid-blastula transition (MBT; approximately 2.5 hours post-fertilization (hpf) in zebrafish).

In zebrafish, a number of maternal HPI-axis transcripts are expressed in the mature oocyte or zygote. There is an abundance of transcripts for CRF, CRFBP, CRF receptors (CRFR1 andR2), and GR, while there are very few transcripts for StAR, 11β-hydroxylase and 11βHSD2. In addition, there is a maternal deposit of cortisol (4 pg/egg in zebrafish). Although present, the exact roles of maternally derived cortisol or HPI-axis transcripts in the early embryo are unknown.

Embryogenesis

During embryogenesis, there are dramatic changes in the expression of HPI-axis genes. In addition, the maternal cortisol deposit is being continuously depleted, but cortisol levels in the embryo are not responsive to a stressor (**Figure 2**).

CRF signaling system. CRF transcripts are detected throughout zebrafish embryogenesis. CRF signal is observed by 25 hpf in the primordial hypothalamus, which has begun to form as a ventral expansion of the diencephalon. By 48 hpf, CRF-positive cells are observed in bilateral pairs of cells in the preoptic region of the hypothalamus, as well as outside the hypothalamus, in the thalamus and rostral medulla oblongata (**Figure 3**(**b**)). The distribution of CRF expression outside the hypothalamus suggests that CRF may be involved in processes other than HPI-axis signaling, especially since the cortisol stress response is not activated at this time in response to a stressor. Indeed, CRF has been shown to play other roles in mammals, where it induces astrocyte proliferation in the developing rat brain. CRFBP is also expressed in many brain regions (**Figure 3**(**d**)), although the exact role of CRFBP in CRF signaling is unclear. Studies, to date, suggest that CRFBP prevents CRF from binding to its receptors and subsequent signaling.

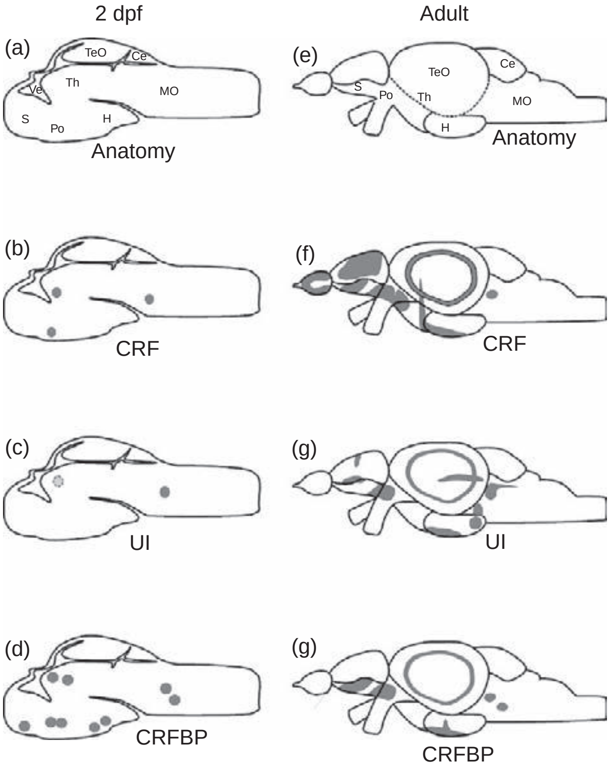

Figure 3 Summary of regional gene expression for corticotrophin-releasing factor (CRF), urotensin I (UI), and CRF-binding protein (CRFBP) in the zebrafish brain at 2 days post-fertilization (dpf; left panel) and in adult male fish (right panel). Schematics of the brain for 2 dpf (a) and adults (e) in rostro-caudal orientation are shown for reference, and brain regions that are identifiable at 2 dpf are indicated. A comparison between 2 dpf and adult regional expression is shown for CRF ((b) and (f), respectively), UI ((c) and (g), respectively), and CRFBP ((d) and (h), respectively). Each gray circle in (b), (c), and (d) represents the approximate location of a pair of cells that expressed the respective gene of interest in all 2 dpf brains analyzed. The open circle in (c) represents the approximate location of a pair of cells that expressed UI in half of the brains analyzed. Ce, cerebellum; H, hypothalamus; MO, medulla oblongata; Po, pre-optic region; S, subpallium; TeO, optic tectum; Th, thalamus; Ve, ventricle. Courtesy of Sarah Alderman and Nicholas Bernier, University of Guelph, Canada.

UI was not detected in the embryonic or larval hypothalamus, although low levels were observed in the thalamus and medulla oblongata (**Figure 3**(**c**)). In contrast, UI is highly expressed in the adult brain (**Figure 3**(**g**)).

CNSS. There is no change in CRF or UI transcript abundance in the tail region during embryonic or larval development, although levels are much higher in the adult. The functional significance or stress responsiveness of the CNSS during development is unknown in fish.

POMC/ACTH. POMC is first detected in the pituitary anlage at 24 hpf and is expressed in an anterior/posterior organization starting around 48 hpf. At this time, the anterior corticotropic cells synthesize the ACTH peptide. It is unknown whether development of corticotropic cells is regulated by the hypothalamus and CRF secretion, as is the exact timing of corticotropic responsiveness to CRF. Regardless, POMC and ACTH are strongly localized in the anterior pituitary prior to hatch, although the stress response is nonfunctional.
